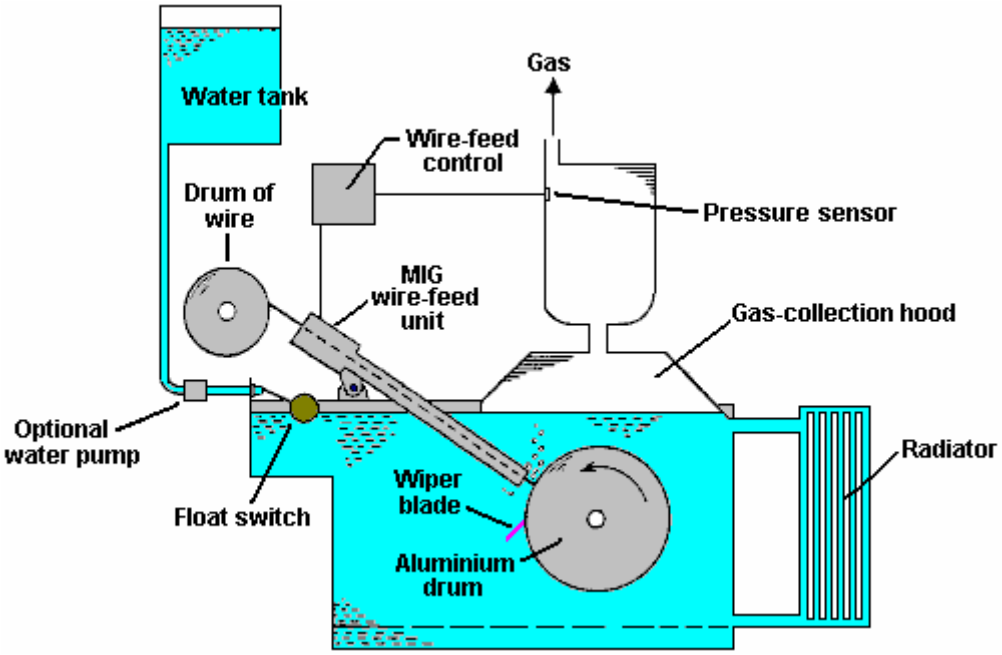
This looks as if the pressure tank is under considerable pressure, but that is not so, as the header tank is open to atmospheric pressure. I have concerns about controlling purely chemical processes rapidly enough for practical use. The above system would be more suited to a fixed engine, such as an electrical generator, where the gas requirement does not fluctuate greatly. The KOH tank shown above should be large enough to contain all of the KOH solution in case the gas production just does not stop when it should. The vent from the header tank should be capable of venting excess hydrogen with no possibility of it ponding on a ceiling and forming an explosive mixture with air. As far as I am aware, the above system has never been constructed and it is just shown here for discussion purposes.



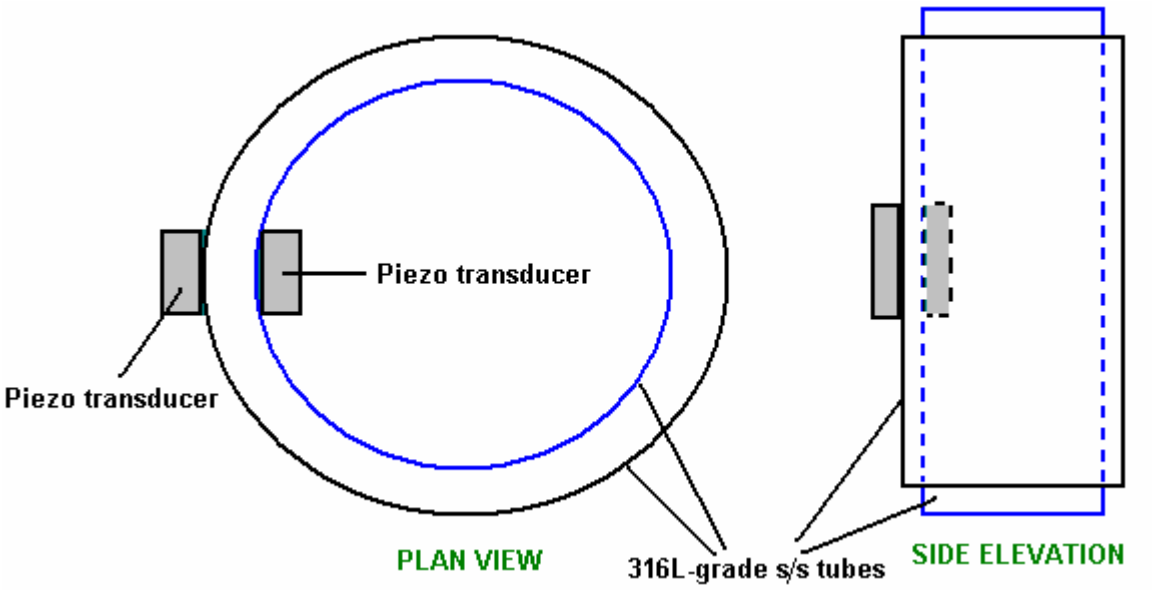
Only 5 pounds per square inch of pressure is needed for electrolyser systems to feed a car engine satisfactorily, so a relatively low pressure is quite satisfactory, provided that the piping is of reasonable internal diameter. It should be remembered that the car engine will be applying a slight vacuum through the bubbler. As with all of these systems, it is vital that at least one bubbler is used between the gas production and the engine, to guard against flashback from the engine ignition if faulty ignition should occur. All bubblers should have a tightly fitting pop-off cap which can ease the effect of an explosion, and they should contain only a small amount of gas. The method of connection to the engine and the necessary timing adjustments are shown and explained in Chapter 10.

Francois Cornish. The method of using aluminium for a fuel in an on-demand hydrogen system for vehicle propulsion has been presented in detail by several people. One of the best known is the 1987 US Patent 4,702,894 by Francois Cornish, where he uses a feed mechanism for aluminium wire to maintain an underwater electrical arc which raises the water temperature high enough to make the aluminium react with the water. The rotating drum is made of aluminium but as it has a much larger thermal capacity than the aluminium wire being fed towards it, the drum temperature is much lower than that of the wire. As a result of this, the wire reaches the temperature required to make the aluminium react with the water. The chemical reaction releases hydrogen and converts the aluminium wire to aluminium oxide powder, which settles on the bottom of the tank, passing through a grid just above the bottom of the tank.

The bubbles of hydrogen gas released by the reaction tend to stick to the rotating aluminium drum, so a wiper blade is provided to sweep the bubbles off the drum. The bubbles then rise to the surface of the water and are directed into the gas collection chamber by a funnel located above the arc. If the engine demand drops and the pressure in the gas collection tank rises, a sensor located in the tank causes the wire-feed control electronics to stop the wire feed which cuts off the gas production.

At first glance, a system like this appears to have limited appeal. It uses aluminium wire which requires manufacturing by a process which uses substantial amounts of energy and while a vehicle using hydrogen produced by this method will generate very little pollution, the pollution occurs at the point of manufacture. Also, the device uses a mechanical wire feed and any device of that nature will need regular maintenance and may not be 100% reliable. In addition, the aluminium oxide powder will have to be cleaned out of the generating tank on a routine basis.

But, having said all that, the system has some very significant advantages. It does not use any fossil fuel (directly). It can be readily installed in a vehicle and the consumption of aluminium wire is surprisingly low. Figures quoted indicate that typical consumption is of the order of 20 litres of water, plus one kilogram of aluminium used to cover 600 kilometers distance (1 pound per 170 miles). This is probably a good deal cheaper than using fossil fuel to drive the vehicle. However, the aluminium oxide produced by this system is a serious pollutant as it is **highly toxic**, producing a wide range of serious illnesses, including Alzheimer's. The system is set up like this:



Another system of interest is the self-powered electrolysis system of the 1992 US Patent 5,089,107 granted to Francisco Pacheco where sacrificial anode plates of magnesium and aluminium are placed in seawater opposite a stainless steel cathode. Electrical power is generated and hydrogen produced on demand. There is also surplus electrical power available to run a standard electrolyser if so desired.

An Ultrasonic System:

I have been told (by a rather doubtful source) of a very high-performance water-splitting system which produces enough hydroxy gas to power a vehicle engine while only drawing 3 milliwatts at 3 volts which is a mere 9 milliwatts of power. I have never seen one of these units, and I have no evidence that the system works, other than word of mouth, so please treat the following entry as just a suggestion rather than a matter of hard fact.

The system is so interesting and simple that it is very attractive, Basically, you have two stainless steel pipes placed in a bath of tap water:

The objective is to get two stainless steel tubes resonating together at the same frequency. That is, they should both produce the same "musical" note when suspended on a thread and tapped. As the inner tube is smaller diameter, it will have a higher note than the larger diameter tube if they are the same length, so for them to match, it would be necessary for the inner tube to be longer, or the outer tube have a slot cut in it as Stan Meyer did and which is discussed in Chapter 10.

The piezo transducers are presumably glued to the cylinders, perhaps as shown above, and they are fed with a 2.24 MHz signal. The tubes need to resonate with the electronics signal, so they are ground down very slowly and carefully until they do resonate. This will presumably be at a much lower harmonic of the electronics signal, one in the standard ultrasonics range. Presumably, there will be three spacers top and bottom, maintaining the gap between the tubes. If the frequency were down in the mains region of about 50 Hz or 60Hz, then the device would just act as a water heater of the type designed by Peter Davey. At ultrasonic frequencies, the result is quite different as cavitation bubbles form in the water. A highly respected textbook on ultrasonics points out that these cavitation bubbles have a positive charge on one side and a negative charge on the other side and these charges cause electrolysis of the water surrounding the bubbles. Lots of bubbles - lots of hydroxy gas produced. So, background theory supports the possibility of this device working, however, I am not aware of anyone who has attempted to replicate it.

What we have not been told is:

1. The size, length and thickness of tubes which work well.
2. The gap between the tubes.
3. The specific transducers used in the prototype.
4. What type of spacers were used.
5. Where and how the transducers were fixed to the cylinders.

However, even without this information, this could be an interesting investigation project using absolutely minimal power at trivial voltage levels.

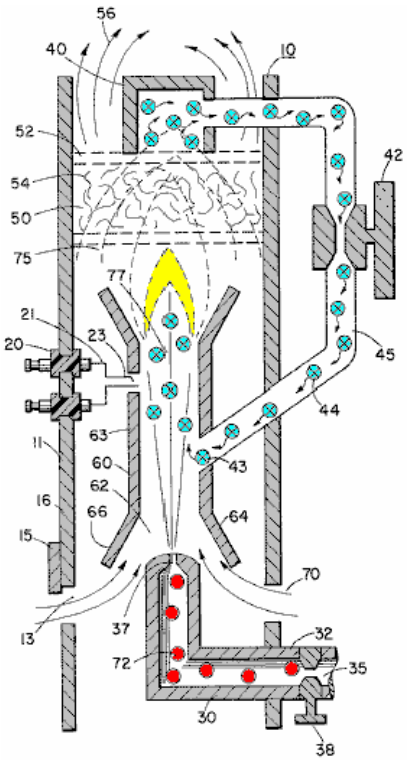
Chapter 14: Renewable Energy Devices

Heaters

The devices described here are not “free-energy” devices as such, but in spite of that, it is an area of considerable interest to many people, and the subject is included here because of that.

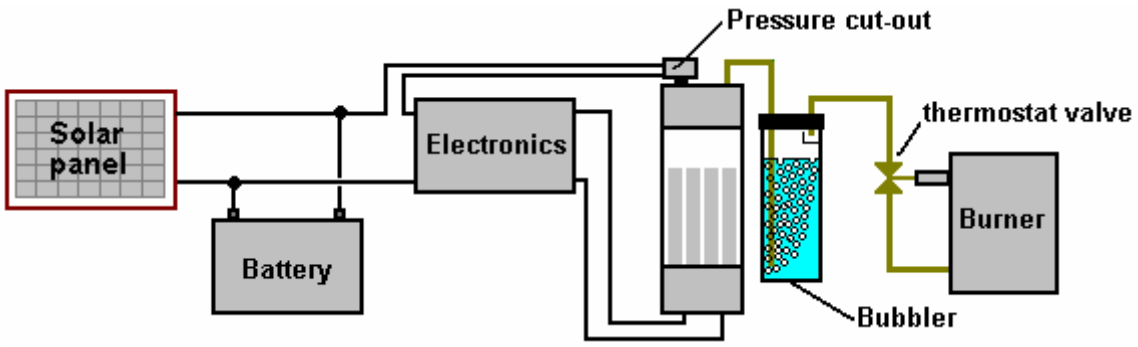
If you do not live in an urban area, then a solid fuel stove can be an economic solution, especially if the fuel can be collected free from wooded areas. Stove design has advanced considerably and it is now possible to make a simple stove with very high efficiency and very low emissions as shown here:

Although this stove is a very simple construction, it’s efficiency is very high indeed. The best fuel is made of smaller pieces which rest on a simple shelf. Branches work better than large pieces of wood as the consumption is more complete. As the fuel is consumed, it is pushed further into the stove, which gives the user an appreciation of the rate of consumption. Having the fuel resting on a shelf has the major advantage of allowing air to flow both above it and below it, which gives improved combustion. The operation is said to be so good that there is virtually no residue and no emissions.



Again, if land space is available, a solar oven (or Stirling motor) can be used, either to store energy for later use or generate heat for cooking or home heating, as can hot-water solar panels. However, it is only realistic to consider the application to be during the night in a built-up area with little or no spare space for equipment.

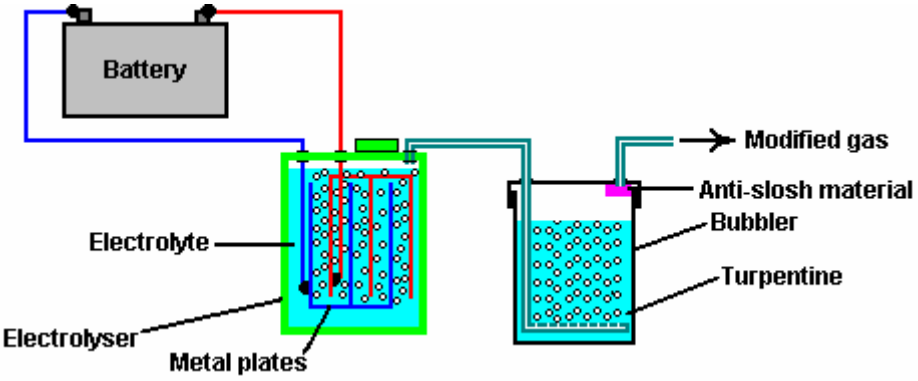
Electrical heating, while very convenient, is usually expensive, and it often seems that the effectiveness of an electric heater is not directly related to its power consumption. In theory it definitely is, but in practice it just does not seem that way. There are other alternatives.



One of the other documents in this set, shows how to construct a Stanley Meyer style electrolyser which uses ordinary tap water and splits it into burnable fuel using just a low power electrical input:

The difficulty in creating a heating system which uses the gas produced by this unit, is in the very high temperature produced when the gas is burnt. Stan overcame this problem with by designing a special burner which mixes air and burnt gasses in with the gas before it is burnt. That lowers the flame temperature to a level which is suitable for heating and cooking:

While this looks a bit complicated, it's construction is really quite simple. The combination of the Meyer electrolyser and Meyer burner form a system which has the potential of being operated from a solar panel and battery as shown here:



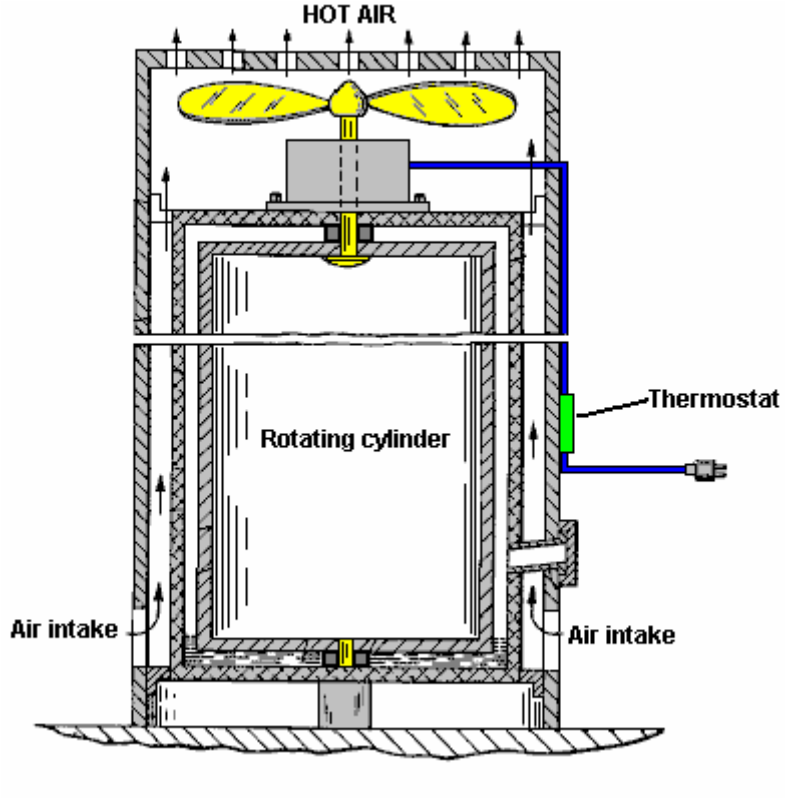
A system like this needs extreme care as the hydrogen / oxygen ("hydroxy") gas produced is explosive. So:

1. It is very important that the electrolyser has the ability to provide sufficient gas to keep the flame(s) sustained.

2. The electrolyser must be fitted with a pressure switch, typically operating at 5 pounds per square inch or so. This is included so that should the gas usage drop, then the drive from the electronics is cut off to stop further gas production, and incidentally, stopping the current draw from the battery.

3. It is absolutely essential that there be a flame-operated valve on the gas supply line to the burner, so that should the flame go out for any reason whatsoever, then the gas supply will be cut off. This type of valve is common on town-gas operated fires for use in homes.

There is an alternative method which it is claimed can convert the explosive hydroxy gas into a much more docile fuel, more suited to conventional burners and stoves. It must be stressed that this system is over 120 years old and it should not be used until you have carried out careful tests on it. Initial tests suggest that these claims have no basis in fact, so please be very careful and sceptical. The method was patented by Henry M. Paine in US Letters Patent No. 308,276 dated 18th November 1884 and it is very simple:

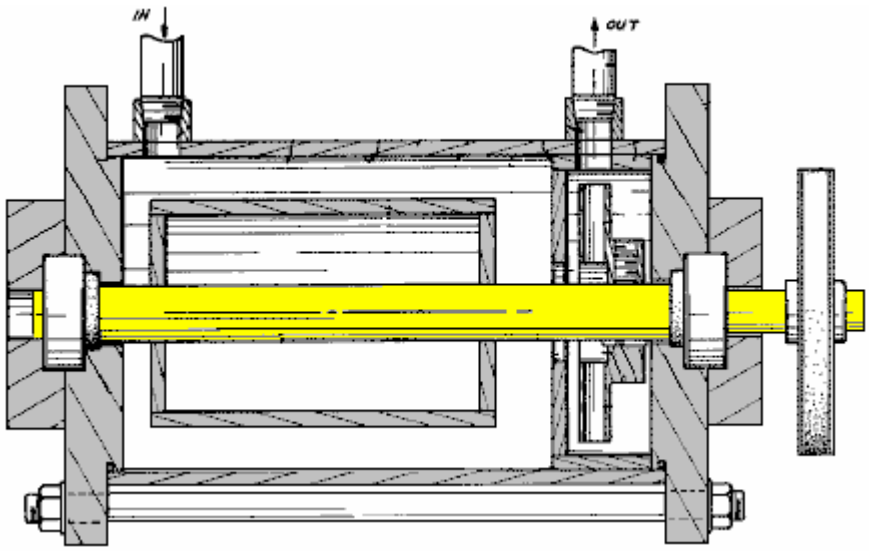


The idea is to bubble the hydroxy gas produced by electrolysis of water, through a liquid hydrocarbon such as turpentine. The bubbler should have a large number of small holes in the incoming tube, so that a very large number of small bubbles of hydroxy gas pass through the hydrocarbon. This brings the majority of the hydroxy gas into intimate contact with the hydrocarbon and the process is claimed to convert the hydroxy gas into a new variety of gas which is not explosive, can be stored for later use, and which burns with the same characteristics as coal-gas ("town gas").

At this point in time, I do not know of any recent tests to confirm this, so the claim should be treated with caution and careful tests carried out in the open, lighting the gas remotely and taking refuge behind a robust protective object. Having said that, in my opinion, it is highly likely that Henry Paine's claim is correct in every respect, but that is only my opinion and I have not confirmed it with any form of practical test,

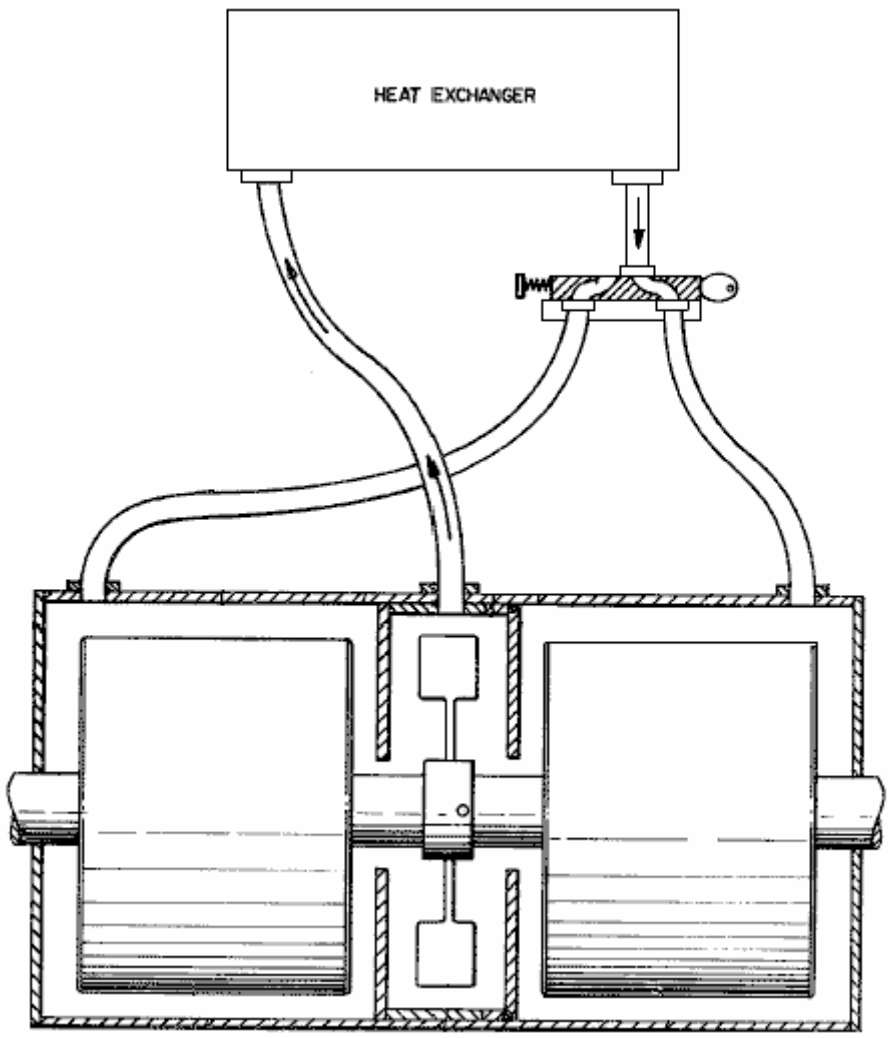
Electric power is very popular for heaters. However, with most appliances, it is a very expensive form of heating. There is a technique which is reputed to improve the efficiency and lower the cost of electric heating. This method involves rotating a cylinder inside an outer cylinder and filling part of the narrow space between the cylinders with some variety of light oil.

This method has been patented more than once. In 1979, Eugene Frenette was granted patent 4,143,639 where a single motor is used to rotate the drum and power a fan to boost the motion of the hot air:



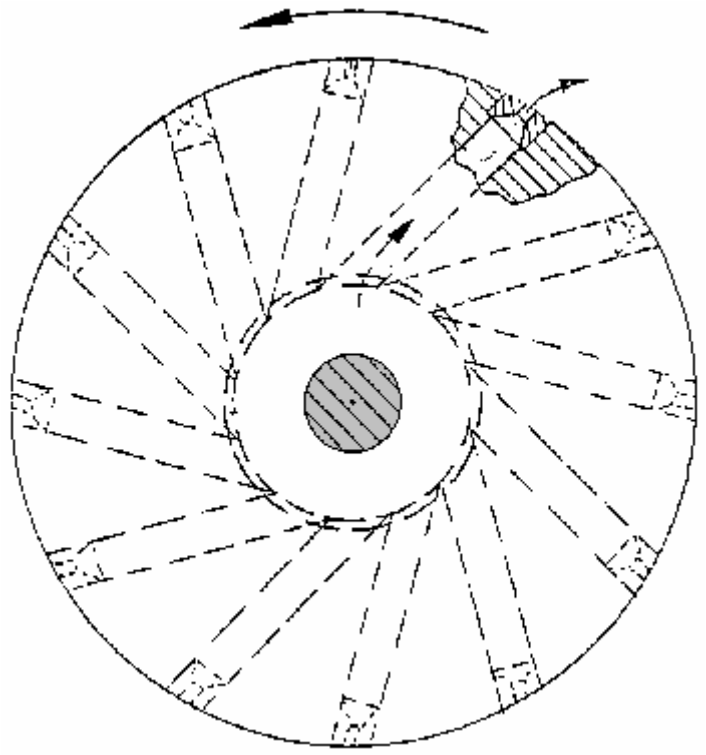
It is not immediately obvious why this arrangement should work well, but it appears that it does. As the inner drum spins around, the oil rises up between the two inner cylinders. It lubricates the bearing under the rotating drum and the rotation causes the oil to heat up. This heats the middle cylinder and air being drawn up around it by the action of the fan blade, is also heated before being pushed out of the top of the heater. After a few minutes, the outer housing becomes so hot that the thermostat attached to it, cuts off the electrical supply.

The heater does not stop heating at this time as air continues to circulate through the heater by ordinary convection. In my opinion, it would be more effective if the fan motor were operated independently and did not cut off when the heater reaches its operating temperature.



Very similar systems were patented by Eugene Perkins: January 1984 patent 4,424,797, November 1984 patent 4,483,277, March 1987 patent 4,651,681, October 1988 patent 4,779,575, and in January 1989 patent 4,798,176.

His first patent shows a horizontal drum which is completely immersed in the liquid:

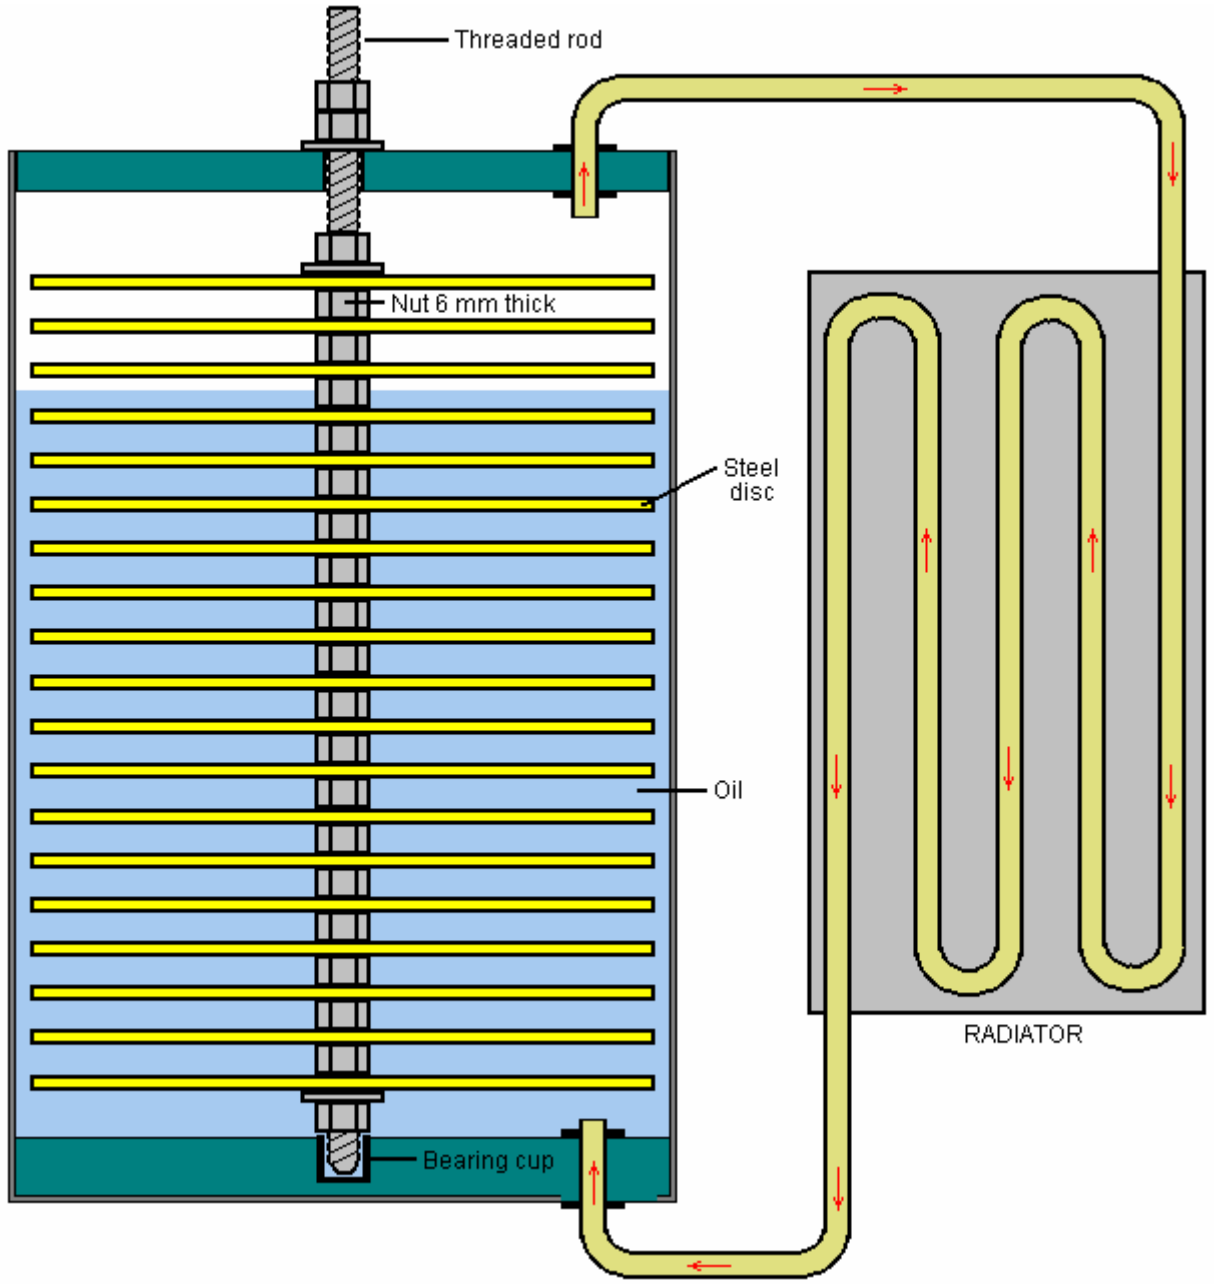


This calls for a much greater accuracy of construction in that the liquid has to be contained even though it has a rotating shaft running through the housing. This device pumps the heated liquid through central-heating piping and radiators.

In his later patent of the same year, he shows a modified version with two drums and an impeller:

The “heat exchanger” is a radiator or set of radiators.

He progressed to a system where the shaft rotation forces the liquid to be expelled through the tips of arms radiating out from the centre of the impeller hub:



Here, the liquid is forced into a small space between the rotor and its drum housing. This system has been used very successfully for water heating and some measurements indicate that it is at least 100% efficient and some people believe that it is well over the 100% efficiency, though they don't want get drawn into long discussions on methods of measurement. It is sufficient to say here, that this method is very effective indeed.

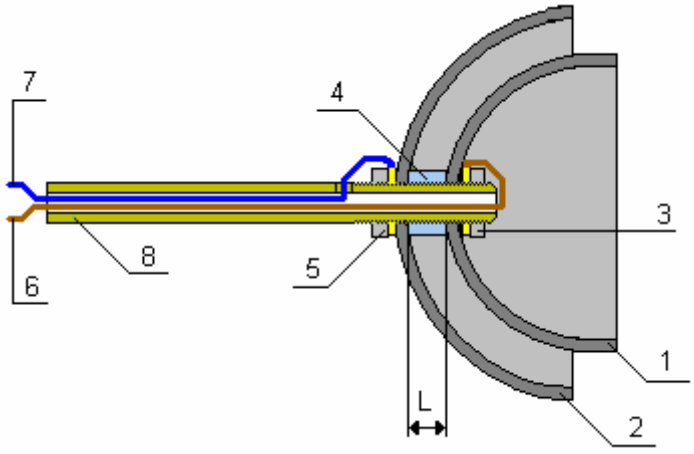
Frenette Variation: The Frenette heater design shown above with it's two vertical cylinders, is not the easiest for the home constructor unless one of the cylinders (presumably the inner one) is constructed from steel sheet, as it is difficult to find two commercially available steel cylinders of just the right relative size to produce the wanted gap between them. A much easier variation replaces the inner cylinder with a stack of circular steel discs. As these can be cut from 20 gauge steel sheet fairly readily by the home constructor, or alternatively, cut by any local metalworking or fabrication company, any available size of outer cylinder can be used and the disc diameter chosen accordingly.

The discs are mounted about 6 mm (1/4") apart on a central steel rod which is rotated in order to drive the discs through the oil contained inside the body of the heater. While this looks like a Tesla Turbine, it is not because the spacing of the discs creates a different effect. The wider disc spacing creates shear as they spin through the surrounding oil, and this shearing creates a high degree of heating. It must be remembered that this is a heater, and the outer canister gets very hot during operation (which is the whole point of the exercise in the first place). For that reason, oil is used as a filling and not water, which boils at a much lower temperature. The larger the diameter of the canister and the greater the number of discs inside it, the greater the heat developed.

To ensure that the discs do not come loose during prolonged operation, a hole can be drilled through them just outside the area covered by the locking/spacing nuts, and a stiff wire run through the holes and the ends either welded to the central rod or pushed through a hole drilled in it and bent over to hold it in place. The heat of the cylinder can be circulated by attaching a simple fan blade to the spinning shaft. This blows air down the hot sides of the canister, moving it towards the floor which is the most effective place for it circulate and heat the entire room.

As the discs spin, the oil is pushed outwards and moves upwards, filling the top of the canister and building up some pressure there. This pressure can be relieved by running an external pipe from the top of the cylinder back to the bottom, allowing the oil to circulate freely. This has the decided advantage the circulating oil can be passed through a radiator as shown in the following diagram:

The central rod can be rotated by any convenient motor, conventional, Adams type, pulse-motor, permanent magnet motor, or whatever. An alternative to this style of operation, is to use the rotating motor to spin a ring of permanent magnets positioned close beside a thick aluminium plate. The eddy currents cause very strong heating of the aluminium plate which then can have air blown across it to provide space heating.



The Peter Davey Heater. During World War II, Peter Daysh Davey, of Christchurch, New Zealand, a fighter pilot and musician, designed and built an unusual water heater. This design is not particularly well known and information is fairly thin on the ground, however, the basic principle and design details are known.

The device is intended to operate on the New Zealand mains power supply of 220 volts 50 Hz and a requirement of the apparatus is that it resonates at that 50Hz frequency. Resonance is a frequent requirement of free-energy systems, and the need for it is often overlooked by people who attempt to replicate free-energy devices. Properly built and tuned, this heater is said to have a COP of 20, which means that twenty times as much heat is produced by the device, compared to the amount of electrical power required to make it operate. This power gain is caused by additional energy being drawn from the immediate environment and it is very important as the largest use of energy in cool climates tends to be that used for heating. If that can be reduced by a serious amount, then your annual power costs should be much lower as a result of it.

Peter was granted a New Zealand patent for his heater on 12th December 1944 but he found that after the war, the opposition from the utility companies was so great that it prevented him from going into commercial production with it. For fifty years, Peter kept up his attempts to get sufficient approval to bring his heater to the marketplace, but the opposition finally won and he never managed it.

The device comprises a hemispherical resonant cavity, formed from two metallic dome shapes, both of which resonate at 50Hz. Initially, Peter used two bicycle bells and he found that when submerged in water, the device brought the water to the boil in a very short time indeed. The construction is like this:

If construction were to use two identical hemispheres, then the cavity between them would be anything but even width throughout, but the resonance would be the same. On the other hand, if you want the resonant cavity between the two hemispheres to be of constant width, then the outer sphere needs to be markedly larger than the inner hemisphere. The outside of both hemispheres needs to be insulated unless mounted in such a way that it is not possible to touch the hemispheres, as each is attached to the mains.

In the above diagram, the mains live wire **6**, is fed through the connecting pipe **8**, and clamped to the inside of the inner hemisphere **1**, by nut **3** which screws on to the threaded section of tube **8**. It is important that it is the live wire which is connected to hemisphere **1**. The mains neutral wire **7**, is also fed through the connecting tube **8**, exits via a small hole and is clamped on to the outside of the outer hemisphere **2**, by nut **5**, also on the threaded section of tube **8**. The two hemispheres are held apart by a spacing washer **4**, which is made from a high-temperature non-conducting plastic. As the tube **8** connects electrically and mechanically to both mains wires via the two locking nuts **3** and **5**, it is essential that this tube is constructed from an electrically non-conducting material such as plastic. As the tube will be in boiling water on a regular basis, it is also necessary that the tube material is also able to handle temperatures over 100^{O} C (212^{O} F), so possible materials include nylon and teflon.

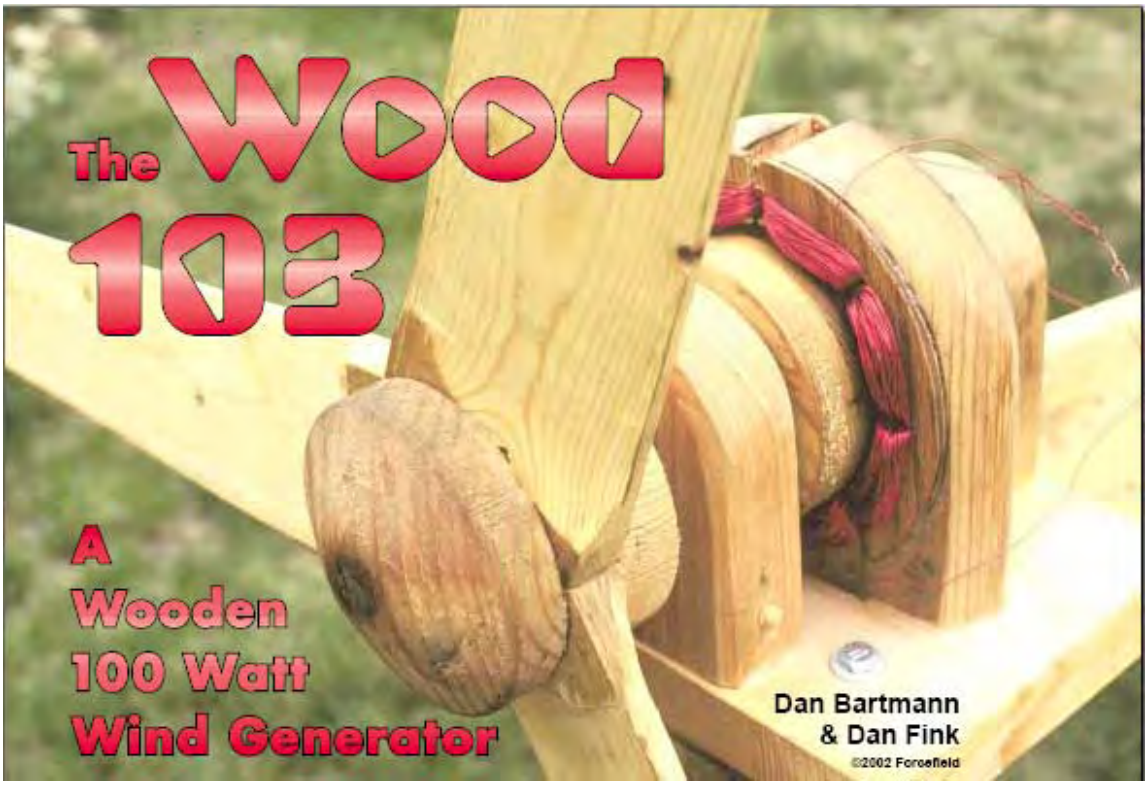
This washer is a key component of the heater and its thickness is key to the efficiency of the whole device. This thickness **L**, is the tuning control for the cavity. The outer hemisphere is about 8 mm greater in diameter than the diameter of the inner hemisphere. Allowing for the thickness of the metal of the bowl, the resonant cavity will therefore be about 3 mm or one eighth of an inch.

The hemisphere **1** is also tuned to 50 Hz by grinding it carefully until it resonates freely at that frequency. Connecting a loudspeaker in series with a resistor of say, 100K ohms, will give a sound of the exact frequency with which this hemisphere needs to resonate. This tuning needs to be done with the unit fully assembled as the connections to the tube will alter the resonant frequency of the hemisphere. When this is being done, the resonance will be felt rather than heard, so hold the tube lightly so that it can resonate freely. The tuning is done by removing a small amount of metal from the face of hemisphere **1** and then testing for resonance again.

When hemisphere **1** resonates well at the mains frequency, (roughly G two octaves below middle C on a keyboard), the search for high-efficiency heating is carried out by very small adjustments of the gap **L**. The adjustment of the gap **L** is carried out by very careful grinding down of the separating washer **4** and the result is best determined by measuring the length of time needed to boil a known volume of water and the current taken to do that. Repeated tests and recorded results, shows when the best gap has been reached and the highest efficiency achieved. The heater can, of course, be used to heat any liquid, not just water.

This heater is unlike a standard kettle heating element. In the standard method, the water is not a part of the main current-carrying circuit. Instead, the mains power is applied to the heater element and the current flowing through the heater element causes it to heat up, and the heat is then conveyed to the water by conduction. In Davey's heater, on the other hand, the current flow appears to be through the water between the two hemispheres. It seems likely that the actual heating is not produced by current flow at all, but from cavitation of the water caused by the resonating of the cavity between the two hemispheres. This technique is used in small jewelry cleaners where and audio frequency is applied to a cleaning fluid in a small container.

A small amount of electrolysis will take place with the Davey heater as it in effect also forms a single parallel-connected electrolyser. The amounts should be very small as only 1.24 volts out of the 220 volts applied will be used in the electrolysis process.



An early construction of the original heater is shown in the photograph below. The coin shown in the picture is 32 mm (1.25 inch) in diameter. The heater is submerged in water when it is being used, and it brings that water to the boil exceptionally quickly. The unit was tested by New Zealand scientists who were able to vouch for its performance, but who were unable to state exactly how its operation allowed it to output such a high level of heat for such a low level of electrical input. You will notice from the photograph, how carefully the electrical connections and outer bowl are insulated.

The original prototype which Peter made was constructed from the tops of two bicycle bells, only one of which was tuned to 50 Hz. This shows that the device will definitely work if the inner hemisphere is tuned correctly. You can find forum investigation at http://www.overunity.com/index.php?topic=4083.msg86151;topicseen and more recent information at http://merlib.org/node/5504.

****

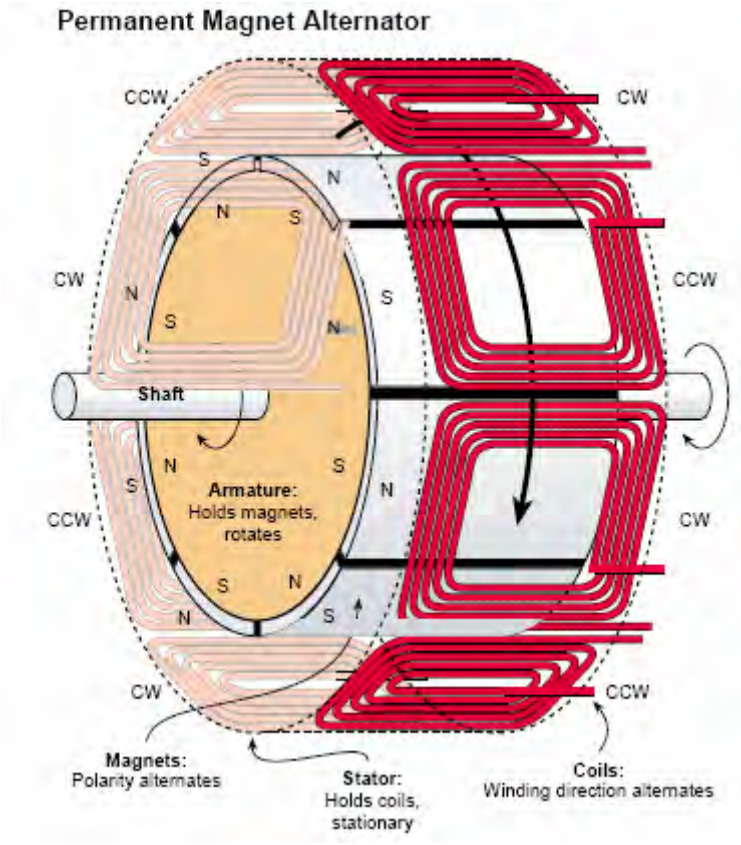
Here is an interesting article from the Home Power web site. If you are interested in renewable power, then I strongly recommend that you visit their web site http://www.homepower.com and consider subscribing to their magazine as they cover many practical topics using simple wording. Here is an example of the high quality material from Home Power:

The Wood 103 was built mostly of wood in just a few hours, with very little number crunching. Producing 100 watts in a 30+ mph wind ain't bad for a weekend project!

The initial goal of our project was to build a functional, permanent magnet alternator from scratch, primarily out of wood. When the alternator was together and working, it became clear that wind was the logical energy source for it. This unit (we call it the "Wood 103") is not intended to be a permanent addition to a remote home energy system, but a demonstration of how simple it really is to produce energy from scratch—and to be a bit silly!

Many home-made wind generator designs require a fully equipped machine shop to build. Our wooden version, built in a day, can be made with mostly local materials and simple hand tools in any remote corner of the world. The alternator design is well suited to hydroelectric, human, or animal power. We plan to use it for a series of magnet and electricity demonstrations at local schools, and for future experiments with different energy sources, windings, cores, poles, and rotors. This project will cost you only US $50–75, depending on what you pay for magnets and wire.

Alternator Basics



Electricity is simply the flow of electrons through a circuit. When a magnet moves past a wire (or a wire past a magnet), electrons within the wire want to move. When the wire is wound into a coil, the magnet passes by more loops of wire. It pushes the electrons harder, and can therefore make more electricity for us to harvest.

The magnetic field can be supplied by either permanent magnets or electromagnets. All of our designs use permanent magnets. In a permanent magnet alternator (PMA), the magnets are mounted on the armature (also sometimes called the "rotor"), which is the part that spins. It is connected directly to the wind generator rotor (the blades and hub). There are no electrical connections to the armature; it simply moves the magnets. Each magnet has two poles, north (N) and south (S). The magnets are oriented in the armature so that the poles alternate N-S-N-S.

The other half of a PMA is the stator, which does not move. It consists of an array of wire coils connected together. The coils in our stator alternate in the direction they are wound, clockwise (CW) and counter-clockwise (CCW). The coils and magnets are spaced evenly with each other. So when the north pole of a

magnet is passing a clockwise coil, the south pole of the next magnet is passing the counter-clockwise coil next door, and so on.

The coil cores are located inside or behind the coils, and help concentrate the magnetic field into the coils, increasing output. The cores must be of magnetic material, but also must be electrically non-conductive to avoid power-wasting eddy currents. The air gap is the distance between the spinning magnets and the stationary coils (between the armature and the stator), and must be kept as small as possible. But the spinning magnets must not be allowed to touch the coils, or physical damage to them will occur.

The more loops of wire that each magnet passes, the higher the voltage produced. Voltage is important, since until the alternator voltage exceeds the battery bank voltage, no electrons can flow. The sooner the alternator voltage reaches battery voltage or above in low winds, the sooner the batteries will start to charge.

Increasing the number of turns of wire in each coil allows higher voltage at any given speed. But thinner wire can carry fewer electrons. Using thicker wire allows more electrons to flow, but physical size limits the number of turns per coil. This also explains why enamelled magnet wire is always used in coils. The enamel insulation is very thin, and allows for more turns per coil than does thick plastic insulation. Any alternator design is a compromise between the number of turns per coil, the wire size, and the shaft rpm.

The electricity produced by an alternator is called “wild” alternating current (AC). Instead of changing direction at a steady 60 times per second like standard AC house current, its frequency varies with the speed of the alternator.

Since we want to charge batteries, the wild AC is fed to them through a bridge rectifier, which converts AC to DC (direct current) for battery charging. The alternator may produce much higher voltages than the battery bank does, but the batteries will hold the system voltage from the wind generator down to their normal level when charging.

The Wood 103 has three, 2 foot, hand-carved blades, creating a swept area of 12.5 square feet.

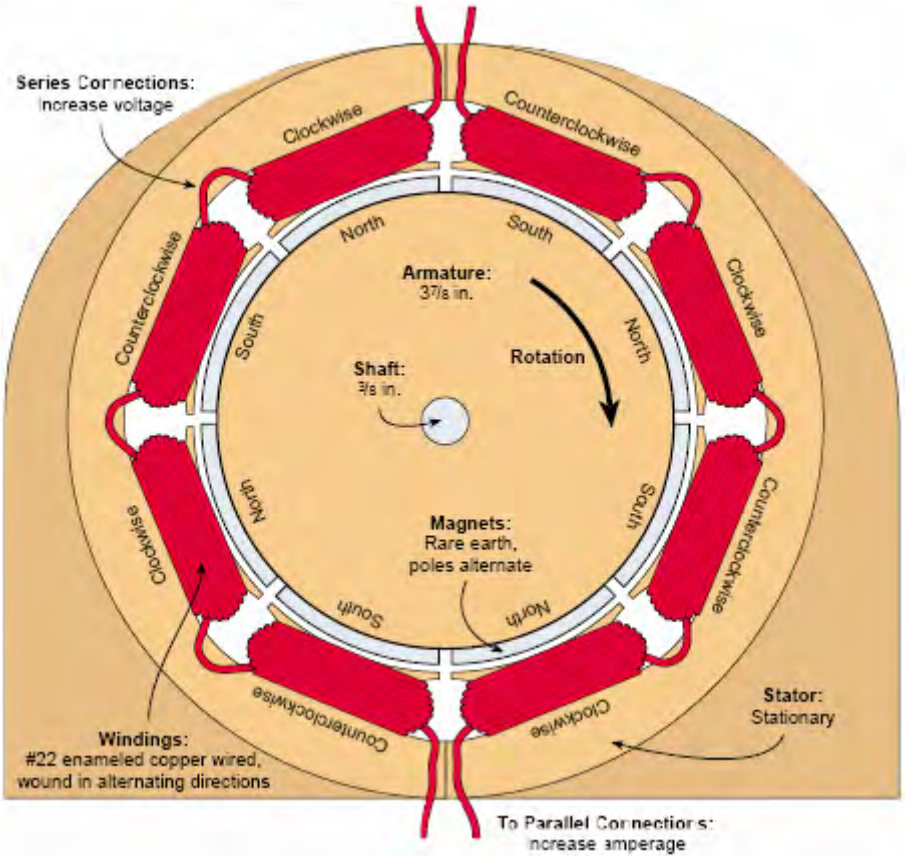
Materials Used

The materials we used are not hard to find:

- Wood, the harder the better. We used pine since it was locally available.
- Copper magnet wire, about 100 feet (30 m), enameled #22 (0.64 mm diameter).
- Eight surplus neodymium-iron-boron magnets, four with the south pole on the convex face, and four with the north pole on the convex face.
- Dirt (magnetite sand).
- A 10 inch (25 cm) piece of 3/8 inch (9.5 mm) steel shaft with a nut on the end to hold the hub on.
- Two, 3/8 inch by 2 inch (9.5 mm x 5 cm) bolts, but these are optional.
- Bridge rectifier, rated for least 15 amps, 100 volts.
- Other supplies—glue and linseed oil.

Design

We had successfully converted AC induction motors into PMA wind generators before. But starting from scratch was truly a first-time experiment. Our design choices for wire size, number of windings, number of poles, blade pitch, and other factors were intuitive rather than calculated.



Every wind generator, waterwheel, and alternator we've built has produced usable energy, no matter how strange the design. The trick is matching the generator, rotor, and energy source. You can do a lot of study and calculation to get there. But if the design is quick, cheap, and easy to build, why not just make adjustments by observing the unit's performance?

If you try this project and change the wire size, magnet type, rotor design, and stator cores, you'd still be making usable energy and have a great starting point for further research. Just change one thing at a time until the unit performs to your satisfaction. We're aware that many design improvements could be made to the Wood 103—and we hope that others will experiment with variations.

Wooden Alternator

The biggest problem with building most wind generator designs at home is the need for machine tools - usually at least a metal lathe is required. Headquarters for our business, Otherpower.com, is high on a mountain, 11 miles (18 km) past the nearest utility line. We are lucky enough to have basic tools up here, but many folks around the world don't. That's the main reason we used so much wood in this design.

Wood 103 PM Alternator: End View

It is possible to build human-powered woodworking tools in almost any location. With some patience, only simple hand tools are required for this project. If you want to build it in a day, though, a lathe, drill press, band saw, and power planer can be very helpful!

Building the Armature

The key to the Wood 103's armature is the neodymium-iron-boron (NdFeB) magnets. They are the strongest permanent magnets available. Ours are surplus from computer hard drives. They are curved, and measure about $1^{3}/4$ by $1^{3}/8$ by $^{1}/4$ inch thick (44 x 35 x 6 mm). Eight fit together in a $3^{7}/8$ inch (9.8 cm) diameter ring. That's why we chose this particular diameter for the armature.

The wooden armature holds eight NdFeB (neodymium-iron-boron) magnets arranged in alternating polarity around its perimeter.

Safety Warning!

The large NdFeB magnets in this project are extremely powerful, and can be dangerous. They are brittle, and if allowed to snap together from a distance, they can break and might send sharp shrapnel flying. They are powerful enough to cause painful damage to your fingers if you allow them to pinch you, and can cause malfunctions in cardiac pacemakers if brought too close.

Use safety glasses, gloves, a firm grip, and Zen-like concentration when handling these magnets. Do not get them anywhere near televisions, computer monitors, floppy discs, videotapes, credit cards, etc. They are not toys, and should be kept out of reach of children!

The magnets are available with either the north or south pole on the convex face. For this project, you will need four of each configuration. Don't start tearing your computer apart to get these, though! They are from very large hard drives, and you won't find any inside your computer. Check the Access section at the end of this article for suppliers.

To construct the armature, we laminated plywood circles together with glue. The $3\frac{7}{8}$ inch (9.8 cm) diameter wooden cylinder is $3\frac{3}{4}$ inches (9.5 cm) long, with a $1\frac{3}{4}$ inch (4.4 cm) wide slot cut into it $\frac{1}{4}$ inch (6 mm) deep to tightly accept the magnets. To assure that the magnets would be flush with the armature surface, we cut the plywood disks a bit oversized, and turned them down on the lathe to the proper diameter. The same procedure was used to cut the magnet slot to exactly the right depth.

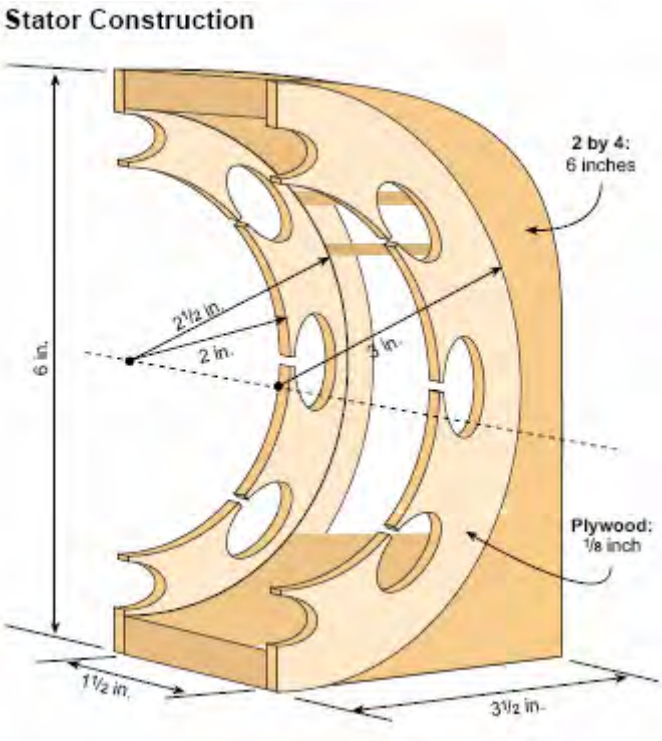
Using a firm grip, we carefully press-fit and epoxied the magnets into place. Remember that these magnets come in two different configurations—north pole on the convex face and south pole on the convex face. The magnets must have alternating poles facing out, and this is how they naturally want to align themselves.

Next, we drilled the shaft hole through the centre of the armature using a lathe, though it could certainly be done with a hand drill if you are careful to align it perfectly. We roughed up the surface of the shaft with a file before epoxying it into the hole. It should be a very tight fit—we had to gently tap it through with a hammer. This may not be strong enough, and it might be wise to actually pin the armature to the shaft. Time will tell!

Construction without a Lathe

We did cheat by using a lathe to shape the armature, but a coping saw and sandpaper would work just fine. If a lathe is not available, our suggestion is to first cut out the disks, making sure that some of them (enough to stack up to $1\frac{3}{4}$ inches; 4.4 cm) are $\frac{1}{4}$ inch (6 mm) smaller in diameter than the rest. Once assembled, the armature will then have a recessed slot for the magnets.

Otherwise some means of "lathing" the slot will have to be devised. It could be done on the alternator's pillow blocks with a sanding block mounted below, or in a drill press. It would also be wise to first drill a shaft hole into each plywood disk, and then assemble, glue, and clamp all the plywood disks together on the shaft before turning.



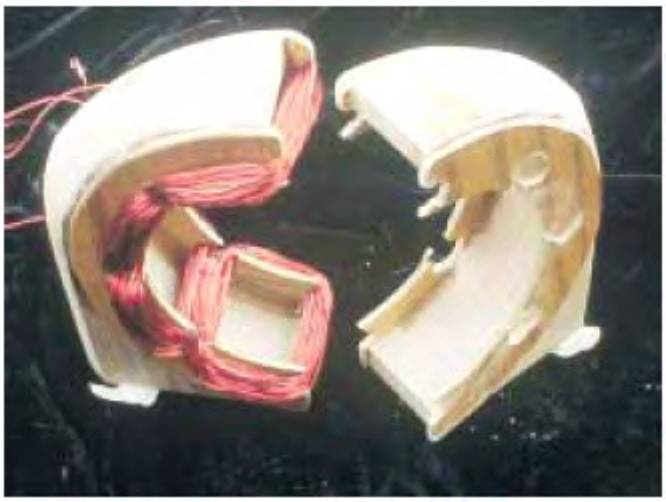
Building the Pillow Blocks

The pillow block bearings were made from pine, since that's the hardest wood we have available up here on the mountain. Certainly hardwood would be much better. First we drilled a hole slightly under $\frac{3}{8}$ inch (9.5 mm) diameter in each pillow block. Using a gas stove burner, we heated the shaft to almost red hot, and forced it through the holes. This gave a good tight fit, hardened the wood, and made a layer of carbon on the inside for better lubrication. We drilled a small hole in the top of each pillow block, down into the shaft hole, so the bearings can be greased

Pillow blocks support the armature. Charred wood creates "carbon" bearings for the shaft to spin on.

After pressing the hot shaft through the pillow blocks, we were very pleased with how freely the armature turned and how little play there was. In a slow waterwheel design, wood/carbon bearings would probably last for years. This wind generator is a actually a fairly high-speed unit, and real ball bearings would be a big improvement. Such bearings could be easily scavenged from an old electric motor of any kind. Wooden bearings were certainly simple, fast, and fun though!

Building the Stator



The stator, on which the coils are wound, is made up of two identical halves. Each half is made from 2 by 4 inch lumber, 6 inches long (5 x 10 x 15 cm). A semi-circular cut-out with a 5 inch diameter (12.7 cm) was made on each half. The tolerances are pretty tight, but this allows more than a $^{1}/_{2}$ inch (13 mm) to fit the coils and core material inside.

On the sides of the 2 by 4s, right over the cut-out, we of this type is often available from electronics stores or glued thin ($^{1}/_{8}$ inch; 3 mm) U-shaped plywood "half disks," which have an inner diameter of 4 inches (10 cm) and an outer diameter of 6 inches (15 cm). They have slots cut large enough to accept the coils. These were made with a hand saw, $^{3}/_{8}$ inch (9.5 mm) drill bit, and a rat tail file. The coils are wound in these slots, and the

space inside and behind the coils is filled with the magnetite core material. There are four coils on each half of the stator, and they must be evenly spaced.

Our twin stator halves are wound with #22 (0.64 mm diameter) enamelled copper magnet wire. Magnet wire of this type is often available from electronics stores or from electric motor repair shops. Each stator half contains four coils. Each coil is 100 turns, and every coil is wound in the opposite direction as its neighbour. It's important to wind the coils neatly and tightly, using a wooden dowel to carefully press each winding loop into place.

The two stator halves—one wound with 100 turns per coil, and one ready to be wound.

Most common alternators use thin steel laminates as cores, to help concentrate the magnetic field through the coils. Magnetism in motion pushes the electrons around in the steel too. The laminates are insulated from each other to block these eddy currents, which would otherwise waste energy.

These laminates are difficult to make in a home shop, so we chose dirt as our stator core—actually magnetite sand mixed with epoxy. It is not as effective as real laminates, but was very easy to use, and available for free by separating it from the dirt in our road. We mixed the magnetite with epoxy and simply spooned it into the open cores. If the cores were left empty (an "air core") the alternator would still work, but with much less power.

Magnetite is a common mineral, a type of iron oxide. It is a by-product of some gold mining operations, and can sometimes be purchased. As an alternative, we simply dragged a large neodymium magnet (just like the ones we used for the armature) around on our local dirt road on a string for a while, attracting all the ferrous sand, which stuck to the magnet.

Magnetite sand collected from Dan's driveway by dragging a magnet around on a string.

An exploded view shows the armature, stator, and pillow blocks ready to assemble into an alternator.

The stator cores are filled with a mixture of epoxy and magnetite sand.

We separated this somewhat magnetic sand into a pile, sifted it through a window screen, and sorted that with the magnet one more time. The remaining black sand sticking to the magnet was nearly pure magnetite. A quick test of any local dirt pile with a neodymium magnet should reveal whether your sand contains magnetite. If not, try dragging the magnet along the sandy bottom of a local river. Any deposits of black sand on the river bottom are most likely nearly pure magnetite.

The clearance between the stator coils and the armature surface is very important. It must be extremely close (within $^{1}/_{16}$ inch; 1.5 mm) without allowing the magnets in the armature to touch the stator. Our model is actually a bit sloppy—the clearances are more like an $^{1}/_{8}$ inch (3 mm). Tighter tolerances would produce more power.

Wiring Configuration

The completed stator consists of two identical sets of four coils. For our wind generator, we connected the stator halves in parallel for more current (amperage). Connecting them in series would double the voltage produced, but halve the amperage. For low wind speeds, a series connection would be the best—the alternator would reach charging voltage at slower speeds. At higher speeds, a parallel connection is optimum for producing the most amperage.

An ideal system would contain a regulator that switched the stator connections from series to parallel when the unit began to spin fast enough. As is the case with many home-brew and commercial wind turbines, we eliminated this entirely, sacrificing a small amount of efficiency for much greater simplicity and reliability. Many people have experimented with such regulators, both solid state and mechanical.

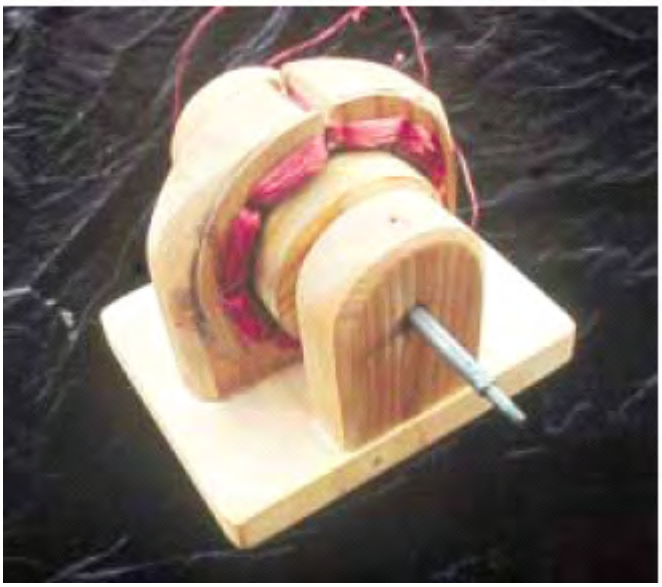
Alternator Performance

We were really surprised by this alternator's performance. We could easily spin it with our fingers and get 12 volts or higher. A cordless drill attached to the shaft would light up a 25 watt, 12 V DU light bulb easily. This might not seem breath-taking, but considering the simplicity of the project and one-day construction time, we were quite impressed.

Our 100 watt rating for the Wood 103 is probably right on, considering the performance we got during testing, and the way commercial wind generator manufacturers rate their products. Our data acquisition system was pretty simple - multimeters and people with pencils and paper to watch them and record measurements.

With a series connection between the stator halves, the unit reached charging voltage for 12 volt batteries at around 300 rpm. With the stator in parallel, it took around 600 rpm to start charging. When installed in our wind machine, the parallel connection gave us 4.8 amps output in a 25 mph (11 m/s) wind.

Building the Frame



To stay with the style of this project, we chose to build the rest of the wind generator out of wood too. It's a very simple design and should be self-explanatory. It's all glued and pinned with dowels. No bolts are used except to connect the alternator to the frame. We admit that we cheated here!

We did not make any provision for over-speed control, since this was intended to be a demonstration unit for all energy sources, not just wind. A canted tail and spring assembly could be added to control speed during high winds. And, of course, making the frame out of surplus steel or aluminium angle would give great improvements in durability.

We also did not include slip rings for power transmission as the wind generator yaws. Instead, we used flexible wire for the first few feet, letting it hang in a loose loop. A piece of aircraft cable cut slightly shorter than the power cable was attached, so if the power wire gets wrapped around the pole too tightly, the connections won't pull loose.

Our normal winds are usually from one direction, and designs without slip rings seem to work fine up here. Wrapping the power wire around the pole is only rarely a problem, and this strain relief cable prevents any damage. Our experience is that if the power cable does wind up all the way, it will eventually unwind itself.

The finished alternator, ready for a power source.

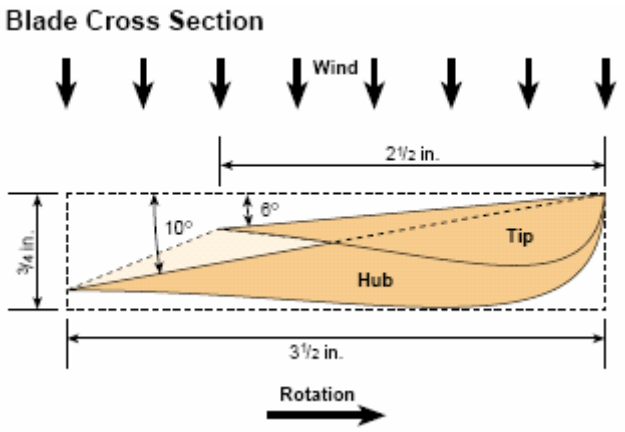
Designing the Rotor

The "rotor" here refers to the blades and hub of the wind generator. We don't profess to be experts in blade design. Once again, we chose our starting point intuitively rather than trying to calculate the proper blades to match our alternator's power curve. Since the blade carving process took us less than an hour for the whole set of three, we figured that any design changes would be quick and easy to make. However, because we glued the blades to the hub, a new hub will be necessary for any blade changes.

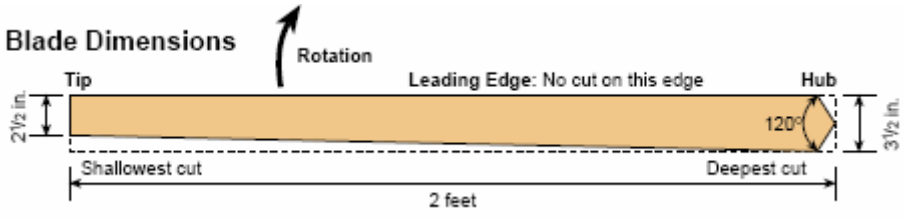
There's a great deal of information out there about building blades. Hugh Piggott's Web site and his Brake-drum Wind Generator plans are some of the best sources around.

The rotor was built from 3/4 inch by 4 inch (19 mm x 100 mm) pine lumber. Each blade is 3 1/2 inches (90 mm) wide at the base and 2 1/2 inches (64 mm) wide at the tip. The three blades are 2 feet long (600 mm), for a total diameter of 4 feet (1.2 m). The pitch of the blades is 10 degrees at the hub, and 6 degrees at the tip.

The hub is made from 2 inch (50 mm) thick wood, press-fit and glued to the roughed-up shaft with epoxy. The blades are held on to the hub by one small nut at the end of the shaft, and several wooden pins with glue.



Carving the Blades



To prepare the blades for carving, we simply drew a few lines so that we knew what material to remove. Each blade starts out life as a 2 foot (0.6 m) long, 1 x 4 inch (25 mm x 100 mm). Starting from the leading edge of the blade at the hub, we simply used a protractor to lay out how far into the wood, 10 degrees of pitch would take us at the trailing edge - about 5/8 inch (16 mm).

At the tip, the pitch is about 6 degrees, so we removed about 3/8 inch (9.5 mm) of material from the trailing edge. We made both marks, and connected the two with a line. We then simply took a power planer, and followed the cut depth line all the way up the blade.

Almost ready—the wooden frame and tail are attached.

For better accuracy (or if you don't have a power planer), you can use a hand saw to make cuts across the blade every inch or so, down to the cut depth line on the trailing edge and not cutting at all on the leading edge. Using a hammer and chisel, it's easy to break out the chunks of wood to the proper depth. Then smooth the blade down to the proper angle with a hand plane. When the saw kerfs disappear, the blade pitch is correct.

The blade width taper occurs on the trailing edge. We simply used a saw to cut the first taper, and used that first blade as a template for cutting the others. No calculations were made for the airfoil shape on the other side of the blades. We picked a likely looking profile and started cutting with the power planer. A hand planer is fine for this process, too. After everything looked good and even, we sanded the blades and treated them with linseed oil.

Balancing the Blades

To avoid vibration problems and enable easy starting, we made some effort to balance the blades. We considered them reasonably balanced when each blade weighed the same (about 8 ounces; 227 g) and had the same centre of gravity. Adjustments can be made quickly with a planer.

Once this is done, and all three blades are assembled on the hub, balance can be double-checked by spinning the rotor and making sure it has no tendency to stop in any one place. This is a quick process, and we certainly were not concerned about great precision here. As it turned out, a small effort in balancing the blades yielded good results, and the machine seems well balanced and vibration free.

Truly, one could write an entire book on blade design, and it can get complicated. Don't worry, though. It is possible to make a very basic blade that will work quite effectively. Often a simple blade with a constant 5 degree pitch from hub to tip and a reasonable airfoil on the backside will work very nicely. If you are interested, explore the books and Web sites listed at the end of this article for more information on blade design.

Testing

For testing, we strapped the Wood 103 to our trusty Model A Ford. The Model A serves as a reliable daily driver, and with the bracket we made, it makes an excellent testing facility for wind turbines. It has a perfectly accurate speedometer, which has been carefully checked by the Fort Collins, Colorado Police Department's radar machines!

We carry a 12 volt battery, a voltmeter, an ammeter, and pencil and paper in the test vehicle. On a still day, we can observe the speedometer and take accurate windspeed versus output measurements on any wind turbine. We've used this rig with props over 8 feet (2.4 m) in diameter. The cost of a good Model A (about US $4,000 if you don't mind a jalopy) is *not* included in the price of this project!

Wind generators should be installed high above human activity. For testing purposes, we've run our generator on low towers within reach of people, and on our Model A. Wind generators have parts that spin very fast! The blades could probably take your head off in a high wind if you were silly enough to walk into them. Make all installations well out of reach of curious organisms. You should treat any wind generator with a great deal of respect. This is not a joking matter, though we always shout "Clear prop!" before we fire up the test vehicle...

Model A Ford—a high tech test vehicle
for a high tech wind machine.

The next generation—the WoodAx is for permanent installation, and produces upwards of 300 watts in 30 mph winds.

Improvements

Many improvements could be made to this design. But the intention was to use mostly wood and hand tools, and keep it fast and simple. The wooden alternator is easy and quick to build, but for longest life, it would need to be protected from rain and snow. Maybe a small shingled roof over it?

Using real ball bearings would help friction loss and longevity a bunch. A metal frame and tail would improve high-wind survivability significantly. A furling system to keep the Wood 103 from destroying itself during a gale would be a great addition too. We plan to experiment with many improvements, and we hope this project piques the interest of others too.

Trade-Offs
Designing and building a permanent magnet alternator involves a long series of trade-offs. For example, thicker wire in the windings would give more possible current, but less room for windings and hence lower voltage at the same rpm. Ceramic magnets might be cheaper, but would give far less power than neodymium magnets.

Series wiring on the stator would allow lower rpm at charging voltage, but parallel gives better charging current—and a regulator to switch between the two would be complicated. Using steel laminates instead of air or dirt stator cores would produce more power, but laminate production is extremely difficult.

The trade-offs involved in designing a complete wind generator (or water turbine, or bicycle generator) are even more lengthy and complicated. Wind speed, rotor diameter, number of blades, blade pitch, width and twist, optimum rpm for your winding configuration, generator diameter, and number of poles all factor into a perfect final design.

Improvise, But Do it!
We've tried to demonstrate how easy it is to produce electricity from scratch. Don't let yourself get hung up on complicated formulas, calculations, and machine tools. Even if you make many changes to this simple design, you'll still almost certainly have a unit that makes usable energy for charging batteries.

Then, you can make small improvements until it performs exactly right for your application. And it could be powered by wind, falling water, a human on a bicycle, a dog on a treadmill, or a yak in a yoke!

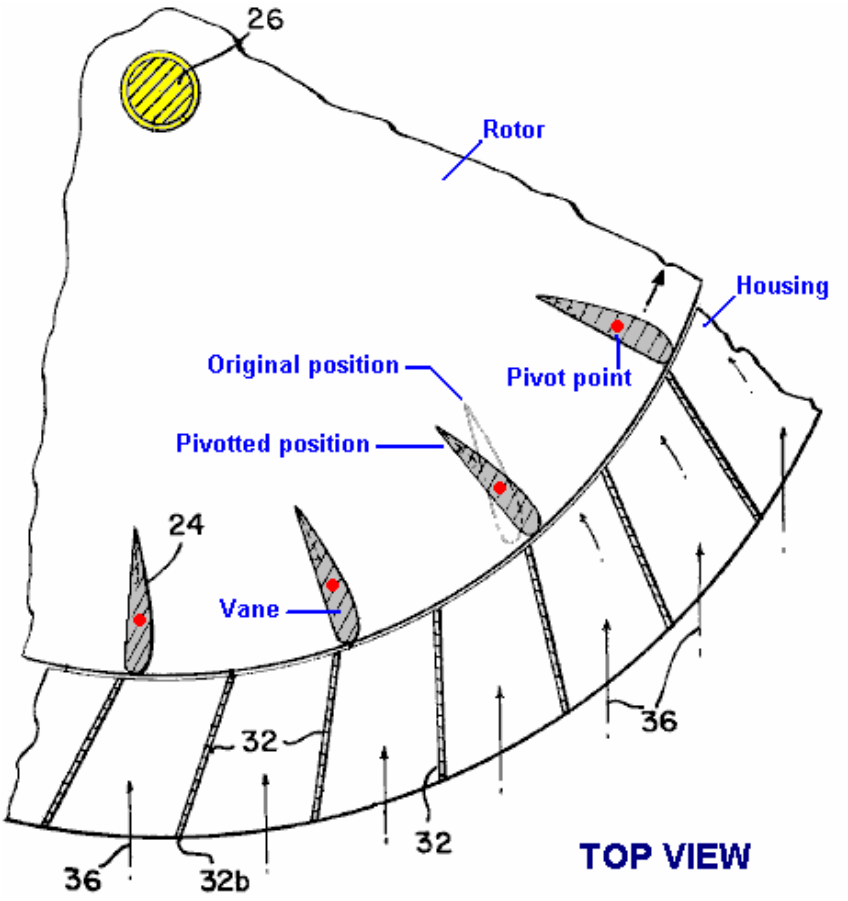
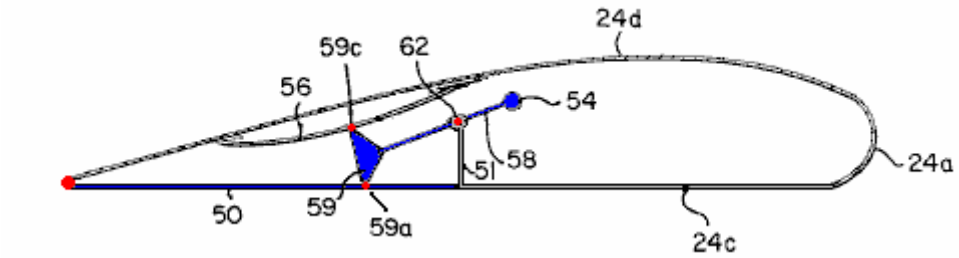
Frank Herbert's Windmill. As has been carefully explained by the above article, if a windmill of the blade variety is mounted low down then it is dangerous, and people on sailing boats have been killed by them. Also, if the blade arrangement is designed to operate well in low wind conditions, then it is not unusual for there to be a problem if the wind rises to gale force or higher, with some generator designs giving up and switching off entirely, even though the available free energy is at its highest level.



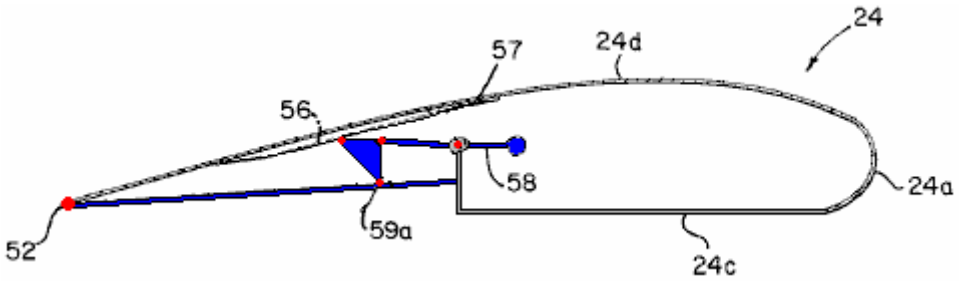
This design by Frank Herbert is perfectly capable of being home-built and yet it overcomes these problems as well as being a high-efficiency wind turbine. It has an outside cage which prevents human access to the moving parts inside and the 'cage' is not just for protection but is there to enhance the performance of the

device. In passing, windmills can be used to compress air and compressed air cylinders can be used to power vehicles and/or power electrical generators during periods of heavy power requirements. The following information is from Frank Herbert's US Patent 4,142,822 of 1979:

The vertical housing **22** shown dotted here, surrounds the vertical power take-off shaft **26**. The wind is allowed to flow through this housing at any angle, so there is no need for the housing to move. In the diagram above small discs **44** are shown at each end of the vertical shaft. These discs have arms **42** extending outwards to support a series of vertical vanes or pressure surfaces **24**. For clarity, just one vane is shown through there will actually be many of these (rather like the cutting blades on a cylinder lawnmower). In reality, there will be no arms on the discs **42** as it is much easier just to have a full-width solid disc supporting the vanes.



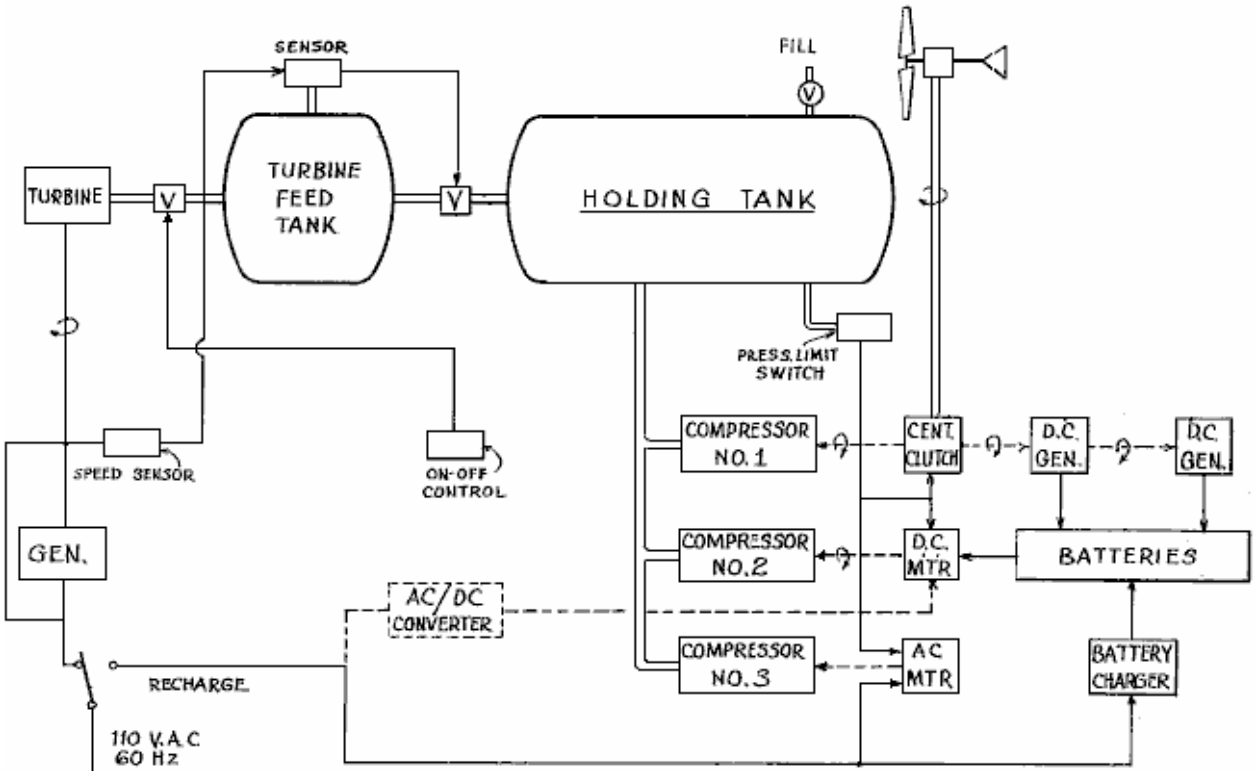
The outer housing has a series of vertical slats which are angled to direct the incoming wind on to the vanes at the best possible angle:



This top view of part of the device, shows the main mounting shaft **26** on which the top and bottom rotor discs are mounted. The red dots show the pivot points where the vanes **24** can turn to take the greatest advantage of the wind pressure. The incoming wind **36**, is deflected by the slats of the housing **32**, to give it a good angle when flowing through the device as well as keeping humans away from the spinning mechanism. As the vanes and slats are located all the way around shaft **26**, sudden changes in wind direction and/or wind strength have no particular effect on this design as it operates with wind coming from any direction and no physical movement of any part of the device is needed for a change in wind direction.

The vanes can have various different profiles and still work well. The shape shown above is the shape of an aircraft wing, where a force acting towards the curved surface is generated when air flows around the shape. This is not a particularly difficult shape to construct and it is very effective in an airflow (which is why it is used to lift aircraft off the ground). There can be any convenient number of vanes and a device built as shown above should be very effective..

As the overall efficiency is improved if there is no turbulence inside the device, Frank has found a method of minimising this. For this, he uses a mechanism which can alter the shape of the vanes when the windspeed gets high. The higher windspeed whirls the vanes around faster, causing higher 'centrifugal' forces on the vanes which Frank uses as follows. Weight **54** gets pushed across by the spin rate of the rotor.



This pushes against the spring **56**, compressing it. The triangle link **59** moves upwards, pivoting at points **59a** and **59c**, and raising section **50** of the vane. This changes the shape of the vane as shown here:

The result of this changed shape is to reduce turbulence inside the device and raise the overall efficiency.

Mead and Holmes. The US patent 4,229,661 dated 1980 from Claude Mead and William Holmes is entitled "Power Plant for Camping Trailer" proposes the use of a wind power generator to store compressed air for later use in providing household electrical current, and simultaneously charge batteries which can be used to drive the compressor in periods of very high electrical demand. There is also an option for a rapid system charge if AC mains power becomes available:

The Solar Funnel Cooker

How to Make and Use The Brigham Young University Solar Cooker/Cooler

by Professor of Physics at Brigham Young University (BYU), with Colter Paulson, Jason Chesley, Jacob Fugal, Derek Hullinger, Jamie Winterton, Jeannette Lawler, and Seth, David, Nathan, and Danelle Jones.

Introduction

A few years ago, I woke up to the fact that half of the people in the world must burn wood or dried dung in order to cook their food. It came as quite a shock to me, especially as I learned of the illnesses caused by breathing smoke day in and day out, and the environmental impacts of deforestation - not to mention the time spent by people (mostly women) gathering sticks and dung to cook their food. And yet, many of these billions of people live near the equator, where sunshine is abundant and free. So.....

As a University Professor of Physics with a background in energy usage, I set out to develop a means of cooking food and sterilising water using the energy freely available from the sun. First, I looked at existing methods.

The parabolic cooker involves a reflective dish which concentrates sunlight to a point where the food is cooked. This approach is very dangerous since the sun's energy is focused to a point which is very hot, but which cannot be seen. (Brigham Young University students and I built one which will set paper on fire in about 3 seconds!). I learned that an altruistic group had offered reflecting parabolas to the people living at the Altiplano in Bolivia. But more than once these parabolas had been stored next to a shed -- and the passing sun set the sheds on fire! The people did not want these dangerous, expensive devices, even though the Altiplano region has been stripped of fuel wood.

The box cooker: Is basically an insulated box with a glass or plastic lid, often with a reflecting lid to direct sunlight into the box. Light enters through the top glass (or plastic), to slowly heat up the box. The problems with this design are that energy enters only through the top, while heat is escaping through all of the other sides, which have a tendency to draw heat away from the food. When the box is opened to put food in or take it out, some of the heat escapes and is lost. Also, effective box cookers tend to be more complicated to build than the funnel cooker.

While studying this problem, I thought again and again of the great need for a safe, inexpensive yet effective solar cooker. It finally came to me at Christmastime a few years ago, a sort of hybrid between the parabola and the box cooker. It looks like a large, deep funnel, and incorporates what I believe are the best features of both the parabolic cooker and the box cooker.

The first reflector was made at my home out of aluminium foil glued on to cardboard, then this was curved to form a reflective funnel. My children and I figured out a way to make a large cardboard funnel easily. (I'll tell you exactly how to do this later on.)

The Solar Funnel Cooker is safe and low cost, easy to make, yet very effective in capturing the sun's energy for cooking and pasteurising water -> Eureka!

Later, I did extensive tests with students (including reflectivity tests) and found that aluminised Mylar was good too, but relatively expensive and rather hard to come by in large sheets. Besides, cardboard is found throughout the world and is inexpensive, and aluminium foil is also easy to come by. Also, individuals can make their own solar cookers easily, or start a cottage-industry to manufacture them for others.

Prototypes of the Solar Funnel Cooker were tested in Bolivia, and outperformed an expensive solar box cooker and a “Solar Coolkit” while costing much less then either. Brigham Young University submitted a patent application, mainly to insure that no company would prevent wide distribution of the Solar Funnel Cooker. Brigham Young University makes no profit from the invention. (I later learned that a few people had had a similar idea, but with methods differing from those developed and shown here). So now I'm trying to get the word out so that the invention can be used to capture the free energy coming from the sun - for camping and for emergencies, yes, but also for every day cooking where electricity is not available and where even fuel wood is getting scarce.

How it Works

The reflector is shaped like a giant funnel, and lined with aluminium foil. (Easy to follow instructions will be given soon). This funnel is rather like the parabolic cooker, except that the sunlight is concentrated along a line (not a point) at the bottom of the funnel. You can put your hand up the bottom of the funnel and feel the sun's heat, but it will not burn you.

Next, we paint a jar black on the outside, to collect heat, and place this at the bottom of the funnel. Or a black pot with a lid can be used. The black vessel gets hot, quickly, but not quite hot enough to cook with. We need some way to build up the heat without letting the outside air cool it. So, I put a cheap plastic bag around the jar -- and, the solar funnel cooker was born! The plastic bag, available in grocery stores as a "poultry bag", replaces the cumbersome and expensive box and glass lid of solar box ovens. You can use the plastic bags used in American stores to put groceries in, as long as they let a lot of sunlight pass. (Dark- coloured bags will not do).

I recently tested a bag used for fruits and vegetables, nearly transparent and available free at American grocery stores, that works great. This is stamped "HDPE" for high-density polyethylene on the bag (ordinary polyethylene melts too easily). A block of wood is placed under the jar to help hold the heat in. (Any insulator, such as a hot pad or rope or even sticks, will also work).

A friend of mine who is also a Physics Professor did not believe I could actually boil water with the thing. So I showed him that with this new "solar funnel cooker" I was able to boil water in Utah in the middle of winter! I laid the funnel on its side since it was winter and pointed a large funnel towards the sun to the south. I also had to suspend the black cooking vessel -- rather than placing it on a wooden block. This allows the weaker sun rays to strike the entire surface of the vessel.

Of course, the Solar Funnel works much better outside of winter days, that is, when the UV index is 7 or greater. Most other solar cookers will not cook in the winter in northern areas (or south of about 35 degrees, either).

I thought that a pressure cooker would be great. But the prices in stores were way too high for me. Wait, how about a canning jar? These little beauties are designed to relieve pressure through the lid -- a nice pressure cooker. And cooking time is cut in half for each 10ºC we raise the temperature (Professor Lee Hansen, private communication). I used one of my wife's wide-mouth canning jars, spray-painted (flat) black on the outside, and it worked great. Food cooks faster when you use a simple canning jar as a pressure cooker. However, you can also put a black pot in the plastic bag instead if you want. But don't use a sealed container with no pressure release like a mayonnaise jar -- it can break as the steam builds up (I've done it)!

How to Build Your Own Solar Funnel Cooker

What You will Need for the Funnel Cooker:

A piece of flat cardboard, about 2 feet wide by 4 feet long. (The length should be just twice the width. The bigger, the better).

Ordinary aluminium foil.

A glue such as white glue (like Elmer's glue), and water to mix with it 50-50. Also, a brush to apply the glue to the cardboard (or a cloth or paper towel will do). Or, some may wish to use a cheap "spray adhesive" available in spray cans. You can also use flour paste.

Three wire brads - or small nuts and bolts, or string to hold the funnel together.

For a cooking vessel, I recommend a canning jar ("Ball" wide-mouth quart jars work fine for me; the rubber ring on the lid is less likely to melt than for other jars I've found. A two-quart canning jar is available and works fine for larger quantities of food, although the cooking is somewhat slower).

The cooking jar (or vessel) should be spray-painted black on the outside. I find that a cheap flat-black spray paint works just fine. Scrape off a vertical stripe so that you have a clear glass "window" to look into the vessel, to check the food or water for boiling.

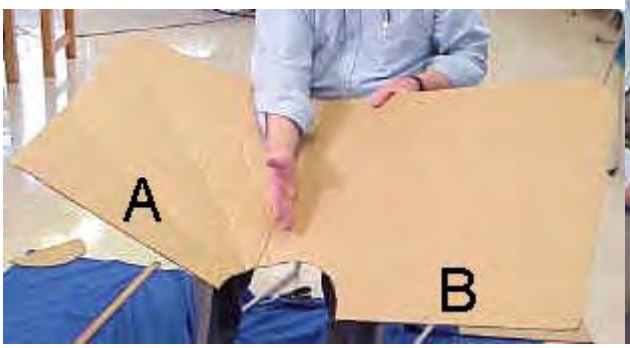
A block of wood is used as an insulator under the jar. I use a piece of 2" x 4" board which is cut into a square nominally 4" x 4" by about 2" thick. (100 mm square x 50 mm thick). One square piece of wood makes a great insulator.

A plastic bag is used to go around the cooking-jar and block of wood, to provide a green-house effect. Suggestions:

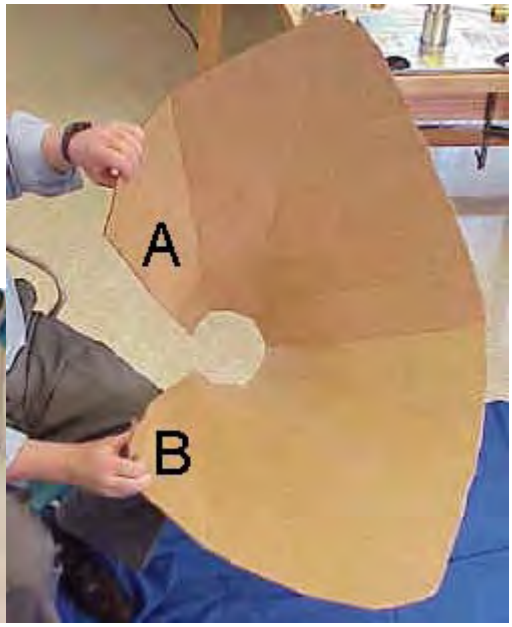
- Reynolds™ Oven Bag, Regular Size works great: transparent and won't melt. (Cost about 25 cents each in U.S. grocery stores.)

- Any nearly-transparent HDPE bag (High-density Polyethylene). Look for "HDPE" stamped on the bag. I've tested HDPE bags which I picked up for free at my grocery store, used for holding vegetables and fruits. These are thin, but very inexpensive. Tested side-by-side with an oven bag in two solar funnels, the HDPE bag worked just as well! **Caution:** we have found that some HDPE bags will melt should they contact the hot cooking vessel. For this reason, we recommend using the oven-safe plastic bag wherever possible.

- An idea attributed to Roger Bernard and applied now to the BYU Funnel Cooker: place a pot (having a blackened bottom and sides) in a glass bowl, and cover with a lid. Try for a tight fit around the bottom to keep hot air trapped inside. The metal pot or bowl should be supported around the rim only, with an air space all around the bottom (where the sunlight strikes it). Put a blackened lid on top of the pot. Then simply place this pot-in-bowl down in the bottom of the funnel - no plastic bag is needed! This clever method also allows the cook to simply remove the lid to check the food and to stir. I like this idea - it makes the solar cooker a lot like cooking over a fire. See Photographs for further details.



Construction Steps



Cut a Half-circle out of the Cardboard

Cut a half circle out of the cardboard, along the bottom as shown below. When the funnel is formed, this becomes a full-circle and should be wide enough to go around your cooking pot. So for a 7" diameter cooking pot, the radius of the half-circle is 7". For a quart canning jar such as I use, I cut a 5" radius half-circle out of the cardboard.

Form the Funnel

To form the funnel, you will bring side A towards side B, as shown in the figure. The aluminium foil must go on the INSIDE of the funnel. Do this slowly, helping the cardboard to the shape of a funnel by using one hand to form creases that radiate out from the half-circle. Work your way around the funnel, bending it in stages to form the funnel shape, until the two sides overlap and the half-circle forms a complete circle. The aluminium foil will go on the INSIDE of funnel. Open the funnel and lay it flat, "inside up", in preparation for the next step.

Glue Foil to Cardboard

Apply glue or adhesive to the top (inner) surface of the cardboard, then quickly apply the aluminium foil on top of the glue, to affix the foil to the cardboard. Make sure the shiniest side of the foil is on top, since this becomes your reflective surface in the Funnel. I like to put just enough glue for one width of foil, so that the glue stays moist while the foil is applied. I also overlap strips of foil by about 1" (or 2 cm). Try to smooth out the aluminium foil as much as you reasonably can, but small wrinkles won't make much difference. If cardboard is not available, one can simply dig a funnel-shaped hole in the ground and line it with a reflector, to make a fixed solar cooker for use at mid-day.

Join side A to side B to keep the funnel together.

The easiest way to do this is to punch three holes in the cardboard that line up on side A and side B (see figure). Then put a metal brad through each hole and fasten by pulling apart the metal tines. Or you can use a nut-and-bolt to secure the two sides (A & B) together.

Be creative here with what you have available. For example, by putting two holes about a thumb-width apart, you can put a string, twine, small rope, wire or twist-tie in one hole and out the other, and tie together.

When A and B are connected together, you will have a "funnel with two wings". The wings could be cut off, but these help to gather more sunlight, so I leave them on.

Tape or glue a piece of aluminium foil across the hole at the bottom of the funnel, with shiny side in.

This completes assembly of your solar funnel cooker.

For stability, place the funnel inside a cardboard or other box to provide support. For long-term applications, one may wish to dig a hole in the ground to hold the Funnel against strong winds.

Final Steps

At this stage, you are ready to put food items or water into the cooking vessel or jar, and put the lid on securely. (See instructions on food cooking times, to follow).

Place a wooden block in the INSIDE bottom of the cooking bag. I use a piece of 2” x 4” board which is cut into a square nominally 4" x 4" by 2" thick. Then place the cooking vessel containing the food or water on top of the wooden block, inside the bag.

Next, gather the top of the bag in your fingers and ***blow air into the bag, to inflate it***. This will form a small "greenhouse" around the cooking vessel, to trap much of the heat inside. Close off the bag with a tight twist tie or wire. Important: the bag should not touch the sides or lid of the cooking vessel. The bag may be called a "convection shield," slowing convection-cooling due to air currents.

Place the entire bag and its contents inside the funnel near the bottom as shown in the Photographs.

Place the Solar Funnel Cooker so that it Faces the Sun

Remember: Sunlight can hurt the eyes: so please wear sunglasses when using a Solar Cooker! The Funnel Cooker is designed so that the hot region is deep down inside the funnel, out of harm's way.

Put the Solar Funnel Cooker in the sun pointing towards the sun, so that it captures as much sunlight as possible. The design of the funnel allows it to collect solar energy for about an hour without needing to be re-positioned. For longer cooking times, readjust the position of the funnel to follow the sun's path.

In the Northern Hemisphere, it helps to put the Solar Funnel Cooker in front of a south-facing wall or

window as this reflects additional sunlight into the funnel. A reflective wall is most important in locations farther from the equator and in winter. In the Southern Hemisphere, put the Solar Funnel Cooker in front of a North-facing wall or window to reflect additional sunlight into your cooker.

After Cooking

Remember that the cooking vessel will be very hot: so use cooking pads or gloves when handling it! If you are heating water in a canning jar, you may notice that the water is boiling when the lid is first removed - it gets very hot!

Open the plastic cooking bag by removing the twist-tie. Using gloves or a thick cloth, lift the vessel out of the bag and place it on the ground or table. Carefully open the vessel and check the food, to make sure it has finished cooking. Let the hot food cool before eating.

Helpful Hints

Avoid leaving fingerprints and smudges on the inside surface of the cooker. Keep the inner surface clean and shiny by wiping occasionally with a wet towel. This will keep the Solar Funnel Cooker working at its best.

If your funnel gets out-of-round, it can be put back into a circular shape by attaching a rope or string between opposite sides which need to be brought closer together.

For long-term applications, a hole in the ground will hold the Funnel Cooker securely against winds. Bring the funnel inside or cover it during rain storms.

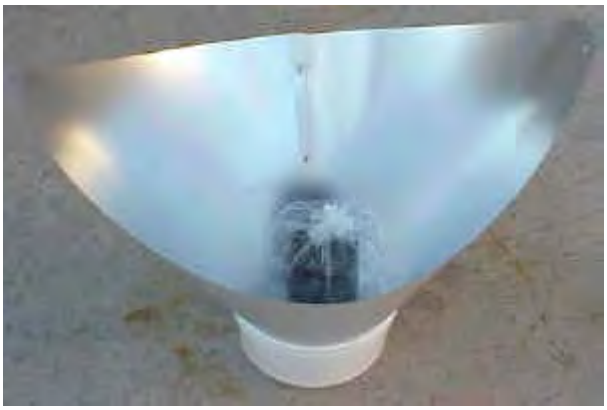
The lids can be used over and over. We have had some trouble with the rubber on some new canning-jar lids becoming soft and "sticky." "Ball canning lids" do not usually have this problem. Running new lids through very hot water before the first use seems to help. The lids can be used over and over if they are not bent too badly when opened (pry off lid carefully).

The jar can be suspended near the bottom of the funnel using fishing line or string (etc.), instead of placing the jar on a block of wood. A plastic bag is placed around the jar with air puffed inside, as usual, to trap the heat. The suspension method allows sunlight to strike all surfaces of the jar, all around, so that heats faster and more evenly. This suspension method is crucial for use in winter months.

Adjust the funnel to put as much sunlight onto the cooking jar as possible. Look at the jar to check where the sunlight is hitting, and to be sure the bottom is not in the shadows. For long cooking times (over about an hour), readjust the position of the funnel to follow the sun's path. During winter months, when the sun is low on the horizon (e.g., in North America), it is helpful to lay the funnel on its side, facing the sun.

Tests in Utah

I have personally used the Solar Funnel Cooker to cook lunches over many weeks. My favourite foods to cook are potatoes (cut into logs or slices) and carrot slices. Vegetables cook slowly in their own juices and taste delicious. I also make rice, melted cheese sandwiches, and even bread in the Solar Funnel Cooker. I usually put the food out around 11:30 and let it cook until 12:45 or 1 pm, just to be sure that it has time to cook. I've never had any food burn in this cooker.



I have also cooked food in the mountains, at an altitude of around 8,300 feet. If anything, the food cooked faster there - the sunlight passes through less atmosphere at high altitudes.

I find that people are surprised that the sun alone can actually cook food. And they are further pleasantly surprised at the rich flavours in the foods which cook slowly in the sun. This inexpensive device does it!

Students at Brigham Young University have performed numerous tests on the Solar Funnel Cooker along with other cookers. We have consistently found much faster cooking using the Solar Funnel Cooker. The efficiency/cost ratio is higher than any other solar cooking device we have found to date. Mr. Hullinger also performed studies of transmissivity, reflectivity and absorptivity of alternate materials which could be used in the Solar Funnel Cooker. While there are better materials, such as solar-selective absorbers, our goal has been to keep the cost of the Solar Cooker as low as possible, while maintaining safety as a first priority.

Tests in Bolivia

The BYU Benson Institute organised tests between the Solar Funnel Cooker and the "old-fashioned" solar box oven. The solar box oven cost about $70 and was made mostly of cardboard. It took nearly two hours just to reach water pasteurisation temperature. The Bolivian report notes that "food gets cold every time the pots are taken from and into the oven." The solar box oven failed even to cook boiled eggs. (More expensive box cookers would hopefully work better.)

An aluminised-mylar Solar Funnel Cooker was also tested in Bolivia, during the Bolivian winter. Water pasteurisation temperature was reached in 50 minutes, boiled eggs cooked in 70 minutes, and rice cooked in 75 minutes. The Bolivian people were pleased by the performance. So were we! (La Paz, Bolivia, August, 1996).

I also donated two dozen solar funnel cookers for people in Guatemala. These were taken there by a group of doctors going there for humanitarian service. The people there also liked the idea of cooking with the sun's free energy. For an aluminised-Mylar Solar Funnel Cooker kit, please contact CRM (licensed manufacturer) at +1 (801) 292-9210.

Water and Milk Pasteurisation

Contaminated drinking water or milk kills thousands of people each day, especially children. The World Health Organisation reports that 80% of illnesses in the world are spread through contaminated water. Studies show that heating water to about 65º - 70º C (150º F) is sufficient to kill coliform bacteria, rotaviruses, enteroviruses and even Giardia. This is called pasteurisation.

Pasteurisation depends on how hot and how long water is heated. But how do you know if the water got hot enough? You could use a thermometer, but this would add to the cost, of course. When steam leaves the canning jar (with lid on tight) and forms "dew" on the inside of the cooking bag, then the water is probably pasteurised to drink. (The goal is to heat to 160º Fahrenheit for at least six minutes.) With a stripe of black paint scraped off the jar, one can look through the bag and into the jar and see when the water is boiling - then it is safe for sure.

Think of all the lives that can be saved simply by pasteurising water using a simple Solar Cooker!

Safety

Safety was my first concern in designing the Solar Funnel Cooker, then came low cost and effectiveness. But any time you have heat you need to take some precautions.

- The cooking vessel (jar) is going to get hot, otherwise the food inside it won't cook. Let the jar cool a bit before opening. Handle only with gloves or tongs.
- Always wear dark glasses to protect from the sun's rays. We naturally squint, but sunglasses are important.
- Keep the plastic bag away from children and away from nose and mouth to avoid any possibility of suffocation.

Cooking with the Solar Funnel Cooker

What do you cook in a crock pot or moderate-temperature oven? The same foods will cook about the same in the Solar Funnel Cooker - without burning. The charts below give approximate summer cooking times.

The solar cooker works best when the UV index is 7 or higher (Sun high overhead, few clouds).

Cooking times are approximate. Increase cooking times for partly-cloudy days, sun not overhead (e.g., wintertime) or for more than about 3 cups of food in the cooking jar.

Stirring is not necessary for most foods. Food generally will not burn in the solar cooker.

Vegetables (Potatoes, carrots, squash, beets, asparagus, etc.)
Preparation: No need to add water if fresh. Cut into slices or "logs" to ensure uniform cooking. Corn will cook fine with or without the cob.
Cooking Time: About 1.5 hours

Cereals and Grains (Rice, wheat, barley, oats, millet, etc.)
Preparation: Mix 2 parts water to every 1 part grain. Amount may vary according to individual taste. Let soak for a few hours for faster cooking. To ensure uniform cooking, shake jar after 50 minutes.
CAUTION: Jar will be hot. Use gloves or cooking pads.
Cooking Time: 1.5-2 hours

Pasta and Dehydrated Soups
Preparation: First heat water to near boiling (50-70 minutes). Then add the pasta or soup mix. Stir or shake, and cook 15 additional minutes.
Cooking Time: 65-85 minutes

Beans
Preparation: Let tough or dry beans soak overnight. Place in cooking jar with water.
Cooking Time: 2-3 hours

Eggs
Preparation: No need to add water. **Note**: If cooked too long, egg whites may darken, but taste remains the same.
Cooking Time: 1-1.5 hours, depending on desired yolk firmness.

Meats (Chicken, beef, and fish)
Preparation: No need to add water. Longer cooking makes the meat more tender.
Cooking Time: Chicken: 1.5 hours cut up or 2.5 hours whole; Beef: 1.5 hours cut up or 2.5-3 hours for larger cuts; Fish: 1-1.5 hours

Baking
Preparation: Times vary based on amount of dough.
Cooking Times: Breads: 1-1.5 hours; Biscuits: 1-1.5 hours; Cookies: 1 hour

Roasted Nuts (Peanuts, almonds, pumpkin seed, etc.)

Preparation: Place in jar. A little vegetable oil may be added if desired.
Cooking Time: About 1.5 hours

MRE's and pre-packaged foods
Preparation: For foods in dark containers, simply place the container in the cooking bag in place of the black cooking jar.
Cooking Times: Cooking time varies with the amount of food and darkness of package.

How to Use the Solar Funnel as a Refrigerator/Cooler

A university student (Jamie Winterton) and I were the first to demonstrate that the Brigham Young University Solar Funnel Cooker can be used - at night - as a refrigerator. Here is how this is done:

The Solar Funnel Cooker is set-up just as you would during sun-light hours, with two exceptions:

1. The funnel is directed at the dark night sky. It should not "see" any buildings or even trees. (The thermal radiation from walls, trees, or even clouds will diminish the cooling effect.).
2. It helps to place 2 (two) bags around the jar instead of just one, with air spaces between the bags and between the inner bag and the jar. HDPE and ordinary polyethylene bags work well, since polyethylene is nearly transparent to infrared radiation, allowing it to escape into the "heat sink" of the dark sky.

During the day, the sun's rays are reflected on to the cooking vessel which becomes hot quickly. At night, heat from the vessel is radiated *outward*, towards empty space, which is very cold indeed (a "heat sink"). As a result, the cooking vessel now becomes a small refrigerator. We routinely achieve cooling of about 20º F (10º C) below ambient air temperature using this remarkably simple scheme.

In September 1999, we placed two funnels out in the evening, with double-bagged jars inside. One jar was on a block of wood and the other was suspended in the funnel using fishing line. The temperature that evening (in Provo, Utah) was 78º F (25.5º C). Using a Radio Shack indoor/outdoor thermometer, a BYU student (Colter Paulson) measured the temperature inside the funnel and outside in the open air. He found that the temperature of the air inside the funnel dropped quickly by about 15º F (8º C), as its heat was radiated upwards in the clear sky. That night, the minimum outdoor air temperature measured was 47.5º F (8.6º C) - but the water in both jars had ICE. I invite others to try this, and please let me know if you get ice at 55 or even 60 degrees outside air temperature (minimum at night). A black PVC container may work even better than a black-painted jar, since PVC is a good infrared radiator - these matters are still being studied.

I would like to see the "Funnel Refrigerator" tried in desert climates, especially where freezing temperatures are rarely reached. It should be possible in this way to cheaply make ice for Hutus in Rwanda and for aborigines in Australia, without using any electricity or other modern "tricks." We are in effect bringing some of the cold of space to a little corner on earth. Please let me know how this works for you.

Conclusion: Why We Need Solar Cookers

The BYU Funnel Cooker/Cooler can:

- Cook food without the need for electricity or wood or petroleum or other fuels.
- Pasteurise water for safe drinking, preventing many diseases.
- Save trees and other resources.
- Avoid air pollution and breathing smoke while cooking.
- Use the sun's free energy. A renewable energy source.
- Cook food with little or no stirring, without burning.
- Kill insects in grains.
- Dehydrate fruits, etc.
- Serve as a refrigerator at night, to cool even freeze water.

(Try that without electricity or fuels!)

The burden for gathering the fuel wood and cooking falls mainly on women and children. Joseph Kiai reports :

From Dadaab, Kenya: "Women who can't afford to buy wood start at 4 am to go collecting and return about noon... They do this twice a week to get fuel for cooking... The rapes are averaging one per week."

From Belize: "Many times the women have to go into the forest dragging their small children when they go to look for wood. It is a special hardship for pregnant and nursing mothers to chop and drag trees back to the village... they are exposed to venomous snakes and clouds of mosquitoes."

And the forests are dwindling in many areas. Edwin Dobbs noted in *Audubon Magazine*, Nov. 1992, "The world can choose sunlight or further deforestation, solar cooking or widespread starvation..."

Americans should be prepared for emergencies, incident to power failures. A Mormon pioneer noted in her journal: "We were now following in their trail travelling up the Platte River. Timber was sometimes very scarce and hard to get. We managed to do our cooking with what little we could gather up..." (Eliza R. Snow) Now there's someone who needed a light-weight Solar Cooker!

Here's another reason to use a solar cooker. Many people in developing countries look to see what's being done in America. I'm told that if Americans are using something, then they will want to try it, too. The more people there are cooking with the sun, the more others will want to join in. A good way to spread this technology is to encourage small local industries or families to make these simple yet reliable solar cookers for others at low cost. I've used this cooker for three summers and I enjoy it. Cooking and making ice with the funnel cooker/cooler will permit a significant change in lifestyle. If you think about it, this could help a lot of people. The BYU Solar Funnel Cooker uses the glorious sunshine -- and the energy of the sun is a free gift from God for all to use!

Answers to commonly-asked questions

Will the cooker work in winter (in the United States)?

As the sun moves closer to the southern horizon in the winter, the solar cooker is naturally less effective. A good measure of the solar intensity is the “UV index” which is often reported with the weather. When the ultraviolet or UV index is 7 or above – common in summer months – the solar cooker works very well. In Salt Lake City in October, the UV index was reported to be 3.5 on a sunny day. We were able to boil water in the Solar Funnel Cooker during this time, but we had to suspend the black jar in the funnel so that sunlight struck all sides. (We ran a fishing line under the screw-on lid, and looped the fishing line over a rod above the funnel. As usual, a plastic bag was placed around the jar, and this was closed at the top to let the fishing line out for suspending the jar.)

The solar “minimum” for the northern hemisphere occurs on winter solstice, about December 21st each year. The solar “maximum” occurs six months later, June 21st. Solar cooking works best from about 20th March to 1st October in the north. If people try to cook with the sun for the first time outside of this time window, they should not be discouraged. Try again when the sun is more directly overhead. One may also suspend the jar in the funnel, which will make cooking faster any time of the year.

It is interesting to note that most developing countries are located near the equator where the sun is nearly directly overhead all the time. Solar Cookers will then serve year-round, as long as the sun is shining, for these fortunate people. They may be the first to apply fusion energy (of the sun) on a large scale. They may also accomplish this without the expensive infrastructure of electrical power grids that we take for granted in America.

How do you cook bread in a jar?

I have cooked bread by simply putting dough in the bottom of the jar and placing it in the funnel in the usual way. Rising and baking took place inside the jar in about an hour (during summer). One should put vegetable oil inside the jar before cooking to make removal of the bread easier. I would also suggest that using a 2-quart wide-mouth canning jar instead of a 1-quart jar would make baking a loaf of bread easier.

What is the optimum “opening angle” for the funnel cooker?

A graduate student at Brigham Young University did a calculus calculation to assess the best shape or

opening angle for the Solar Funnel. Jeannette Lawler assumed that the best operation would occur when the sun's rays bounced no more than once before hitting the cooking jar, while keeping the opening angle as large as possible to admit more sunlight. (Some sunlight is lost each time the light reflects from the shiny surface. If the sunlight misses on the first bounce, it can bounce again and again until being absorbed by the black bottle). She set up an approximate equation for this situation, took the calculus derivative with respect to the opening angle and set the derivative equal to zero. Optimising in this way, she found that the optimum opening angle is about 45 degrees, when the funnel is pointed directly towards the sun.

But we don't want to have to "track the sun" by turning the funnel every few minutes. The sun moves (apparently) 360 degrees in 24 hours, or about 15 degrees per hour. So we finally chose a 60-degree opening angle so that the cooker is effective for about 1.2 hours. This turned out to be long enough to cook most vegetables, breads, boil water, etc. with the Solar Funnel Cooker. We also used a laser pointer to simulate sun rays entering the funnel at different angles, and found that the 60-degree cone was quite effective in concentrating the rays at the bottom of the funnel where the cooking jar sits.

For questions regarding the complete Solar Funnel Cooker kit using aluminised Mylar and a jar for the cooking vessel, please contact CRM at +1 (801) 292-9210.

Tests of the Solar Funnel and Bowl Cookers in 2001

Christopher McMillan and Steven E. Jones
Brigham Young University

Introduction

With an increase in population and a decrease in available fuels such as wood and coal in developing countries, the need for alternative cooking methods has increased. Solar cookers are an alternative to conventional methods such as wood-fires and coal-fires. They provide usable heat for cooking and pasteurising water, without the harmful side effects such as smoke inhalation that non-renewable sources create. In many countries such as Haiti, Bolivia and Kenya, the need for cheap, effective, and safe cooking methods has increased due to poverty and deforestation. Solar cookers are ideal because they rely on the sun's free energy which is abundant in many of the world's poorest countries. Though there are good designs, more testing and improvement is desirable.

There are three areas of comparison that were focused on during the course of the study. The first area of comparison is in the reflective material used. The original material is a mirror-finished aluminium Mylar. Due to the mirror finish, the reflection light is very bright and can be difficult to work over when cooking. An alternative material is a matt-finish Mylar. This material diffuses the sunlight and is not as harsh on the eyes as is the mirrored finish.

The second area of concentration is on the method of containing the air that surrounds the cooker so that the cooker is kept from being cooled by convection currents. A common method is to use a clear plastic oven-safe bag around the cooking vessel. However, this method is rather tedious and awkward to use, and such bags are rarely available in developing countries. Another technique is to use a disk or window make out of a clear plastic or glass. This makes the cooker easier to use.

The third main area of focus is in the cooking containers used. The present cooking vessel for the Solar Funnel Cooker is a black-painted canning jar. This method is also tedious and awkward. The canning jars can be hard to clean, and they can break. Design changes are tested that would allow people to use their own cookware. This too would make the cooker more convenient to use.

The fourth area of testing pitted the wooden block support which we have been using for years against a rabbit-wire support. A rabbit-wire cylinder holds the cooking vessel up off the bottom of the cooker, and allows sunlight to strike essentially all surfaces of the cooking vessel, including the bottom.

The effectiveness of these methods is tested and compared both qualitatively and quantitatively. In addition to acquiring temperature-rise versus time data, we also cooked numerous meals in the solar cookers so as to get hands-on experience with cooking. Several students participated in these cooking tests.

Cooker Designs:

Several solar cooker designs were used during these tests. The Solar Funnel Cooker was the main cooker tested. A Solar CooKit and a bowl-shaped variation of the Solar Funnel Cooker were also tested. Most experiments were comparative tests between the various designs, and the cooker set-up was varied from test to test. The basic design of the Solar Funnel Cooker is a funnel-shaped aluminium Mylar collector. A highly reflective material is necessary to collect and concentrate the sun's rays. The funnel walls are at a 60 degree angle (with respect to the horizontal) since this collects sunlight for a two hour time period without requiring re-orientation to follow the sun. Due to the way the Mylar sheets are cut and folded, a pair of wings on opposite ends of the funnel is formed. The wings increase the collector size and create an elliptical shape at top. At the tips of the wings, the cooker stands about 20 inches high and has a diameter of about 28 inches. At the top, along the minor axis of the elliptical funnel, the cooker stands about 15 inches high, and has a diameter of about 20 inches. Since the Aluminium Mylar does not support itself well, a nine inch diameter by five inch high bucket is used to support the funnel.

The cooking container primarily tested is a glass canning jar that has been painted flat black. The black paint allows the jar to absorb the sun's rays. The canning jar works well due to the added pressure-cooker effect caused by the rubber ring on the inside of the lid. A black-enamel pot and a black-painted stainless steel canister were also used. We found immediately that raising the vessel off the bottom of the cooker using a rabbit-wire stand provided more rapid and even heating than the wooden block used previously. Placing the jar or pot on a wire stand allows as much reflected light onto the cooking vessel as possible. This allows even the bottom of the cooking container to absorb thermal energy that is reflected off the lower portion of the funnel.

Two methods of closing the cookers off from convection currents were used. It is important to keep the air that surrounds the container from circulating, thus keeping the cooking container from being cooled by convection currents or breezes. This first method used was to enclose the cooking vessel and wire stand in a clear plastic bag, such as a heat resistant Reynolds Oven Bag. It is important to make sure that the bag is not touching the cooking vessel, so once the vessel is placed into the clear bag, air is blown into the bag and the bag is tied off. This is the most common method used for solar panel cookers, such as the Solar CooKit, because of the bags' ability to withstand the temperatures attained in these types of cookers. But these bags tear rather easily and they are not readily available in developing countries and must be imported.

The second method of closing off the cooking vessel from convection currents, designed by Dr. Jones, is to place a clear plastic disk down into the funnel above the cooking vessel. The funnel used in the test was a conventional-shaped funnel that was constructed out of thin sheet metal and aluminium-foil lined for better reflectivity. The diameter of this funnel is about 30 inches at the top, and it stands about 16 inches high. The walls also form about a 60 degree angle with respect to the horizontal. This funnel was designed to hold a larger cooking container such as a pot. The diameter of the plastic disk is large enough that the disk does not touch the top of the container. For the experiments that tested this method, a one-sixteenth inch (1.6 mm) thick Lexan disk was used.

Data Collection

To collect the temperatures as a function of time, a Texas Instruments Calculator Based Laboratory (CBL) was used. This portable interface is capable of recording real-time data from multiple channels. The data were downloaded into a graphing calculator, where they can be analysed and graphed immediately. From the calculator, the data can be transferred to a computer spreadsheet such as Microsoft Excel for further analysis. Due to the nature of these experiments and the low cost to purchase the CBL, this is an ideal data collector to use. A graphing calculator was used to program the CBL and to tell it what data to collect, how many points to collect, and the time period between data points collected. Since the CBL does not have any internal programs for data collection, a program must be written into the graphing calculator. There are ready-made programs that can be uploaded into the calculator, or a custom program can be made to fit the needs of the test. The program that the CBL used allowed multiple thermocouples to collect data simultaneously. To ensure that the thermocouples were calibrated against each other, both were run on the same constant temperature sample in very close proximity. Both temperature probes agreed to within $0.21^{O}C$ of each other. For these experiments, this temperature difference was considered to be acceptable.

Procedure

Each experiment was conducted on the campus of Brigham Young University during mid-day, usually between 11:00 am and 2:00 pm to ensure that the sun was close to being directly over-head. This allowed as much sun light as possible to enter the solar collector. Each experiment included several steps, as listed below.

Before each experiment was set up, the volume of the water and the mass of the container were measured and recorded. The heat capacity of the water and the container were also found. The area of the cooker perpendicular to the sun's rays was also measured. To collect temperature data using thermocouple probes, small holes were drilled into the top of the canning jar and stainless steel canister lids. The jar and canister were both painted ultra-flat black to absorb as much of the sun's energy as possible.

On the morning of each test, the designated volume of water was measured out and poured into the cooking vessel. This volume ranged from 0.6 litre for one-quart jars, to 1.2 litters for half-gallon canning jars. For simultaneous testing, the same amount of water was poured into each container. The temperature probes were wired through the holes in the lids of the containers and secured about 13 mm into the water. For comparative tests, the probes were placed the same depth into the water to ensure that the probes did not read different measurements due to depth-related temperature differences within the containers. To enable later analysis; the time, ambient temperature, and solar irradiance were also noted and recorded. These numbers gave a reference point for each test. Each cooker that was to be tested was then completely set up. The temperature probes were secured through the lids, and the jar was placed into the clear oven bag – supported by a wire cage. Each bag was inflated so that no part of the bag touched the sides or top of the cooking container. The cord from the thermocouple to the CBL was passed through the top of the bag, and the bag was tied off with a twist-tie.

The test began once both cookers were completely ready and the CBL had been programmed. Care was taken to block the sun from radiating directly onto the cookers until both were ready to begin. This ensured that the water in both cookers started at very nearly the same temperature. Most tests were set up to collect one data point every four to five minutes, for up to two hours. This allowed the cooker temperatures to reach maxima and then remain at a nearly constant temperature. Once a test was complete, the cooker was disassembled and the data downloaded into the graphing calculator. Though the graphing calculator does allow analysis, a spread sheet such as Microsoft Excel is easier to use. Thus, the data from each test were downloaded from the calculator into Microsoft Excel. The elapsed time (in seconds) and the corresponding temperatures were listed next to each other. A graph of temperature versus time was made, with the Time being the horizontal axis for each test. For comparative tests, the Temperature versus Time data for both cookers was plotted on the same graph. As a reference, a trend-line was fitted to the linear portion of the graph, along with the linear regression and the coefficient of correlation (R2). It is important to have a coefficient of correlation close to one, as this is how close the linear regression fits the data. In a separate column, the temperatures were again listed, however only from 30^{O}C to 70^{O}C. The change in temperature for every ten or twelve minutes was found and logged next to the temperature column. The power output (in Watts) of each cooker could then be calculated.

To calculate the power output of the cookers for each specific test, the mass of the water and of the container were both measured. Though the thermal energy content of the container was relatively small compared to that of water (due to the large heat capacity of water), it was important to add it into the calculation. Also, since several different containers were compared, the energy content of the container was important. The power is found by:

$$Q_{(out)} = Q_{(water)} + Q_{(container)}$$

$$Q_{(out)} = (m_w c_w + m_c c_c)\Delta T$$

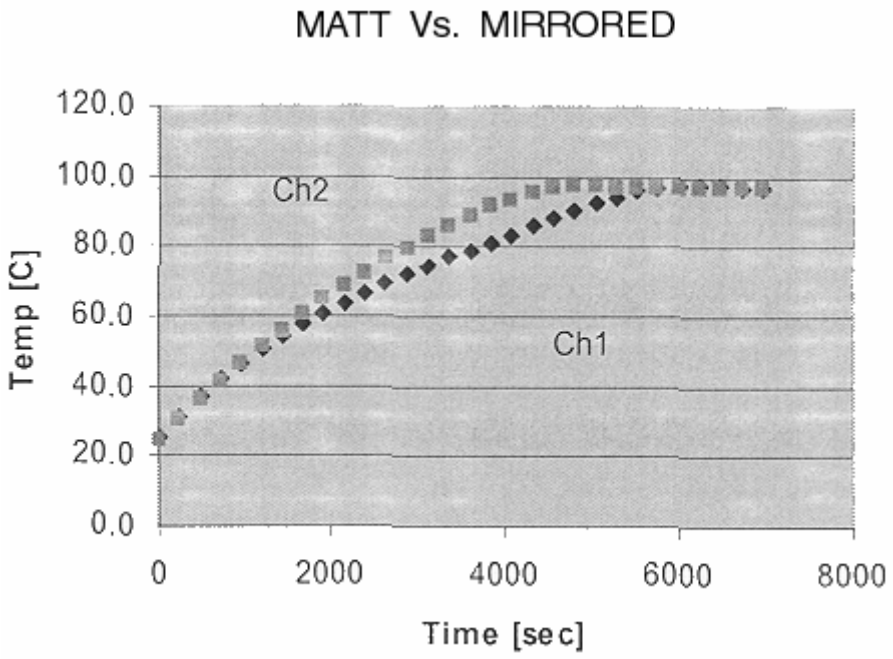
$$Power_{(out)} = \frac{Q_{(out)}}{\Delta t}$$

The power is found in Watts. A power output for each change in temperature for the time interval is calculated and logged next to the T column. Since there are uncertainties in all of the measurements, it is important to include the error in each power output. To do this, the error in the water's and container's measurements is taken into consideration. The error is found by:

$$\pm \Delta P = \sqrt{(\frac{\partial P}{\partial m_w}\Delta m_w)^2 + (\frac{\partial P}{\partial m_c}\Delta m_c)^2 + (\frac{\partial P}{\partial t}\Delta t)_w^2 + (\frac{\partial P}{\partial t}\Delta t)_c^2 + 2(\frac{\partial P}{\partial T}\Delta T)_w^2 + 2(\frac{\partial P}{\partial T}\Delta T)_c^2}$$

Where ±dP is the total error in the calculated error, dmw and dmc are the error in the mass of the water and container respectively, delta-Tp is the error in the temperature difference, and delta-t is the error in the time interval.

This simplifies to:

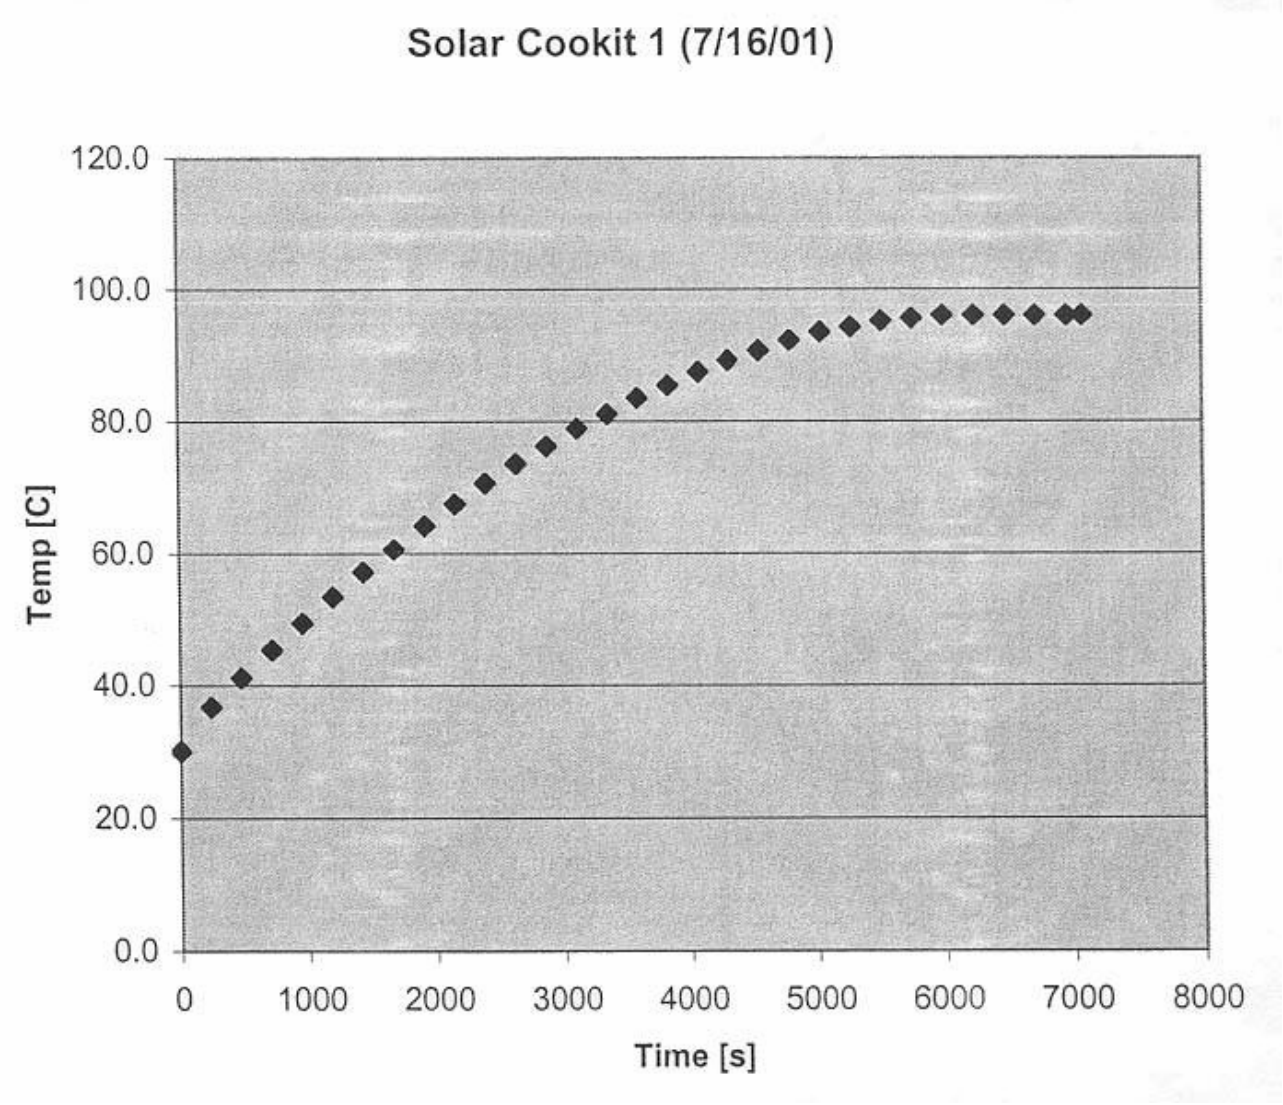


$$\pm \Delta P = \sqrt{[(\frac{c_w \Delta T}{t}\Delta m_w)^2 + (\frac{c_c \Delta T}{t}\Delta m_c)^2 + (\frac{m_w c_w \Delta T}{t^2}\Delta t)^2 + (\frac{m_c c_c \Delta T}{t^2}\Delta t)^2 + 2(\frac{m_w c_w}{t}\Delta T_p)^2 + 2(\frac{m_c c_c}{t}\Delta T_p)^2]}$$

The error was found only for the average change in temperature, rather than for each individual temperature measurement. Since the power output is dependant on the amount of energy coming in from the sun, the cooker efficiency is a good factor to calculate. To find the efficiency, the total amount of local solar radiation must be known. This should be given in watts per square metre, so that the input wattage can be found. To find the power coming in, the area of the cooker perpendicular to the sun's rays was multiplied by the solar radiation to give the amount of power that was being collected by the cooker. Since the Solar Funnel is able to be kept on track with the sun, and since the tests were done during mid-day, it was not necessary to calculate any angles. The efficiency is simply the power output divided by the power input. The solar radiation for each test was supplied by the Department of Physics and Astronomy weather station at Brigham Young University in Provo, UT, where the tests took place.

Results:

Matt vs. Mirror: Several tests were conducted on the matt versus mirror finishes. In each test, the matt finish outperformed the mirror finish. On 27 July, 2001, a matt funnel and a mirror funnel were simultaneously tested with 650 cc of water. The average power output for the mirror finish was 46.4 W ± 1.7 W, while the matt funnel put out an average of 59.4 W ± 2.1 W. The efficiency of the mirror funnel was 15.8%, while the matt was 20.2% efficient.



The following graph shows the temperatures reached by the matt and mirror funnels.

Channel 1 (Ch1) was the mirror finish, and channel 2 (Ch2) was the matt finish. This shows that both funnels peaked at about the same temperature: 97^{O}C (207^{O}F). The matt funnel peaked in about 76 minutes, whereas the mirror funnel peaked in 96 minutes, twenty minutes later. Though this perhaps a tolerable time difference for actual cooking, it is substantial. Every matt vs. mirror test performed in a similar way. These results are due to the way the matt funnel reflects the sun's rays. The mirror finish seems to focus a strip of light onto the cooking vessel more than the matt finish does. As a result, the matt finish diffuses the light

more and the cooker is heated more uniformly. This is good, since the matt finish is easier to work with, delivering much less glare to the eyes.

The following graph shows the temperature rise with time for a Solar CooKit:

Comparing the two graphs above, we find that the Solar CoolKit performed very well, comparable to the Funnel Cooker. We should note that in both cases, we used a canning jar (pressurised) supported by a wire stand. We found that the wire stand improves the performance of the Solar CooKit significantly and hope that this support stand will be used in countries where the Solar CooKit is in use.

In tests where the use of the clear plastic disk was tested against the oven-bag, an aluminium pot was used in the disk-set-up. In these tests, the cooker with an oven bag outperformed the cooker using a plastic disk. On 10 August, 2001, a test was run which compared the disk/pot set-up against the oven-bag/jar set-up. Both cookers follow similar heating paths with time, but the oven-bag/jar did slightly better. Due to the higher mass of the jar compared to the mass of the aluminium pot, and the much higher heat capacity of the water, the average power output for the oven-bag/jar was 39.8 ± 1.4 W, while the disk/pot put out 30.3 W ± 1.2 W. The efficiency of the oven-bag/jar was 14.7% and the efficiency of the disk/pot set-up was 10.4% for this test. This is also partly due to the pressure-cooker effect that the canning jar produces. Though this is a considerable efficiency difference, the disk/pot set-up did very well in subjective tests where food was actually cooked and tasted. In all cases where the disk/pot set-up was used to cook food, the food cooked in about the same amount of time. The ease of the disk/pot set-up is also an important consideration. Overall, in tests where food was cooked, the disk/pot set-up was preferred over the oven-bag/jar set-up.

Conclusions:

As many countries are depleting their natural resources due to increased population and the resulting deforestation, methods other than burning wood are needed to cook food and pasteurise water. Solar

cookers provide a sustainable technology that relies on the sun's free energy. We report several advances to make them better. The need for cheap and effective solar cookers is very great and growing.

The Solar Funnel Cooker has been designed to meet the growing need by being inexpensive and effective. We determined that the Solar CooKit was nearly as effective when a rabbit-wire stand was used to support the cooking vessel. By collecting time vs. temperature data, quantitative analysis has been done. This analysis approach is useful for further development of the cookers.

Several areas of research were explored in 2001. Two finishes were tested for the reflector, a matt finish and a mirror finish. The benefits of the matt over the mirror finish are:

1) The matt finish is easier to work over because the sun's glaring reflection is diffused, and
2) the matt finish out-performs the mirror finish in temperature vs. time tests.

The method of closing off the cooker from convection current was tested and compared with an alternative method – a clear plastic disk. The use of a pot rather that a canning jar was also tested. Though the present oven-bag/jar method does outperform the disk/pot method, the disk/pot method is easier to use and seems to be nearly as efficient. Finally, we showed that a wire-mesh stand is a considerable improvement over the use of a wooden block or other opaque stand for the cooking vessel. We join with our fellow researchers around the world in pursuing further development of solar cookers, particularly to benefit people in developing countries.

Recent Advances in Solar Water Pasteurisation

Boiling isn't necessary to kill disease microbes

The main purpose of solar cookers is to change sunlight into heat which is then used to cook foods. We are all familiar with how successful solar cookers are at cooking and baking a wide variety of foods. In this article I want to consider using the heat in solar cookers for purposes other than cooking. My main focus will be solar water pasteurisation, which can complement solar cooking and address critical health problems in many developing countries.

The majority of diseases in developing countries today are infectious diseases caused by bacteria, viruses, and other microbes which are shed in human faeces and polluted water which people use for drinking or washing. When people drink the live microbes, they can multiply, cause disease, and be shed in faeces into water, continuing the cycle of disease transmission.

World-wide, unsafe water is a major problem. An estimated one billion people do not have access to safe water. It is estimated that diarrhoeal diseases that result from contaminated water kill about 2 million children and cause about 900 million episodes of illness each year.

Boiling contaminated water

How can infectious microbes in water be killed to make the water safe to drink? In the cities of developed countries this is often guaranteed by chlorination of water after it has been filtered. In developing countries, however, city water systems are less reliable, and water from streams, rivers and some wells may be contaminated with human faeces and pose a health threat. For the billion people who do not have safe water to drink, what recommendation do public health officials offer? The only major recommendation is to boil the water, sometimes for up to 10 minutes. It has been known since the time of Louis Pasteur 130 years ago that heat of boiling is very effective at killing all microbes which cause disease in milk and water.

If contaminated water could be made safe for drinking by boiling, why is boiling not uniformly practised? There seem to be five major reasons:

1) people do not believe in the germ theory of disease,
2) it takes too long,
3) boiled water tastes bad,
4) fuel is often limited or costly,
5) the heat and smoke are unpleasant.

Some examples of the cost of boiling water are worth mentioning. During the cholera outbreak in Peru, the Ministry of Health urged all residents to boil drinking water for 10 minutes. The cost of doing this would amount to 29% of the average poor household income. In Bangladesh, boiling drinking water would take 11% of the income of a family in the lowest quartile. In Jakarta, Indonesia, more than $50 million is spent each year by households for boiling water. It is estimated that in the city of Cebu in the Philippines, population about 900,000, about half the families boil their drinking water, and the proportion is actually higher for families that obtain their water from an unreliable chlorinated piped supply. Because the quantities of fuel consumed for boiling water are so large, approximately 1 kilogram of wood to boil 1 litre of water, and because firewood, coal, and coke are often used for this purpose, an inadequate water supply system significantly contributes to deforestation, urban air pollution, and other energy-related environmental effects.

If wood, charcoal, or dung is used as fuel for boiling water, the smoke creates a health hazard, as it does all the time with cooking. It is estimated that 400 to 700 million people, mainly women, suffer health problems from this indoor air pollution. As a microbiologist, I have always been perplexed as to why boiling is recommended, when this is heat far in excess of that which is necessary to kill infectious microbes in water. I presume the reason boiling is recommended is to make sure that lethal temperatures have been reached, since unless one has a thermometer it is difficult to tell what temperature heated water has reached until a roaring boil is reached. Everyone is familiar with the process of milk pasteurisation. This is a heating process which is sufficient to kill the most heat resistant disease causing microbes in milk, such as the bacteria which cause tuberculosis, undulant fever, streptococcal infections and Salmonellosis. What temperatures are used to pasteurise milk? Most milk is pasteurised at 71.7^{O} C (161^{O} F) for only 15 seconds. Alternatively, 30 minutes at 62.8^{O} C (145^{O} F) can also pasteurise milk. Some bacteria are heat resistant and can survive pasteurisation, but these bacteria do not cause disease in people. They can, however, spoil the milk, so pasteurised milk is kept refrigerated.

There are some different disease microbes found in water, but they are not unusually heat resistant. The most common causes of water diseases, and their heat sensitivity, are presented in Table 1. The most common causes of acute diarrhoea among children in developing countries are the bacteria Escherichia coli and Shigelia SD. and the Rotavirus group of viruses. These are rapidly killed at temperatures of 60^{O} C or greater.

Solar water pasteurisation

As water heats in a solar cooker, temperatures of 56^{O} C and above start killing disease-causing microbes. A graduate student of mine, David Ciochetti, investigated this for his master's thesis in 1983, and concluded that heating water to 66^{O} C in a solar cooker will provide enough heat to pasteurise the water and kill all disease causing microbes. The fact that water can be made safe to drink by heating it to this lower temperature - only 66^{O} C - instead of 100^{O} C (boiling) presents a real opportunity for addressing contaminated water in developing countries.

Testing water for faecal contamination

How can one readily determine if the water from a well, pump, stream, etc. is safe to drink? The common procedure is to test the water for bacterial indicators of faecal pollution. There are two groups of indicators which are used. The first is the coliform bacteria which are used as indicators in developed countries where water is chlorinated. Coliform bacteria may come from faeces or from plants. Among the coliform bacteria is the second indicator, Escherichia coli. This bacterium is present in large numbers in human faeces (approximately 100,000,000 per gram of faeces) and that of other mammals. This is the main indicator used if water is not chlorinated. A water source containing 100 E. coli per 100 ccs poses a substantial risk of disease.

The standard method of testing water for the presence of coliforms and E. coli requires trained personnel and a good laboratory facility or field unit which are usually not present in developing countries. Thus, water supplies are almost never tested.

A new approach to testing in developing countries

In 1987, the Colilert MPM Test (CLT) was introduced as the first method which used a defined substrate technology to simultaneously detect coliforms and E. coli. The CLT comes as dry chemicals in test tubes containing two indicator nutrients: one for coliforms and one for E. coli. The CLT involves adding 10 ml of water to a tube, shaking to dissolve the chemicals, and incubating at body temperature for 24 hours. I prefer incubating tubes under my belt against my body. At night I sleep on my back and use night clothes to hold the tubes against my body.

If no coliform bacteria are present, the water will remain clear. However, if one or more coliforms are present in the water, after 24 hours their growth will metabolise ONPG and the water will change in colour from clear to yellow (resembling urine). If E. coli is among the coliform bacteria present, it will metabolise MUG and the tube will fluoresce blue when a battery-operated, long-wave ultraviolet light shines on it, indicating a serious health hazard. I have invited participants at solar box cooker workshops in Sierra Leone, Mali, Mauritania, and Nepal to test their home water supplies with CLT. One hundred and twenty participants brought in samples. In all four countries, whether the water was from urban or rural areas, the majority of samples contained coliforms, and at least half of these had E. coli present. Bacteriological testing of the ONPG and MUG positive tubes brought back from Mali and Mauritania verified the presence of coliforms/E. coli in approximately 95% of the samples. It is likely that soon the Colilert MPN test will be modified so that the test for E. coli will not require an ultraviolet light, and the tube will turn a different colour than yellow if E coli is present. This will make the test less expensive and easier to widely use in developing countries to assess water sources.

Effect of safe water on diarrhoea in children

What would be the effect if contaminated water could be made safe for drinking by pasteurisation or boiling? One estimate predicts that if in the Philippines, families at present using moderately contaminated wells (100 E. coli per 100 ml) were able to use a high-quality water source, diarrhoea among their children would be reduced by over 30%. Thus, if water which caused a MUG (+) test were solar pasteurised so it would be clear, this would help reduce the chance of diarrhoea, especially in children.

Water pasteurisation indicator

How can one determine if heated water has reached 65^{O} C? In 1988, Dr. Fred Barrett (USDA, retired) developed the prototype for the Water Pasteurisation Indicator (WAPI). In 1992, Dale Andreatta, a graduate engineering student at the University of California, Berkeley, developed the current WAPI. The WAPI is a polycarbonate tube, sealed at both ends, partially filled with a soybean fat which melts at 69^{O} C

("MYVEROL" 18-06K, Eastman Kodak Co., Kingsport, TN 37662). The WAPI is placed inside a water container with the fat at the top of the tube. A washer will keep the WAPI on the bottom of the container, which heats the slowest in a solar box cooker. If heat from the water melts the fat, the fat will move to the bottom of the WAPI, indicating water has been pasteurised. If the fat is still at the top of the tube, the water has not been pasteurised.

The WAPI is reusable. After the fat cools and becomes solid on the bottom, the fish line string is pulled to the other end and the washer slides to the bottom, which places the fat at the top of the tube. Another pasteurisation indicator has been developed by Roland Saye which is based on expansion of a bi-metal disc which is housed in a plastic container. This also shows promise and is in the early testing stages. The WAPI could be useful immediately for people who currently boil water to make it safe to drink. The WAPI will indicate clearly when a safe temperature has been reached, and will save much fuel which is currently is being wasted by excessive heating.

[Editor's note: Using Beeswax & Carnauba Wax to Indicate Temperature: In SBJ #15 we discussed using beeswax, which melts at a relatively low 62^{O} C, as an indicator of pasteurisation. We have now found that mixing a small amount of carnauba was with the beeswax (~1:5 ratio) raises the melting temperature of the beeswax to 70^{O} - 75^{O} C. Carnauba wax is a product of Brazil and can be bought in the US at woodworking supply stores. Further testing needs to be done to confirm that the melting point remains the same after repeated re-melting.

Different strategies for solar water pasteurisation

The solar box cooker was first used to pasteurise water. David Ciochetti built a deep-dish solar box cooker to hold several gallons of water. At this time of the year in Sacramento, three gallons could be pasteurised on our typical sunny days.

Dale Andreatta and Derek Yegian of the University of California. Berkeley, have developed creative ways to greatly increase the quantity of water which can be pasteurised, as we will hear about at this conference.

I am also excited about the possibility of pasteurising water using the simple solar panel cookers. By enclosing a dark water container in a polyester bag to create an insulating air space, and by using lots of reflectors to bounce light onto the jar, it is possible to pasteurise useful amounts of water with a simple system. It takes about four hours for me to pasteurise a gallon of water in the summer with the system I am using. Solar panel cookers open up enormous possibilities for heating water not only for pasteurisation, but also for making coffee and tea, which are quite popular in some developing countries. The heated water can also be kept hot for a long time by placing it in its bag inside an insulated box. In the insulated container I use, a gallon of 80^{O} C water will be approximately 55^{O} C after 14 hours. Water at a temperature of 55^{O} C will be about 40^{O} C after 14 hours, ideal for washing/shaving in the morning.

I will close with some advice from the most famous microbiologist, who pioneered the use of vaccinations in the 1890s: Louis Pasteur. When he was asked the secret of his success, he responded that above all else, it was persistence. I will add that you need good data to be persistent about, and we certainly have that with solar cookers; the work in Sacramento, Bolivia, Nepal, Mali, Guatemala, and wherever else the sun shines. Continued overuse of fuel-wood is non-sustainable. We need to persist until the knowledge we have spreads and becomes common knowledge world-wide.

Editor's Note: Testing Water in Developing Countries

The Colilert system makes it possible to test water without the need for a laboratory. IDEXX Laboratories, the manufacturer, recommends that you use five test tubes for each sample. Bob Metcalf explains that five tubes would comprise 50 ml, which is the minimum sample size permitted by US law. This is an unrealistically high standard by which to judge the water in developing countries where you are examining water that is already being drunk, in spite of the fact that it may be making people sick. By using a single test tube (10 ml) there is a very small chance that your sample missed the small number of bacteria that might have been present.

IDEXX Laboratories will also tell you that you need an incubator to achieve valid results. Again, Bob Metcalf tells us that all that is needed is to keep the tubes close to your body for 36 hours, since body temperature is the correct incubation temperature.

What you are actually measuring in the test is the presence of 1) coliform bacteria, and 2) E. coli, a type of coliform bacteria that is largely found in faecal matter. A positive test for coliform bacteria might be due to coliform bacteria that has washed off of plant leaves , and thus be fairly innocuous. A positive test for E. coli, however, would indicate that any bacteriological contamination was from a faecal source, which might also contain Giardia, cholera, or other serious infectious microbes.

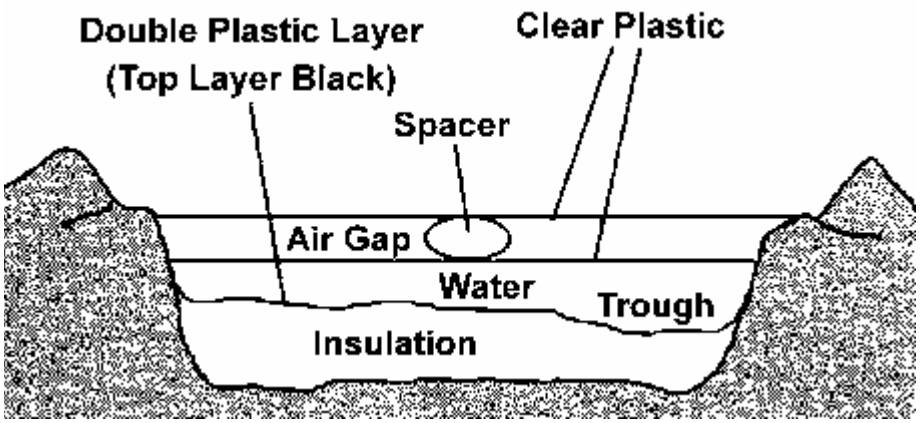
The Solar Puddle

A new water pasteurisation technique for large amounts of water



The lack of clean drinking water is a major health problem in the developing world. To reduce this health risk ways of producing clean water at an affordable cost are needed, and people need to be educated about germs and sanitation, lest they accidentally re-contaminate their clean drinking water. Recently, several of us at the University of California at Berkeley have attacked the first of these requirements. Previous issues of this newsletter have included stories about our water pasteurisation indicator and our flow-through water pasteurises based on a design by PAX World Service. In this article we describe a new low-cost device that pasteurises water.

For those not familiar with the pasteurisation process, if water is heated to 149^{O} F (65^{O} C) for about 6 minutes all the germs, viruses, and parasites that cause disease in humans are killed, including cholera and hepatitis A and B. [Ed. We have reports from the field that at 145^{O} F (63^{O} C) in a solar puddle, bacterial growth might actually be increased. Since this temperature is very close to the minimum pasteurisation temperature mentioned in this article, we suggest that you heat the water to a higher

temperature and perform tests before adopting a solar puddle as your method of pasteurisation]. This is similar to what is done with milk and other beverages. It is not necessary to boil the water as many people believe. Pasteurisation is not the only way to decontaminate drinking water, but pasteurisation is particularly easy to scale down so the initial cost is low.

The new device is called a solar puddle, and it is essentially a puddle in a greenhouse. One form of the solar puddle is sketched in the figure below, though many variations are possible.

One begins by digging a shallow pit about 4 inches deep. The test device was a "family-size" unit, about 3.5 feet by 3.5 feet, but the puddle could be made larger or smaller. If the puddle is made larger there is more water to pasteurise, but there is also proportionately more sunshine collected. The pit is filled with 2 to 4 inches of solid insulation. We used wadded paper, but straw, grass, leaves, or twigs could be used. This layer of insulation should be made flat, except for a low spot in one corner of the puddle.

Put a layer of clear plastic and then a layer of black plastic over the insulation with the edges of the plastic extending up and out of the pit. Two layers are used in case one develops a small leak. We used inexpensive polyethylene from a hardware store, though special UV stabilised plastic would last longer. Put in some water and flatten out the insulation so that the water depth is even to within about 0.5 inch throughout the puddle, except in the trough which should be about 1 inch deeper than the rest. Put in more water so that the average depth is 1 to 3 inches depending on how much sunshine is expected.

A pasteurisation indicator (available from Solar Cookers International at 916/455-4499) should go in this trough since this is where the coolest water will collect. Put a layer of clear plastic over the water, again with the edges extending beyond the edges extending beyond the edges of the pit. Form an insulating air gap by putting one or more spacers on top of the third layer of plastic (large wads of paper will do) and putting down a fourth layer of plastic, which must also be clear. The thickness of the air gap should be 2 inches or more. Pile dirt or rocks on the edges of the plastic sheets to hold them down. The puddle is drained by siphoning the water out, placing the siphon in the trough and holding it down by a rock or weight. If the bottom of the puddle is flat, well over 90% of the water can be siphoned out.

Once the puddle is built it would be used by adding water each day, either by folding back the top two layers of plastic in one corner and adding water by bucket, or by using a fill siphon. The fill siphon should NOT be the same siphon that is used to drain the puddle, as the fill siphon is re-contaminated each day, while the drain siphon MUST REMAIN CLEAN. Once in place the drain siphon should be left in place for the life of the puddle.

The only expensive materials used to make the puddle are a pasteurisation indicator (about $2 for the size tested). All of these items are easily transportable, so the solar puddle might be an excellent option for a refugee camp if the expertise were available for setting them up.

Many tests were done in the spring and summer of this year in Berkeley, California. On days with good sunshine the required temperature was achieved even with 17 gallons of water (2 1/2 inch depth). About 1 gallon is the minimum daily requirement per person, for drinking, brushing one's teeth, and dish washing. With thinner water layers higher temperatures can be reached. With 6 gallons (1 inch depth) 176^{O} F was achieved on one day.

The device seems to work even under conditions that are not ideal. Condensation in the top layer of plastic doesn't seem to be a problem, though if one gets a lot of condensation the top layer should be

pulled back to let the condensation evaporate. Small holes in the top layers don't make much difference. The device works in wind, or if the bottom insulation is damp. Water temperature is uniform throughout the puddle to within 2^{O} F.

After some months the top plastic layers weaken under the combined effects of sun and heat and have to be replaced, but this can be minimised by avoiding hot spots. Another option would be to use a grade of plastic that is more resistant to sunlight. The two bottom layers of plastic tend to form tiny tears unless one is very careful in handling them, (that is why there are two layers on the bottom). A tiny hole may let a little water through and dampen the solid insulation, but this is not a big problem.

There are many variations of the solar puddle. We've been able to put the top layer of plastic into a tent-like arrangement that sheds rain. This would be good in a place that gets frequent brief showers. Adding a second insulating layer of air makes the device work even better, though this adds the cost of an extra layer of plastic. As mentioned the device can cover a larger or smaller area if more or less water is desired. One could make a water heater by roughly tripling the amount of water so that the maximum temperature was only 120° F or so, and this water would stay warm well into the evening hours. This water wouldn't be pasteurised though. One could help solve the problem of dirty water vessels by putting drinking cups into the solar puddle and pasteurising them along with the water. The solar puddle could possibly cook foods like rice on an emergency basis, perhaps in a refugee camp.

The "Easy Lid" Cooker Designed by Chao Tan and Tom Sponheim

Although designs for cardboard cookers have become more simple, fitting a lid can still be difficult and time consuming. In this version, a lid is formed automatically from the outer box.

Making the Base

Take a large box and cut it in half as shown in Figure 1. Set one half aside to be used for the lid. The other half becomes the base.

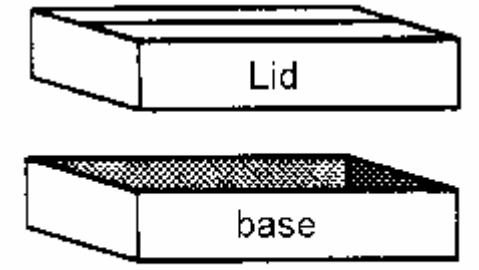

Figure 1

Fold an extra cardboard piece so that it forms a liner around the inside of the base (see Figure 2).

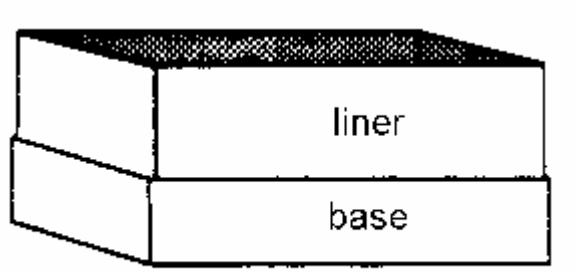

Figure 2

Use the lid piece as shown in Figure 3 to mark a line around the liner.

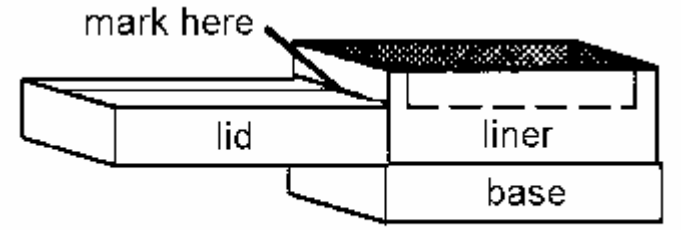

Figure 3

Cut along this line, leaving the four tabs as shown in Figure 4.

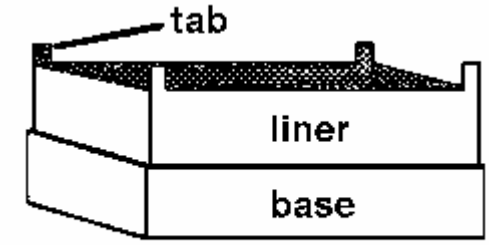

Figure 4

Glue aluminium foil to the inside of the liner and to the bottom of the outer box inside.

Set a smaller (inner) box into the opening formed by the liner until the flaps of the smaller box are horizontal and flush with the top of the liner (see Figure 5). Place some wads of newspaper between the two boxes for support.

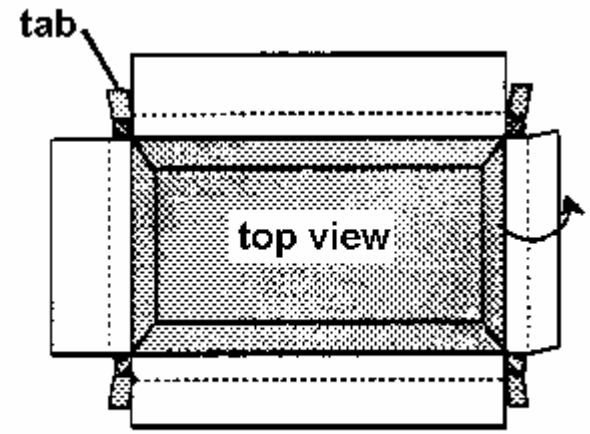

Figure 5

Mark the underside of the flaps of the smaller box using the liner as a guide.

Fold these flaps down to fit down around the top of the liner and tuck them into the space between the base and the liner (see Figure 6).

Fold the tabs over and tuck them under the flaps of the inner box so that they obstruct the holes in the four corners (see Figure 6).

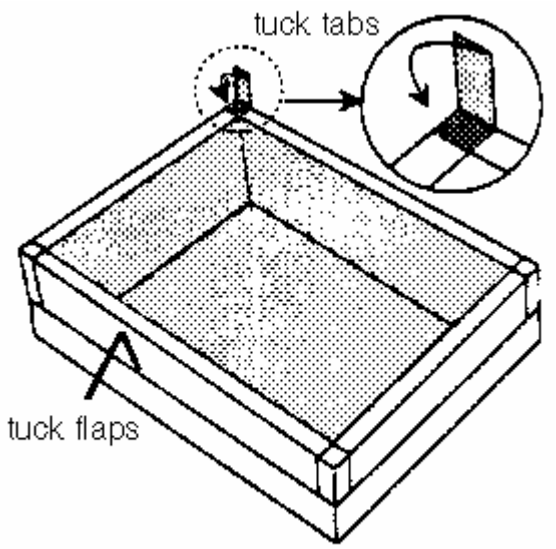

Figure 6

Now glue these pieces together in their present configuration.

As the glue is drying, line the inside of the inner box with aluminium foil.

Finishing the Lid

Measure the width of the walls of the base and use these measurements to calculate where to make the cuts that form the reflector in Figure 7. Only cut on three sides. The reflector is folded up using the fourth side as a hinge.

Glue plastic or glass in place on the underside of the lid. If you are using glass, sandwich the glass using extra strips of cardboard. Allow to dry.

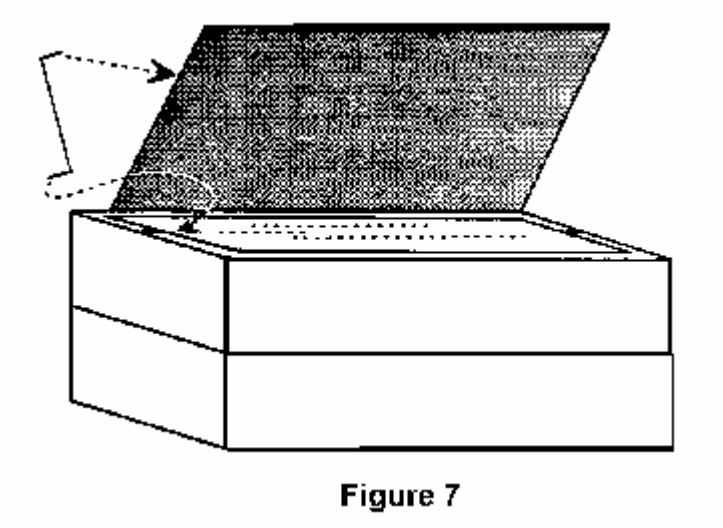

Figure 7

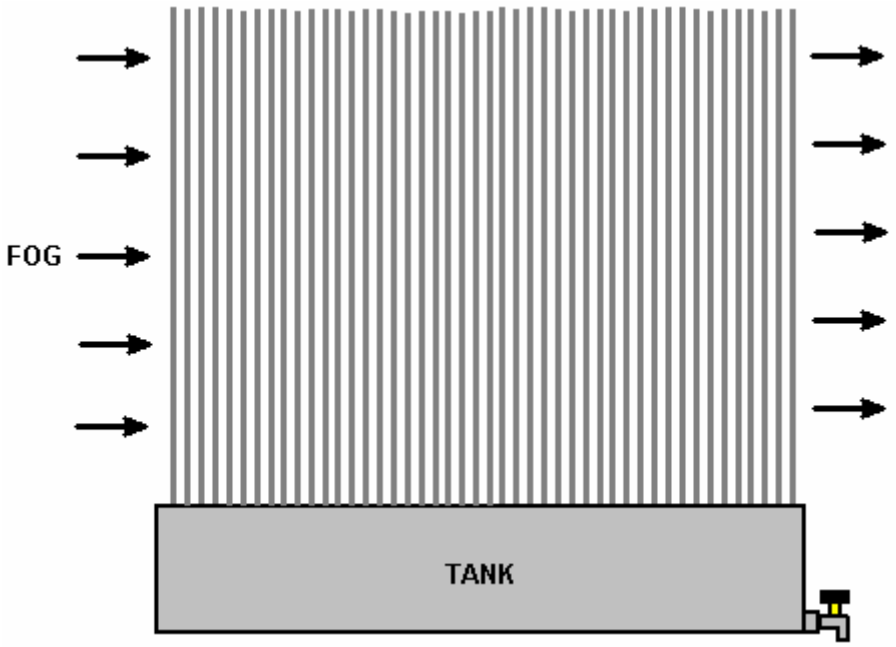
Bend the ends of the wire as shown in Figure 7 and insert these into the corrugations on the lid and on the reflector to prop open the latter.

Paint the sheet metal (or cardboard) piece black and place it into the inside of the oven.

Improving Efficiency

Glue thin strips of cardboard underneath the sheet metal (or cardboard) piece to elevate it off of the bottom of the oven slightly.



Cut off the reflector and replace it with one that is as large as (or larger than) the entire lid. This reflects light into the oven more reliably.

Turn the oven over and open the bottom flaps. Place one foiled cardboard panel into each airspace to divide each into two spaces. The foiled side should face the centre of the oven.

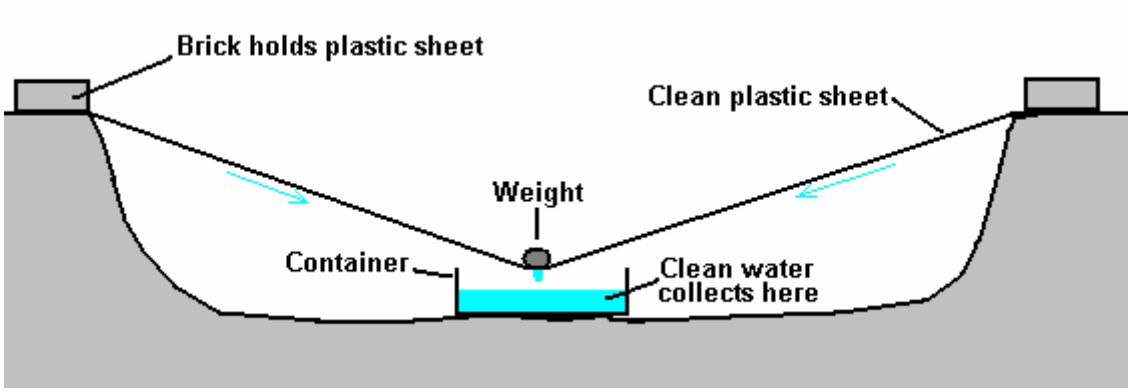
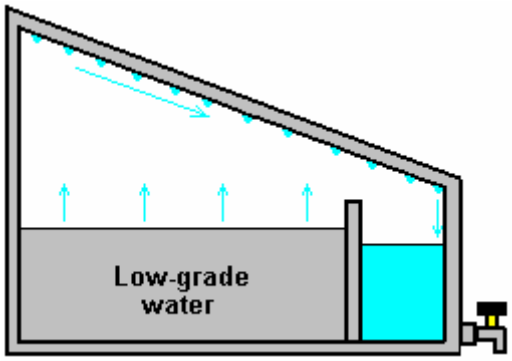
Water Systems. Getting adequate drinking water can often be a problem. One solution introduced for an area where there is almost never any rainfall is particularly interesting. This region gets fogs in the early morning, so plastic devices were constructed to take advantage of this fact. The devices were like plastic clothes brushes with long, slender vertical projections. The fog encountering these, condenses into freshwater droplets on the surface of these vertical fronds and run down the fronds into a plastic tank which forms the base of the device. No moving parts. No input power needed, but the result is large quantities of drinking water every morning. There is very little evaporation from the tanks, due to the small surface area of the stored water:



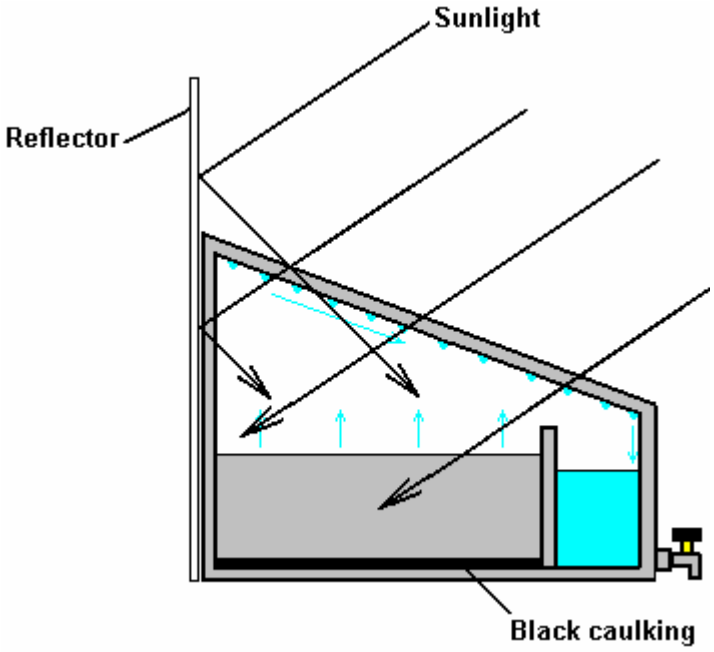
This effect is very noticeable on foggy days where trees drip water extensively due the fog depositing moisture on the leaves and branches.

An emergency measure where water is needed, is to fasten a clean plastic bag around a branch of a tree. Trees lift a large amount of water through their root systems and a good deal of that water exist from the leaves of the tree. The plastic bag intercepts that moisture loss and collects it as clean water:



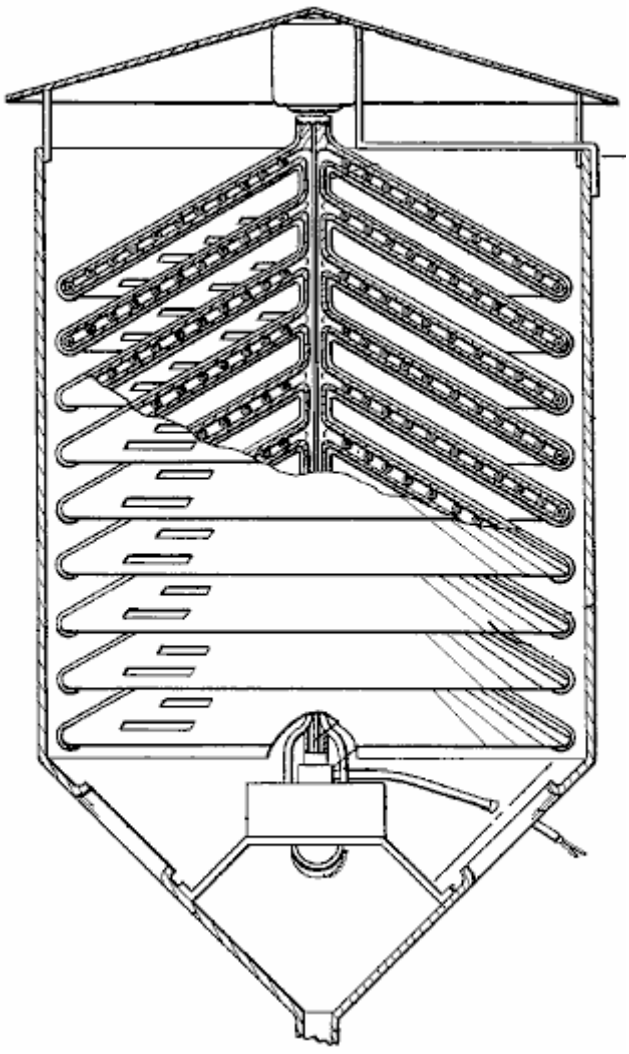
Another emergency measure is to use a clean plastic sheet and a hole dug in the ground. A clean container is placed in the centre of the hole and the plastic sheet used to cover the hold. The sheet is held around the edges of the hole with stones or any other suitable heavy material – bricks, timber, etc. A weight is then placed in the centre of the plastic sheet, pulling it down into a slope in every direction and forming an inverted peak over the container:

The area under the plastic sheet is heated by the greenhouse effect. Moisture also comes from the earth inside the enclosed hole. The moisture in the air in the cavity condenses on the underside of the plastic sheet. But as the plastic sheet is shaped into an inverted pyramid due to the weight just above the container, the water runs down and drips into the container. Again, no input power required and no moving parts.

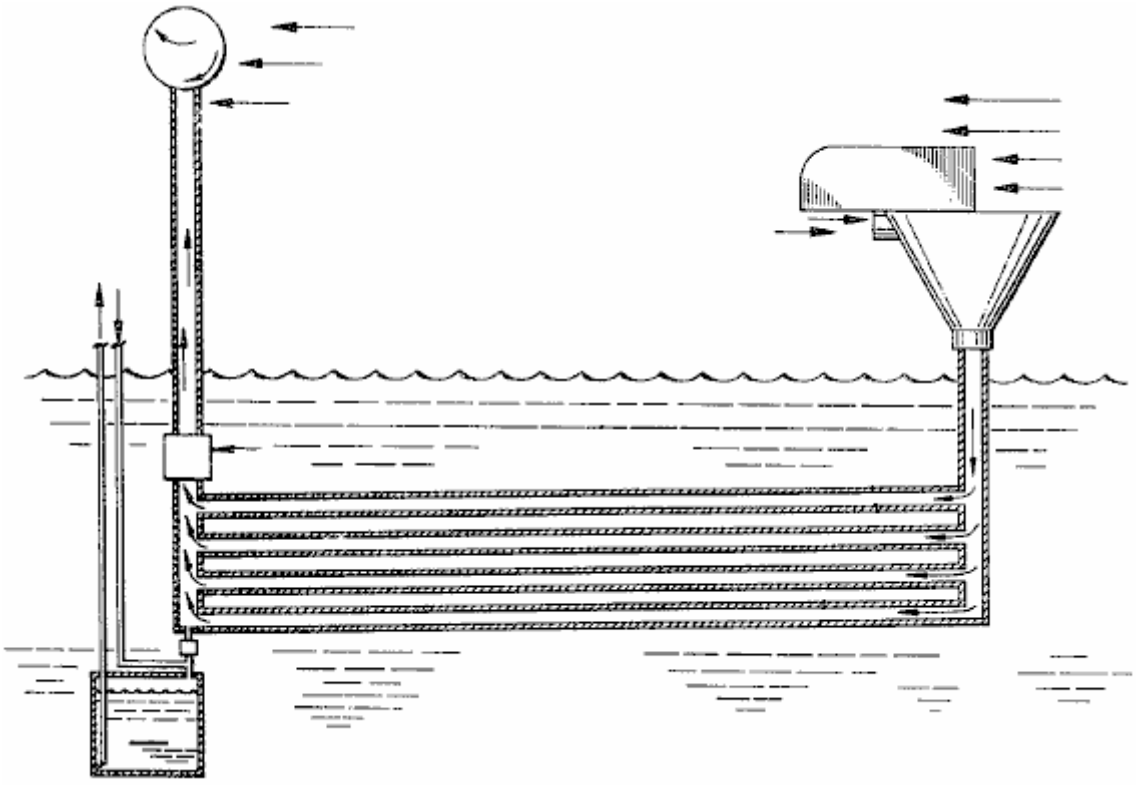


While these methods produce good quality water which is effectively distilled water, it should not be considered to be sterile and immediately ready for human consumption, even though any risk from drinking it 'as-is' is likely to be very low. There will always be air-borne pathogens, and the 'clean' components used to collect the water in the first place may not be as clean as was thought. The same applies to the excellent quality water produced by dehumidifiers, where the inner working surfaces cannot be considered sterile after the equipment has been used for any length of time. To raise the water quality, boiling briefly, microwaving the water or it to UV radiation should kill any remaining harmful organisms in the water and make it fit for consumption.

Applying these same methods on a more permanent basis, leads to the construction of devices of the following type:



There can be many variations on this shape. These devices are generally built either with glass lids or the whole construction in acrylic sheet. Here, the greenhouse effect heats the inside of the box, causing evaporation of the water inside. This condenses on the walls and lid of the box, where it runs down and into the clean-water section.



This particular design can be further enhanced as shown on the http://www.permapak.net/solarstill.htm web site, where the heating inside the box is upgraded by using black high-temperature silicone to coat the inside of the bottom of the case. The black material absorbs sunlight particularly well and so helps to heat the water. Another enhancement is to place a reflector, possibly made from aluminium foil, behind the unit in order to increase the amount of sunlight or UV radiation reaching the water inside the box:

On a larger scale, US patents 2,996,897 (1960) from Elmer Grimes:

and Patent 4,418,549 (1982) from Calice Courneya:

show methods of extracting large amounts of drinking water from moisture in the air:

Another system is using a large Fresnel lens to distil water which is not suitable for drinking. This is possible using the most simple equipment of two glass bottles and a piece of copper tubing. If it is still there, the video at http://www.youtube.com/watch?v=aXjMAItCMl0 shows the method, though I must admit that I would prefer to take the liquid which he drinks and pass it through the system again to improve it's quality further.

Toribio Bellocq. A serious problem for farmers and individuals is the cost of pumping water up from a borehole or well. While the combined Lever / Pendulum system of Veljko Milkovic described in Chapter 4 can reduce the amount of effort required by a substantial margin, there are other methods which could be useful.

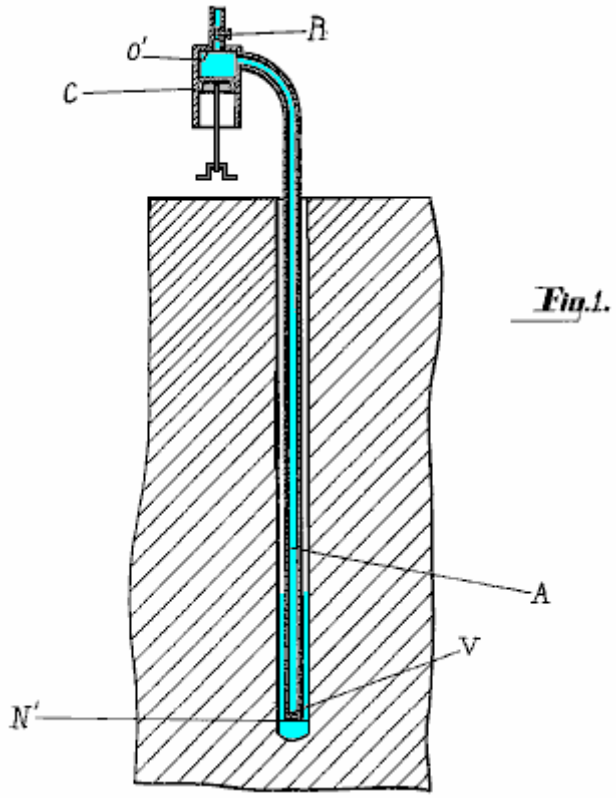
It was originally thought that water could not readily be pumped to a greater height than 32 feet or so unless the pump was located at the bottom of the pipe. Toribio Bellocq demonstrated in 1924 that this is actually not the case and that water can be pumped to any height using a pump mounted at the top of a vertical pipe. He showed a working system to the Patent Office where an 80-foot vertical pipe was used to demonstrate the principle and having proved the point, he was granted US Patents 1,730,336, and 1,730,337, and later, US Patent 1,941,593 in which he describes chamber devices which can enhance the sonic wave operation.

Toribio's system is very straightforward. He places a one-way ball valve at the bottom of the vertical pipe (item **V** in the diagram below). A crank rod is then used to vibrate piston **C** in its pumping cylinder. The pumping cylinder has no valves and the piston stroke is very short. Both the pipe and the pump cylinder are filled with water before the operation is begun.

The rapid movement of the piston creates a pressure wave in the water in the pipe. The pressure wave causes the water pressure inside the pipe to rise and fall rapidly. This altering water pressure at the one-way valve at the bottom of the pipe, causes water to be drawn into the pipe when the pressure is low and the valve prevents the water flowing out again when the pressure rises.

This repeating action causes water to be pumped up the vertical pipe and out through an adjustable valve **R**. When the pumping action is timed correctly, there is an almost continuous flow of water from the pipe.

Toribio quotes an example in his patent, where the vertical pipe has an internal diameter of one inch, placed in a well where the water is twenty metres below the ground level. The valve opening is 30 mm and the sealing ball of the valve has a diameter of about 38 mm and contained in an ordinary cage which allows some 20 mm of vertical movement of the valve.



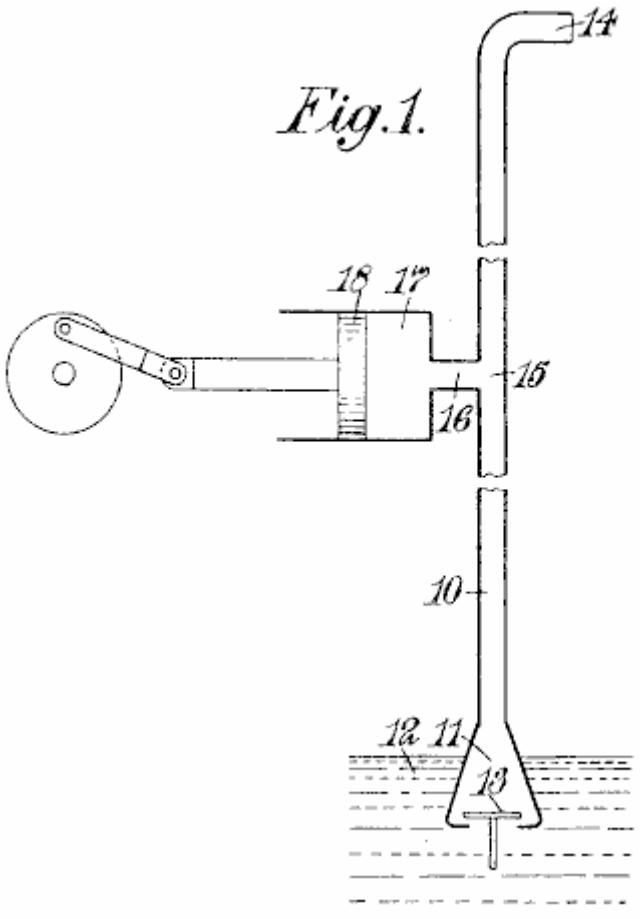


Fig.1.

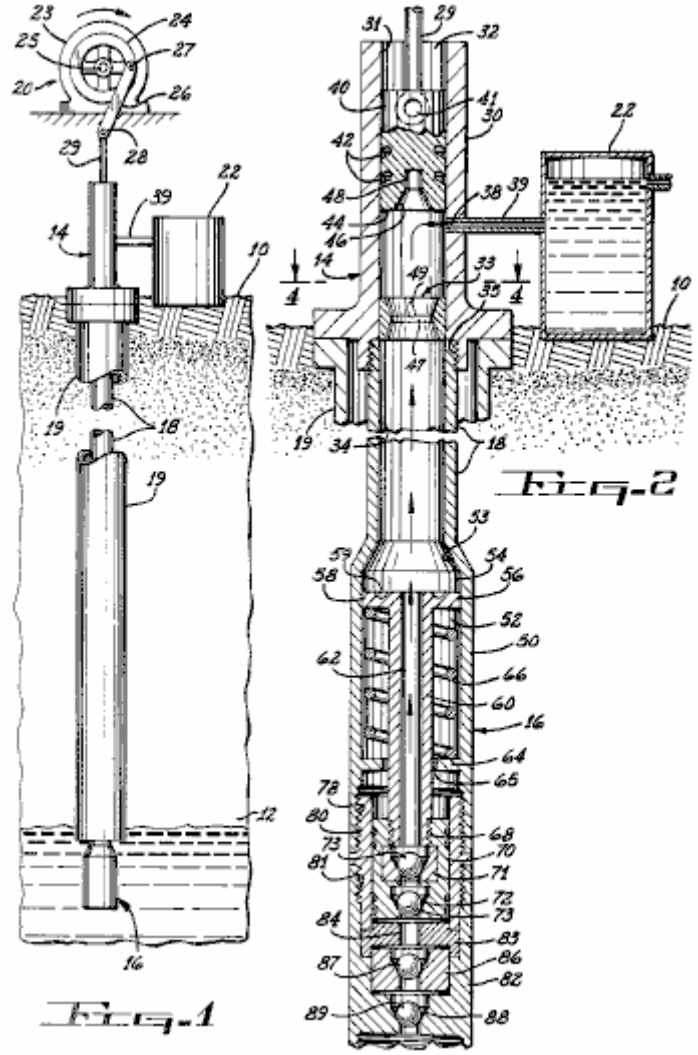

With this arrangement, the piston at the surface has a diameter of 50 mm and a stroke of 38 mm and is driven by an electric motor at about 360 rpm. The outflow pipe has an internal diameter of half an inch and the valve **R** is used to control the rate of flow out of the system. When the valve is adjusted correctly, a continuous flow is achieved and the flow rate is about 1,000 litres per hour (265 US gallons per hour, or 220 Imperial gallons per hour). It is important that the initial filling of the pipe and fully-open piston avoids getting any air trapped along with the water. The compressor cylinder can be horizontal or vertical. The well can be of any depth and there is no need for the pipe to be straight or vertical. When the system is adjusted correctly, there is little or no wear on the valve at the bottom of the pipe. The liquid pumped does not have to be water.

Richard Dickinson. US Patent 2,232,678 of 1937, show a very similar system with a piston being driven in a cylinder without valves, creating a pressure wave in the vertical pipe which has a similar one-way valve at the bottom of the pipe. Interestingly, no mention of Bellocq's patent is made. Dickinson's patent drawing of the system outline is shown here:

Arthur P. Bentley. The grandson of the car designer, Arthur Bentley has some 34 patents to his name, one of which (US 4,295,799) is very much like Toribio Bellocq's pump system. Richard Bruner writing in the Calgary Herald newspaper in 1989, tells how a prototype of the Bentley design was tested on a Navajo reservation in Arizona. Driven by four solar panels, a flow rate of 120 US gallons per hour was achieved, (about half that of Bellocq's rate at 20 metres depth), though the depth of the Navajo well was not mentioned. The manufacturers claim that the pump can operate at depths of up to 4,000 feet.

Neither this Bentley patent nor his earlier patent 3,804,557 makes any mention of Bellocq which seems somewhat strange, especially with the marked apparent similarity between the designs. Again, we see here, a piston being used to generate an acoustic wave in the vertical pipe and a series of one-way valves at the bottom of the tube being used to trap the rising column of water and prevent it from flowing out of the bottom of the pipe again. A variation in this patent is the addition of a spring loaded bottom section to the pipe which is alternately compressed and expanded by the sound waves as part of the pumping process as shown in the following diagrams:

The Ram Pump. In hilly areas, it is frequently necessary to pump water up to locations where it is needed. These locations are usually considerably higher than the source of water. There is a simple device called a "Ram Pump" which is powered by water flow alone and needs no other form of power. In a way, it operates very much like the pumps just described, in that water flowing into a pressure chamber causes fluctuating pressure which with just two valves, and no other moving parts, pumps water to a considerable height.

A Ram Pump can be used if there is a fast-flowing stream of clean water, and more than 50% of the water flow into the pump can be lifted to a higher level. The remainder of the water flows back into the stream at a point lower down. These pumps are readily available commercially and interestingly, they have a COP of infinity as the user does not have to supply any input power and yet substantial pumping power is produced for an unlimited period. As this is a standard Engineering technique, nobody gets upset at the though of 'perpetual motion' or 'free-energy' even though the pump can go on pumping for years with absolutely no fuel being burnt. This is energy being drawn from the environment in the same way as a self-powered compressed air engine draws energy from the environment, and yet, the compressed air engine is considered to be "unbelievable" while the Ram Pump is accepted without question. Could there be a certain degree of bias being seen here? The power operating the pump comes from the water flowing down hill. The water arrives at this height by falling as rain. The rain gets up there by evaporation caused by water being heated by the sun. So, bottom line, the pumping power comes from the sun.

If a fast-flowing stream is not available but the terrain allows it, then a Ram Pump feeding system can be built. Ideally, there should be a drop of at least two metres (six feet) on the inlet pipe. This creates a fast flow into the pump by feeding it through a steeply sloping intake pipe, like this:

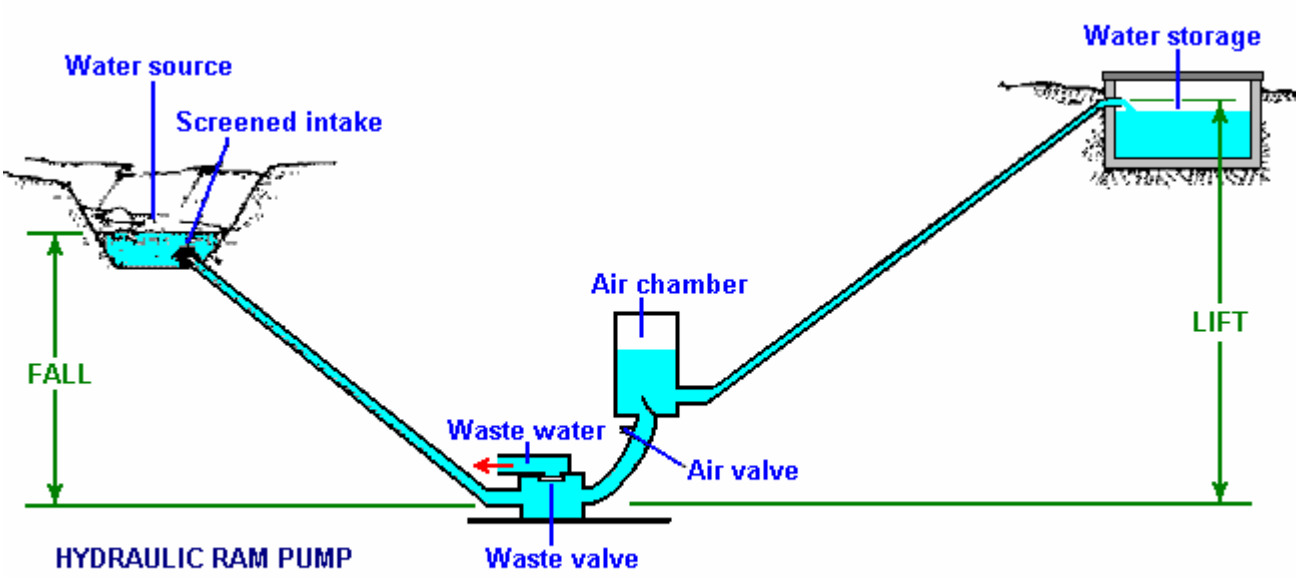

Diagram from: www.thefarm.org/charities/i4at/lib2/hydrpump.htm

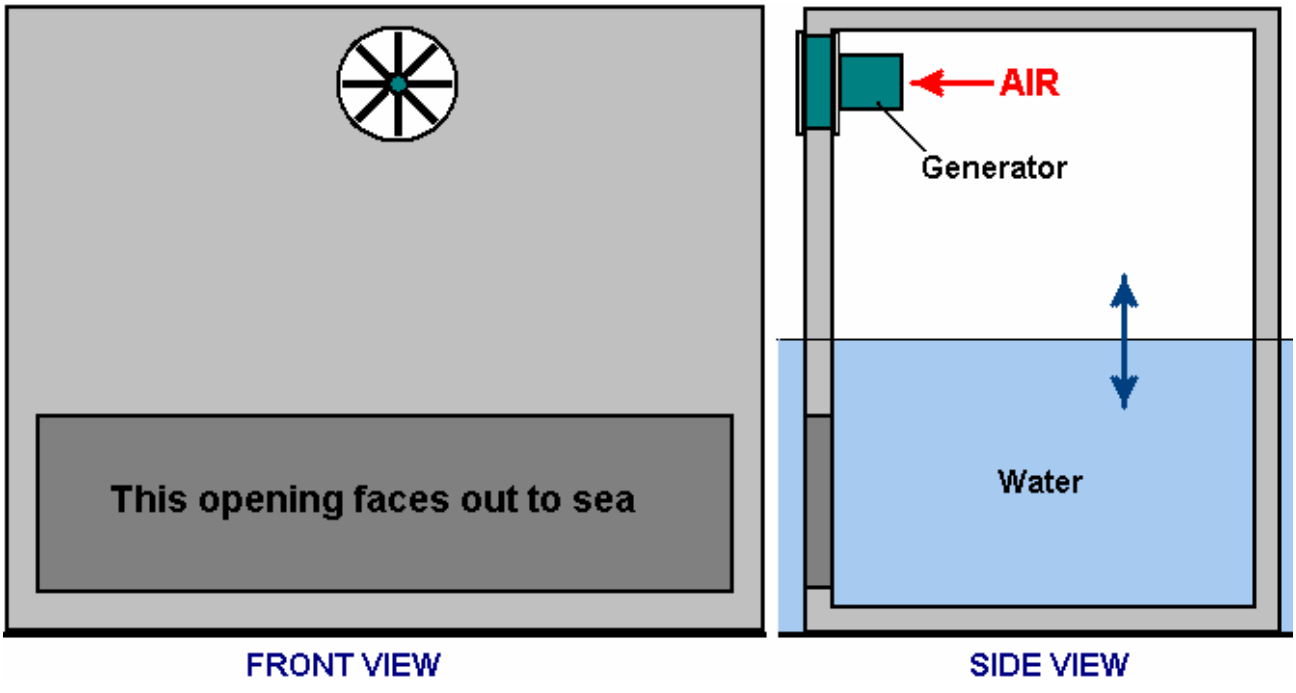
The performance of a Ram Pump is impressive even though it has only two moving parts. With an input fall of just four metres and a small flow rate of just three litres per minute, a Ram Pump can deliver 69 litres per day to a massive height of 100 metres vertically above the pump. Or, 159 lpd to 60 metres above the pump, or 258 lpd to a height of 40 metres above the pump. This is impressive for such a simple device.

It operates by the water rushing into the air chamber. This raises the pressure until the valve at the base of the chamber slams closed. The increased pressure in the chamber pushes water out of the delivery outlet, lowering the pressure again. While this is happening, the closed valve causes a 'water-hammer' wave of reverse pressure which pushes excess water out of the 'waste' pipe and pushes water back up the intake pipe. When the pressure wave in the intake pipe dissipates, the water rushes back down the pipe, pushing the valve at the base of the air chamber, open again, to repeat the cycle. This oscillating pressure wave causes the pumping action, very much in the same way as the previous pumps which use a mechanical oscillator pump as no free-flowing water is available to create the oscillation.

Commercial ram pumps have an efficiency of about 66%. The calculation of performance is:
D = (S x F x E) / L
Where:
D = The quantity of water in litres delivered in 24 hours.
S = The quantity of water, in litters per minute, fed to the pump.
F = The height in metres of the water source above the pump intake.
E = The efficiency of the pump (assume 33% for home built units).
L = The height in metres, of the supply outlet above the pump.

Reproduced here by kind permission of US AID 1982 from the web site shown in the diagram above, is a table of values, calculated from the formula above, and assuming the 66% efficiency of a commercial unit. The input flow for these numbers is a tiny 1 litre per minute trickle. This is less than the hydroxy gas rate produced by the Smack's Booster shown in Chapter 10, so in practice, you will be multiplying the numbers in this table by a realistic number of inflow litres per minute.



Litres Delivered over 24 Hours

Working Fall (m)	Lift - Vertical Height to which Water is Raised Above the Ram (m)

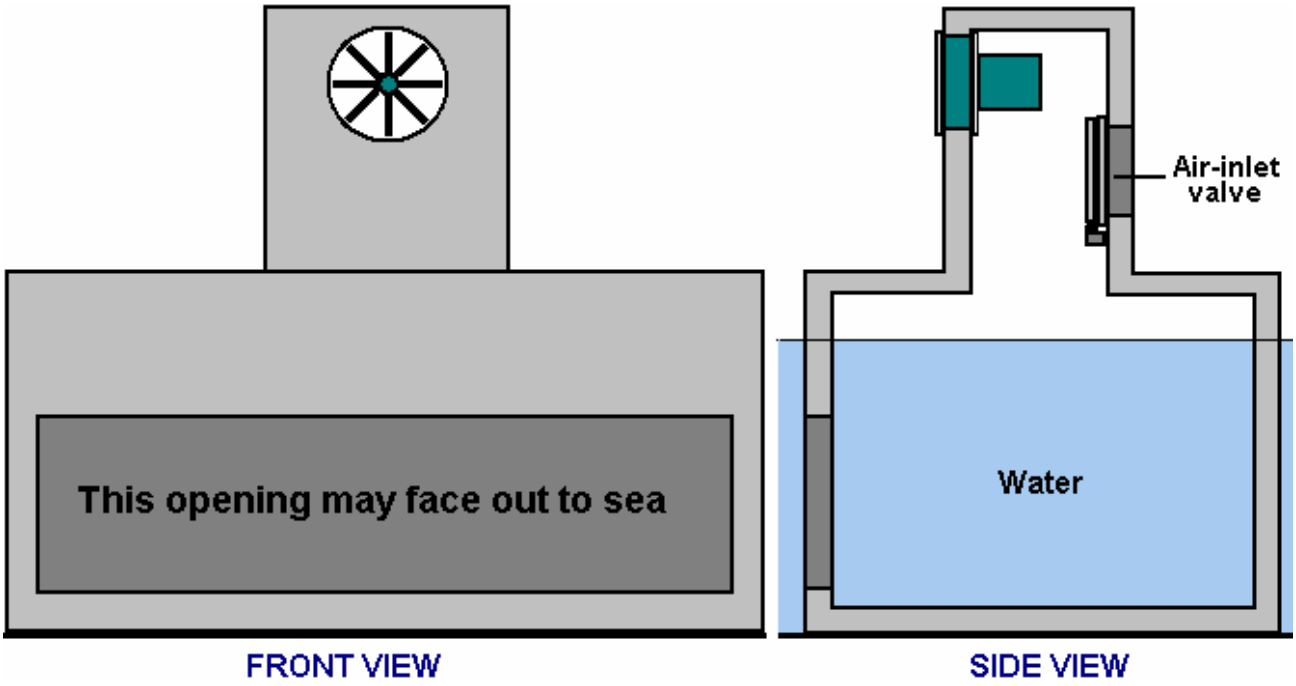
Wave Power

Although not generally thought of as an option for personal use, wave power does have a high potential, although, like wind power and unlike tidal power, not always available. We tend to think of wave power systems as being large scale and very expensive, but that is not always the case. At it's most basic level, most wave power system uses the varying distance between the surface of an ocean or sea and some fixed point on land or the sea bed.

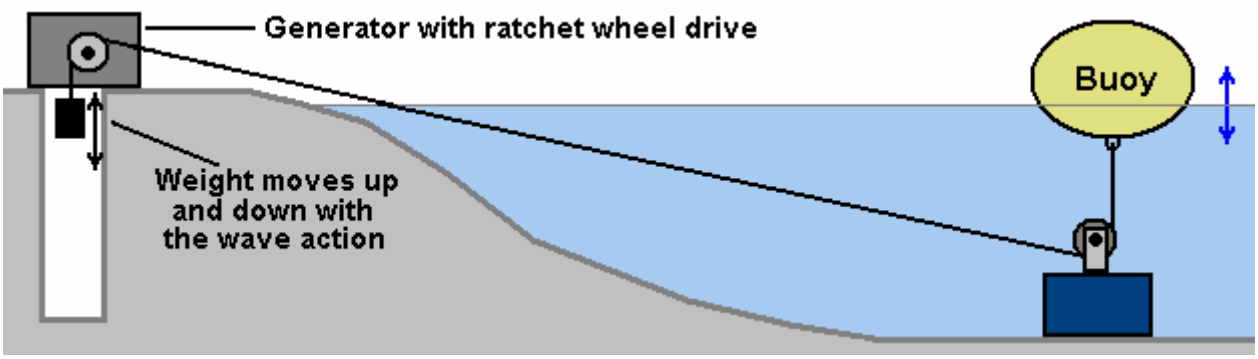


Ideally, there should be a minimum of moving parts. One neat design uses a simple rectangular concrete housing with an electrical generator mounted above sea level. The generator being above sea level is easy to reach for maintenance or replacement and there are no moving parts underwater. It is a very simple design which can be built quite easily. In it's most simple form, it is just a rectangular box with an underwater opening:

Here, a large opening allows the sea to flow into the structure which makes the water level inside the box move up and down with the wave motion outside. As a wave passes by, it compresses the air inside the box and the air is driven out through the generator opening, spinning the generator blades in the same way as a wind-powered generator has it's blades spun by the wind.

Some generators operate well with the air flowing backwards and forwards through the blades, generating electricity no matter which way the blades are spun. With a generator which works better with just one direction of spin, then a large flap valve is installed and it allows air to flow into the structure when the water level is falling but closes immediately the water level starts rising again.

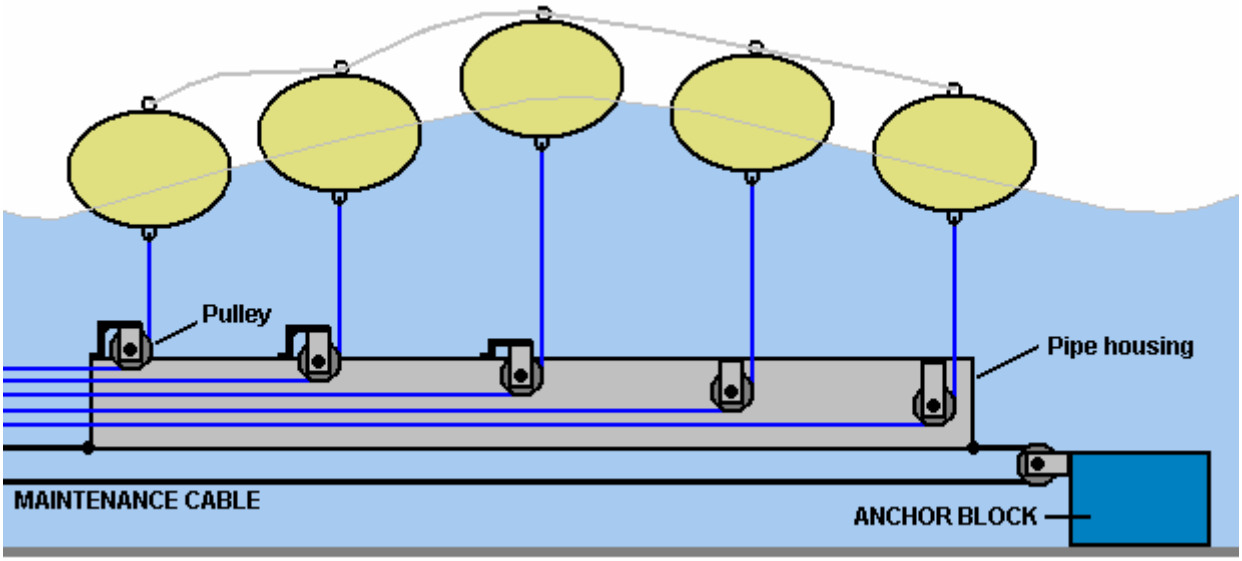
Even though this style of wave power generator is so simple, it works very well in practice, provided that the vertical dimensions are arranged so that the top of the underwater opening is below the lowest neap tide and the bottom of the generator opening is above the highest spring tide. A baffle arrangement can be used to protect the generator from spray and storm debris. There is no need to have the structure full width above the water level:



This has the very considerable advantage that the area of the water surface inside the structure is very much larger than the cross-sectional area of the generator housing column and so the air rushes out through the generator much faster than the wave rises. This amplification factor can be increased by increasing the length of the base of the unit, further enlarging the water surface area inside the structure. If wave action is frequently very strong, then it may be preferred to have the undersea opening facing inshore or sideways in order to reduce the amount of material driven into it by very strong surges.

Another fairly simple wave power generator system design which is based on simple principles, is suggested on Stefan Nystrom's website http://www.wavepartner.eu/page_1219330357093.html and is called the "WaveReaper" system. It operates using a large number of separate buoys. Plastic barrels are suggested as suitable buoys but almost any non-dangerous containers which will not corrode in the sea and which have a considerable internal volume, can be used in this system.

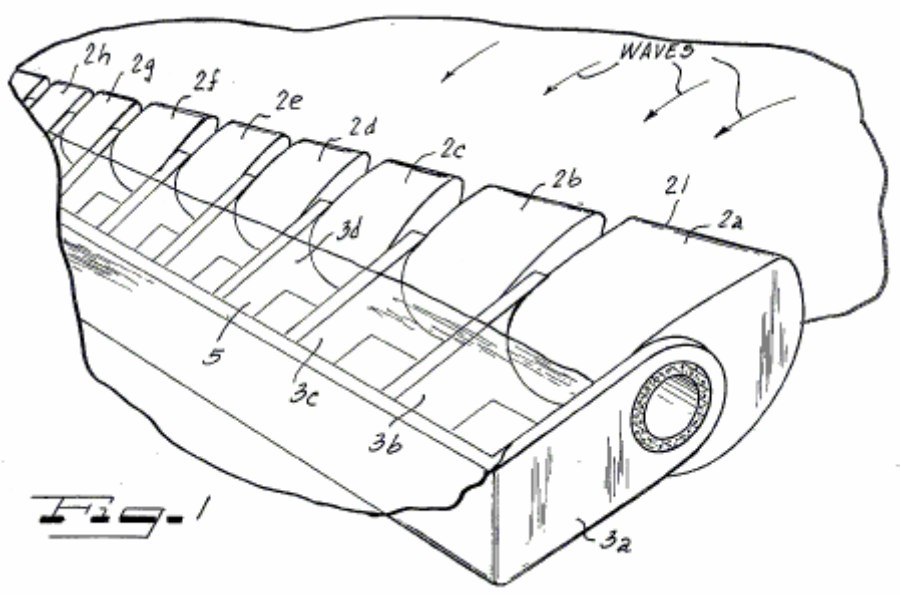
Each basic unit consists of a float, a pulley, a cable and a ratchet drive connection to the shaft of an electrical generator. The power provided by the movement of the buoy can be very substantial as sea water weighs a considerable amount. The connecting cable is kept taught by a heavy weight, and the cable runs over a pulley which is mounted on a shaft which connects to the shaft of the generator. Bicycle parts are suggested for this section of the drive as they are cheap and readily available in most places and they come with a toothed sprocket wheel which already has a suitable ratchet built into it.



The reason for the shaft is that a whole series of buoys are used. These buoys are positioned progressively further and further from the shore so that an incoming wave raises the buoys one after the other in a regular

sequence. This means that while one buoy is letting its cable run back inshore (pulled by it's inshore weight), one or more of the other buoys will be rising and applying drive to the shaft linked to the generator. This arrangement allows the generator shaft to receive a continuous drive. Having a heavy flywheel on this shaft is an added advantage as it will smooth out the repeated drive strokes provided by the buoys:

Having a sheaf of moving cables threaded through the sea near the shore is asking for a major tangle with seaweed and all kinds of other drifting material. Very sensibly then, Stefan suggests that the cables be housed in a protecting pipe. Considerable care needs to be taken to make sure that the cables do not rub against anything as the movement is constant and the forces involved are high. Each cable needs to have it's own space keeping it clear of all the other cables and having a pulley mounted at any points where there is a change of direction.



To make maintenance easier, it is also suggested that these protecting pipes are not fixed in position but are themselves on a pulley system so that they can be hauled ashore:

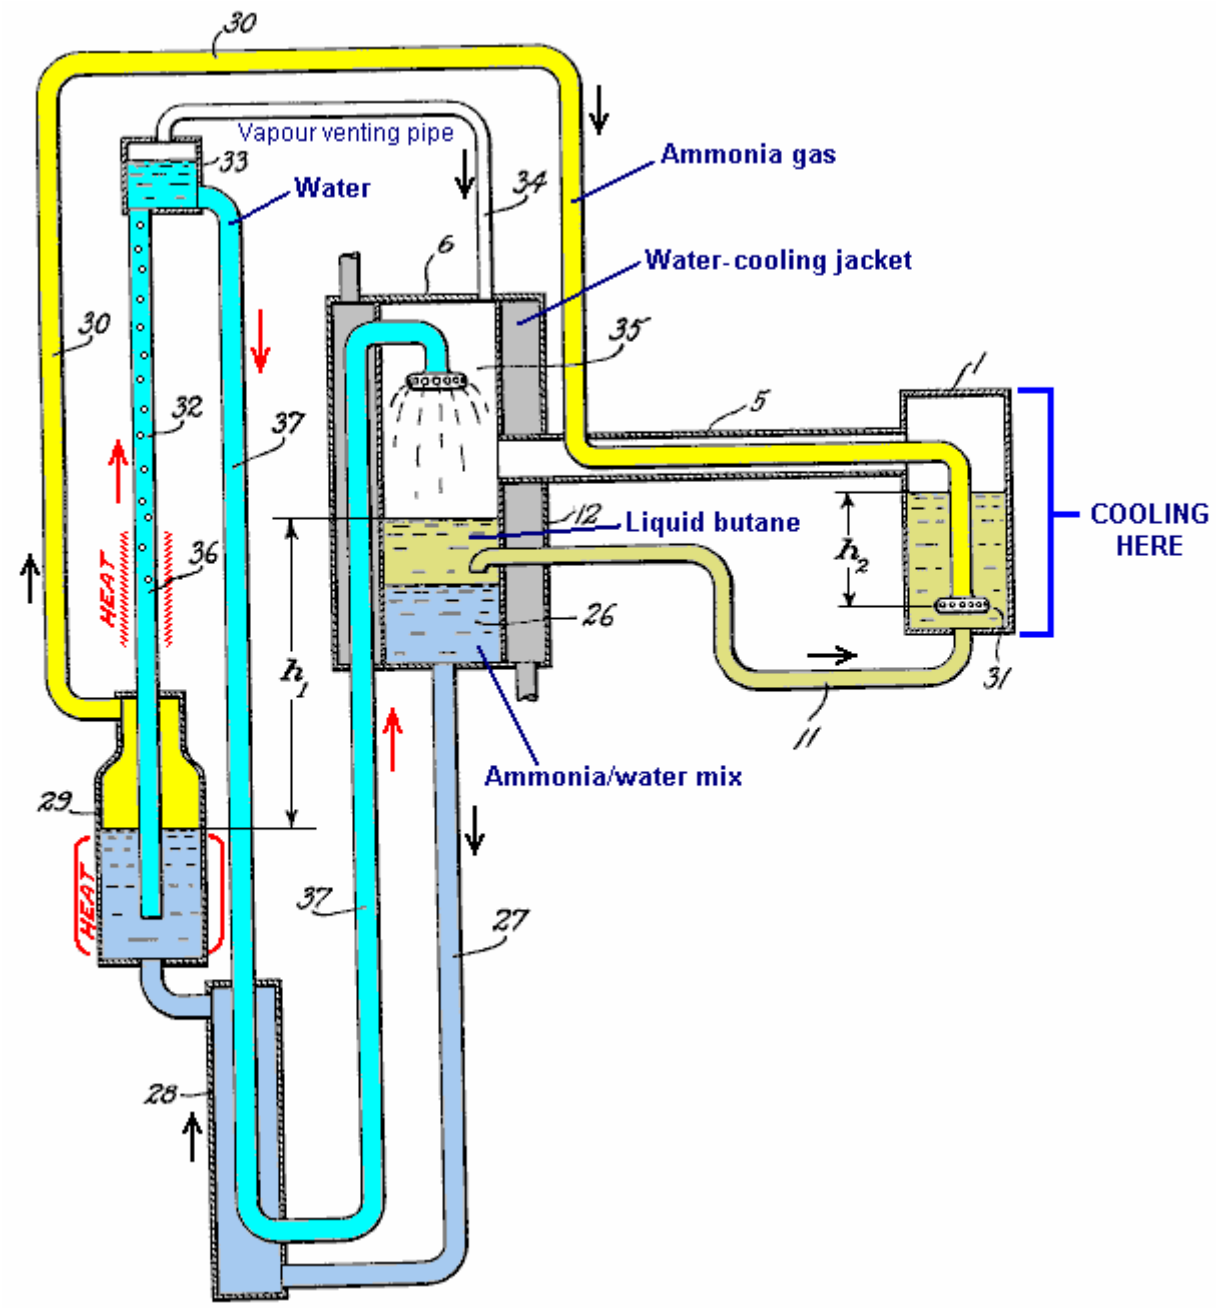
The buoys are also linked together loosely on top with a securing cord so that they always stay in a compact group, though there is little chance of any great sideways movement as the tension in the buoy cables is high. Stefan requests that anyone who constructs his design makes a donation via http://www.o2gruppen.se/ though how that is done is by no means clear to me as there does not appear to be a "Donate" button on that website.

There are many other wave-power devices, some with excellent efficiencies, but most are not generally capable of construction by the average amateur. One example is the "Nodding Duck" design by Stephen

Salter of Edinburgh in Scotland, and shown in the US patent 3,928,967 where the wave power is extracted by a raft-like construction with cam-shaped floats. These floats have a rippling movement on the surface of the water and the movement of each section relative to the other sections is used to generate power. This is not exactly a back-yard construction.

Other Systems

Not included in this eBook, but on the website http://www.free-energy-info.com there are articles from the highly recommended Home Power website http://www.homepower.com/home/ which are on this general topic. There is a system for producing blocks of ice using sun power alone and no other energy input at all:



Above: Steven Vanek with his machine which uses solar thermal energy to make ice.

Also, a two-part article on Solar cooling, which concentrates on heat absorption with different colours, the strategic positioning of buildings and vegetation, practical roof overhangs and the like, to lower the temperature inside buildings in very hot locations.

There are articles is on cooking with hydrogen, heating your house with hydrogen and using hydrogen with a barbecue. On the Home Power site there is information on how to use solar power to heat household water and you may find the Google video on how to make your own hot-water solar panel interesting and useful. The video is at http://video.google.com/videoplay?docid=7459531367428847841&q=solar+heating&ei=NHluSPPzC4yqiwKvy52iDw and it shows very simple construction methods. It makes sense to reduce your essential costs by doing a few simple things which help.

Cooling Using Heat.

Most of our current refrigerators use electricity to drive a compressor to achieve cooling. Here is a patent from Albert Einstein (whom you may have heard of) and Leo Szilard which uses heat to power refrigeration instead of electricity. It is US Patent 1,781,541 titled "Refrigeration" and dated 11th November 1930.

Our invention relates to the art of refrigeration and particularly to an apparatus and method for producing refrigeration where the refrigerant evaporates in the presence an inert gas and more particularly, to the type disclosed in the Von Platen and Munters Patent No. 1,685,764 of 25th September 1928 and our British Patent No. 282,428.

The objects and advantages of our invention will be apparent from the following description considered in conjunction with the accompanying drawing which shows more or less diagrammatically, a preferred embodiment of our invention.

In the drawing, **1** is an evaporator which is normally placed inside the chamber which is to be cooled. A pipe **5** connects the upper part of evaporator **1** to the more intermediate portion of the condenser **6**. Pipe **11** connects with the bottom of the evaporator **1** and extends into the condenser 6, at a level which is below the level of pipe **5**. A cooling water jacket **12**, surrounds the condenser and allows cooling water to flow through it.

Pipe **27** connects the bottom of the condenser **6**, to the lower part of a heat-exchanger jacket **28**. The upper part of jacket **28**, is connected to the lower part of generator **29** which is heated by any suitable method. Pipe **30** connects the upper part of generator **29** to a point near the bottom of evaporator **1** where it terminates in a distributor head **31**. Pipe **30** runs inside pipe **5** so that there is a heat exchange between the fluids in those two pipes.

Pipe **32** runs upwards from the lower part of generator **29** to connect with a container **33** which is positioned at a level which is above that of condenser **6**. A source of heat **36**, is applied to pipe **32** at a point above generator **29**. Pipe **37** runs down from container **33**, passing through the heat-exchanger jacket **28** and then on up to the top of condenser **6** where it terminates in a distributor head **35**. Pipe **37** runs inside the cooling water jacket **12** so that the fluid passing through it will be cooled as it flows. A venting pipe **34** connects the upper part of container **33** with the upper part of condenser **6**.

The operation of the apparatus is as follows:

A suitable refrigerant, for example, butane in liquid form, is held inside the evaporator **1**. An inert gas, such as ammonia, is introduced into evaporator **1** through pipe **30** and it's distributor head **31**. The refrigerant evaporates in the evaporator in the presence of the inert gas due to the fact that the partial pressure of the refrigerant is reduced thereby and the resulting gaseous mixture passes through pipe **5** and into condenser **6**. Here, the mixture comes into intimate contact with an absorption liquid, for example, water, which is fed into the condenser through pipe **37** and it's distributor head **35**. The ammonia gas is very soluble in water but the butane is quite insoluble, so the ammonia is absorbed into the water freeing the butane from the gaseous mixture. Thus, the butane assumes substantially the entire pressure inside the condenser, and that pressure is sufficiently high to cause its liquefaction at the temperature maintained by the cooling water.

The specific gravity of liquid butane is less than that of the solution of ammonia in water and so stratification of the two liquids occurs with the liquid butane floating on top of the ammonia solution **26**. The liquid butane passes from condenser **6**, through pipe **11**, and returns to evaporator **1**, where it is again evaporated and the cycle repeated.

Gravity causes the ammonia solution to flow from condenser **6** through pipe **27** and heat-exchanger jacket **28**, into generator **29**. Here, the application of heat causes the ammonia to be expelled from the solution in the form of a gas, which then passes through pipe **30** and distributor head **31**, into evaporator **1**, where it reduces the partial pressure of the butane, causing it to evaporate as already described.

Water, containing very little ammonia in solution, passes from generator **29** through pipe **32** where it is further heated by the source of heat **36**. This heating causes the formation of vapour in pipe **32** which lifts the liquid through this pipe and into container **33** and on from there under gravity through pipe **37** to condenser **6** and during its flow, this hot, low-concentration liquid is cooled by the heat-exchanger jacket **28**. It is further cooled by the cooling water in jacket **12**, and so reaches a condition where it can rapidly absorb ammonia in the condenser **6**. Vapour entering container **33** through pipe **32**, continues on it's journey to the condenser **6** via the venting pipe **34**.

During the operation of this piece of equipment, the pressure existing in the various components is uniform with the exception of slight differences caused by columns of liquid needed to cause the fluids to flow. The pressure existing in generator **29** must be sufficiently greater than the pressure in the upper part of evaporator **1**, in order to make vapour flow through distributor head **31**. In other words, the pressure difference must be sufficient to overcome the liquid head marked $\mathbf{h_2}$. This excess pressure in the generator is balanced by the pressure created by the column of liquid marked $\mathbf{h_1}$ in the drawing. This means that $\mathbf{h_2}$ must be less than $\mathbf{h_1}$, otherwise there would be no flow.

This patent of Einstein and Szilard seems to indicate that any source of heat such as a fire or a solar oven, should be able to produce cooling using a device which has no moving parts. It would probably be necessary to provide a trickle of water through the water cooling jacket, but apart from that, it looks like a device which could be used effectively by people who live “off the grid” and have little or no access to electricity. All in all, it is an interesting design.

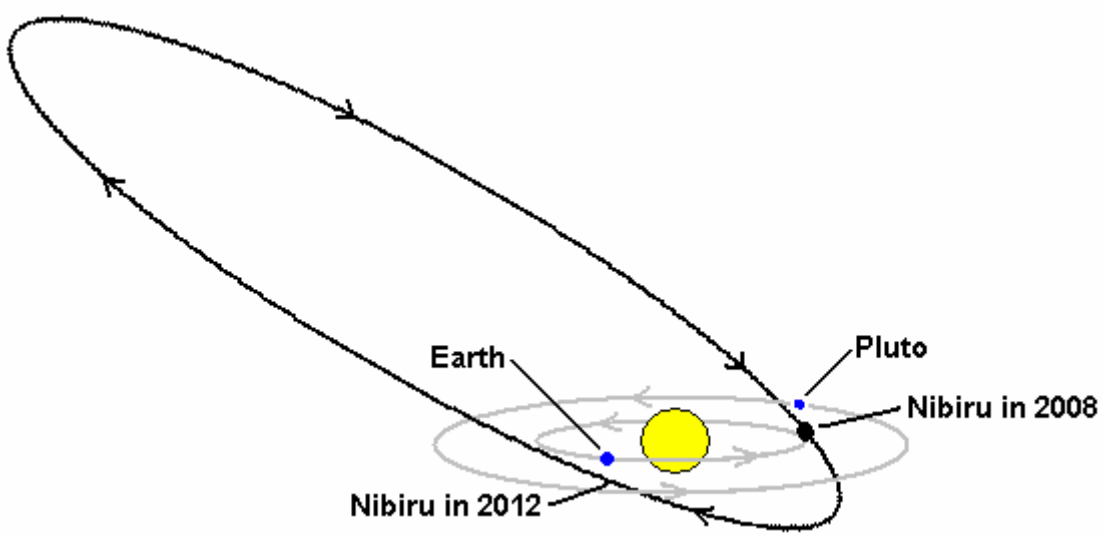
Chapter 15: The Time Available

I suggest that we need to develop and build free-energy devices as a matter of urgency. This is because we may have only a limited amount of time before the assets of our present civilization become no longer available to us. We have a number of problems facing us and a quick assessment suggests that there is no way around these problems for most of us. Let me stress that what follows should be considered to be a personal opinion and no proof or evidence whatsoever will be presented so please feel free to ignore it all without a moment's hesitation. This subject attracts the most bizarre weirdoes and some incredibly outlandish theories, very few of which are likely to have the slightest basis in fact, so we need to stick with details which have some scientific, measurable basis, and avoid many of the weird ideas being put forward (typically by people who are selling books and DVDs on the subject).



When we are very young we believe that our personal world is completely safe and protected by our parents. When we grow up we discover that that impression was never actually correct. However, we now understand how the world works and we feel secure because we know that no matter what happens to us personally, the world rolls on unchanging, day after day, always the same. If we are lucky and live to become older again, we get to realise that the only certain and unchanging thing about the world **is** change. If we go back to a place which we knew well thirty years ago, we discover that it has changed so much that we have difficulty in recognising it. If we pay attention to what goes on around us, then we discover that the universe, while being visually magnificent, is a savage and devastatingly destructive place and our secure little place on this planet is actually only habitable because of protecting layers around the planet - the Van Allen radiation belt, the ozone layer, the atmosphere and the magnetic field which deflects most of the harmful emissions from the sun around to the poles. But then, those protecting factors will always be there - won't they? Well.... will they? The time has come to mature to another stage of awareness and realise that we have been living on borrowed time and that time is about to end. We now face several serious problems, and if you feel that "ignorance is bliss", then stop reading this and go and watch one of those wonderful TV programmes based on the assumption that you will find it amusing to watch people falling down and hurting themselves.

1. Unfortunately, there is a large 'planet' which may well be a very massive 'brown dwarf' star orbiting around our sun. It's orbit is inclined to the plane of the other planets in our system and it orbits once every 3,600 years or so, orbiting in the opposite direction to our main planets. It is probable that this planet originated outside our solar system and came in from outer space, collided with a planet, causing the asteroid belt, and the impact altered the motion of the planet, causing it to start orbiting around our Sun. The orbit is nothing whatsoever like the orbits of our main planets which are all in the one plane and are nearly circular. Instead, this orbit is a highly elongated ellipse, inclined at about thirty degrees to the plane of the other planets, and in addition to that, it is orbiting in the opposite direction to the other planets.

This planet goes by several different names, but for convenience, I will just use one - "Nibiru". Nibiru gives us further problems in that it's orbit will get changed every time it goes past, due to the gravitational effects of our other planets. This makes it **very** difficult to predict it's exact orbit on the next passage. Nibiru has orbited many, many times and we are still here, so, short of a direct impact with the Earth, it is unlikely that mankind will get totally wiped out by Nibiru in the near future.

That is not to say that it has not already caused us serious problems. Three or four orbits ago, Nibiru came past and happened to line up with several of the other planets. The combined gravitational attraction of this grouping caused the water in the oceans to bulge upwards, leaving parts of the seabed visible and inundating major land masses. This "flood" is recorded in a vast number of ancient records, including the Bible which states that the flood covered the land for a period of five months and took a further three months to go down to near normal levels. I sincerely hope that this does not happen again when Nibiru passes this time, as Noah was a farmer, both low-tech and self-sufficient, while nowadays, large numbers of people are high-tech 'consumers' who are quite incapable of supporting themselves in a low-tech world with no fossil fuels, no telephones, no internet, no tap water, no shops, no electricity, no industry, no paid jobs, etc. We have a wholly unwarranted inclination to dismiss old records as "myths" but we should realise that these old records are frequently based on actual happenings and are not works of fiction. The massive flood of Noah's time is shown in the records of literally dozens of different cultures most of which will not have been in any kind of contact with each other in those days.

At this time (late in 2008), Nibiru has already passed Pluto and is orbiting around the Sun and will approach the Earth, coming up underneath the Sun in the year 2012. Unfortunately, other long-term events will also happen in 2012 and it is possible that these events may affect each other - but more of that later. A very rough not-to-scale diagram of the present situation is:

It is believed that the approach of Nibiru is causing the global warming which is being seen on the various planets in the solar system. On Earth, it is being argued that man made carbon dioxide emissions, especially from vehicles, is the cause of global warming. While it is an excellent goal to reduce emissions and improve air quality, man made carbon dioxide has nothing to do with global warming. The combined emissions of all 800,000,000 vehicles on the roads of the world accounts for about 1.7% of the carbon dioxide entering the atmosphere. The film "An Inconvenient Truth" points out the correlation between global temperature and carbon dioxide concentrations in the atmosphere. The historical record shows an undeniable correlation, **but** the film omits to point out that the carbon dioxide concentration follows the global temperature lagging behind it by some six hundred years. That is too vague a link anyway as carbon dioxide creation and absorption are affected by many other factors. However, it seems almost certain that our Sun is being affected by Nibiru at this time.

It appears that Nibiru has a mass of four or five times that of the Earth and it may have as many as five planets of its own, orbiting around it. This, of course, makes the prediction of the gravitational situation when it passes Earth on its loop back out into deep space, extremely difficult, especially since the gravitation of the Sun's other planets will affect the orbit of both Nibiru and it's planets between now and 2012. In that period, the Earth will orbit the Sun three or four times. To be able to predict the orbit of Nibiru, many measurements would need to be made between now and 2012. It is interesting to note that two underground grain repositories have already been set up and stocked, their stated aim being to be a reserve against any form of natural disaster, to allow these grains to be grown again after the disaster. Does that seem to you to be anything like what was done in Noah's time?

There is a certain amount of confusion as NASA has detected another small body outside the orbit of Neptune and they have named it "Eris". That body is not a problem but the coincidence of the discovery is causing some minor confusion. Eris is small, while Nibiru or "Planet X" is very big. A NASA press release in 1992 states "Unexplained deviations in the orbits of Uranus and Neptune point to a large outer solar system body of 4 to 8 Earth masses, on a highly tilted orbit, beyond 7 billion miles from the Sun". That is Nibiru and not Eris.

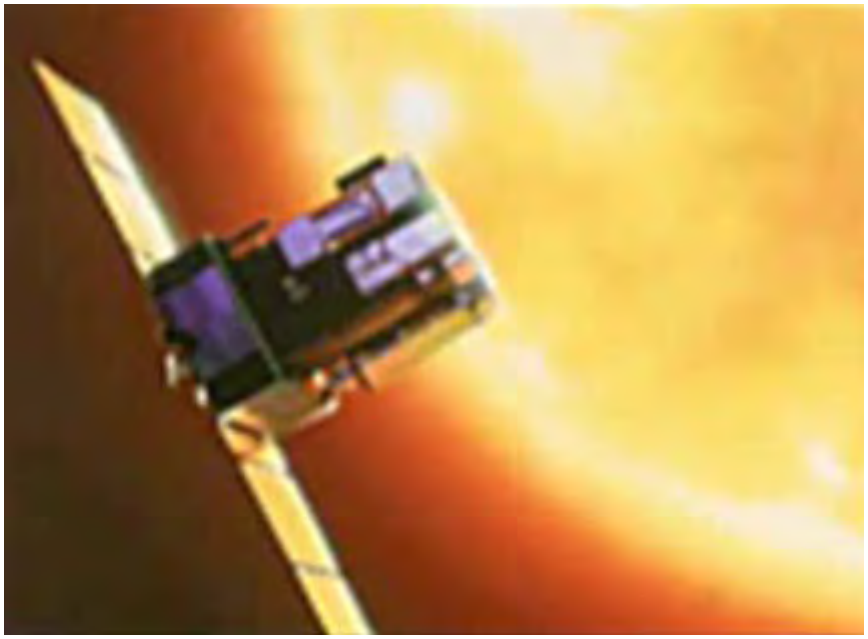
The effects caused by Nibiru passing by are not what you would expect. It creates increased heat an volcano activity in the nearby planets and the same sort of effects in our Sun. Solar system planets are already showing these effects and on Earth a strange situation is occurring. Increased volcanic action near the North pole is causing unusually large ice melting and global warming in the northern hemisphere, while increased precipitation in the southern hemisphere is causing lower than normal temperatures and global cooling. These effects are temporary as things will get a lot worse when Nibiru orbits back towards us. Then, the volcanic action will become severe, probably triggering the Yellowstone Park super-volcano and Sun flares will become so severe that the ozone layer and Van Allen radiation belt will be destroyed, removing the essential protection which they provide for life on Earth. A major proportion of sea life in the upper ocean layers will be destroyed, all green land vegetation and a third of all trees. This charming situation is very likely to be followed by a severe nuclear winter spanning some years and due to the dust in the upper atmosphere, it is likely that there will be no sunlight reaching the surface of the Earth. However, volcanic activity is the greatest source of carbon dioxide in the Earth's atmosphere, so that might actually offset much of the cold.

In passing, the "global warming caused by human activity" has no basis in reality and is just part of a scam to siphon off billions in taxpayer money.

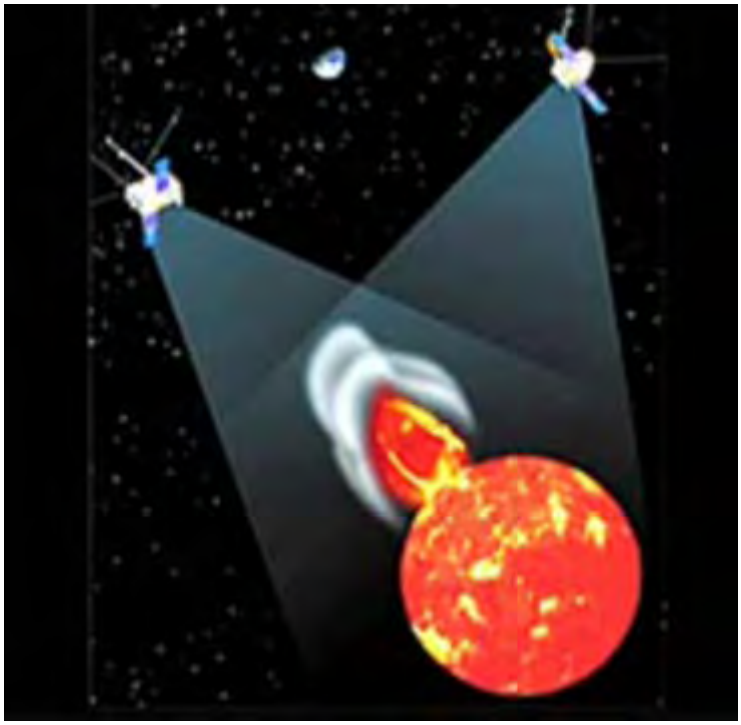
This is a transcript of the web video from ‘childofgod33’ at http://in.youtube.com/watch?v=ESt9YkaFe2w

Follow The Money

I’m often asked “How do you know that this Nibiru thing is REAL?”. I say ... “FOLLOW THE MONEY” Scoffers say “If this thing were real, then more people would know about it”. When you follow the money you see that the US government is taking this threat seriously. They are spending immense sums to understand and cope with this threat.

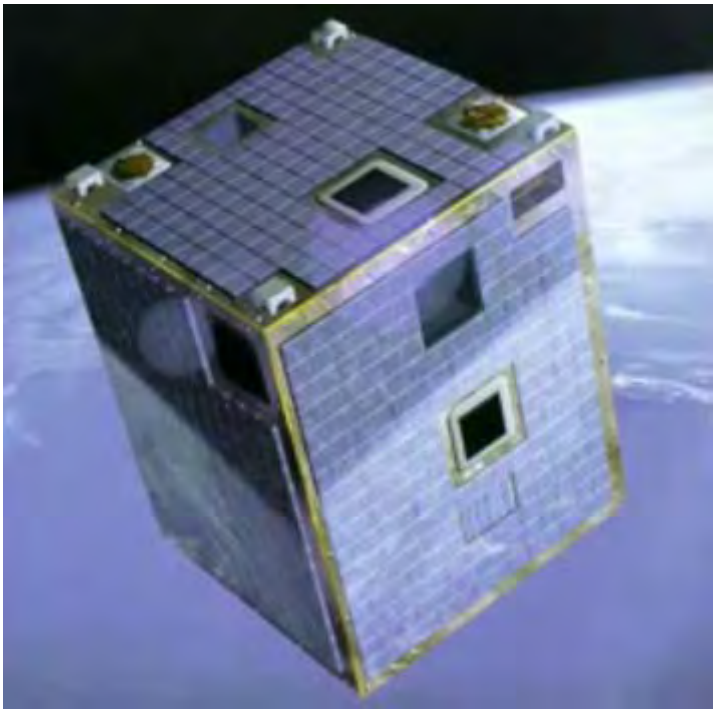


How does NASA know about Nibiru? Well, like any government agency, NASA spent US tax dollars to find it. It’s not just US tax dollars and European tax payers are footing the bill too and JAXA (Japan) has been spending lots of money - an estimated six billion spent since 2003. ESA (Europe) and CNES (France) have been spending money like a drunken sailor on leave. A good detective follows the money. In the early 1990’s, NASA, ESA, CNES and JAXA started creating a new fleet of space-based solar observatories.



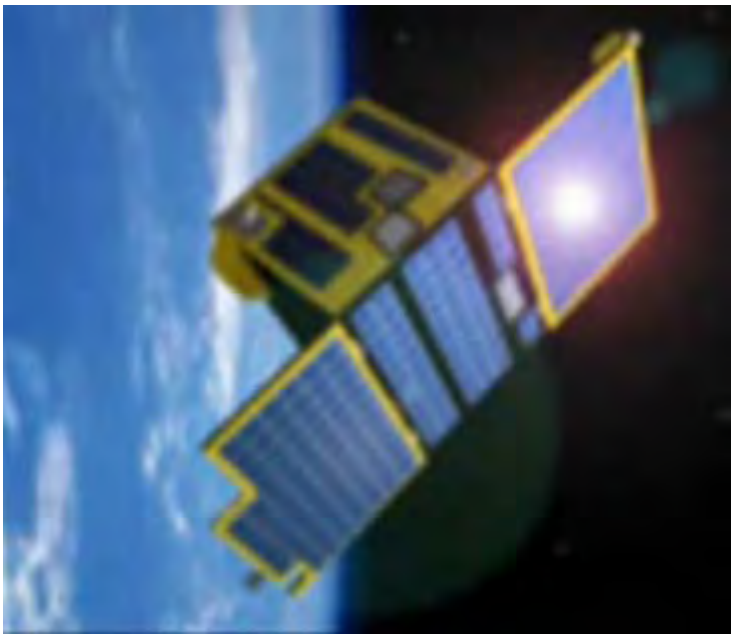
The interaction between our Sun and a massive object approaching it could present us with one of the greatest threats EVER. Earth has experienced violent storms, quakes, floods, etc. and a Solar alignment flare could reach the Earth in less than 18 hours.

Launched on 2nd December 1995, the Solar and Heliospheric Observatory (SOHO) from ESA has provided a never before seen view of the Sun.



New funding has extended it's mission up to December 2009. In August 2006 NASA launched it's Solar Terrestrial Relations Observatory "STEREO" spacecraft into orbit around the Sun.

In October 2006, NASA, ESA and JAXA, launched Solar-B (Hinode)



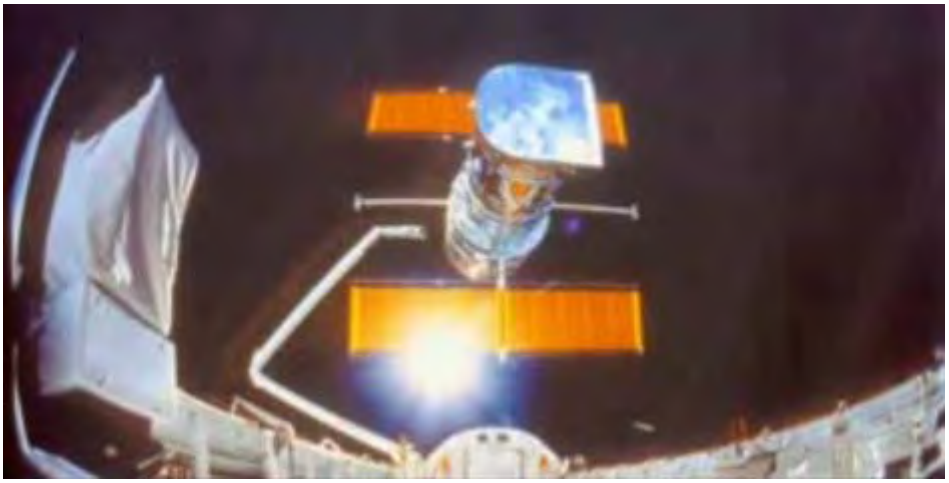
Pointed directly at Nibiru. Solar scientists have observed that magnetic features in the solar photosphere are **changing**. Did I mention that the orbit of Nibiru has it coming up behind the Sun?

NASA launched Proba-1 in October 2001 and the European Space Agency hopes to launch Proba-2 in the spring of 2008. By the way, ESA spent 2.9 billion Euros in 2007 alone and that is US $4 billion at the current rate of exchange.

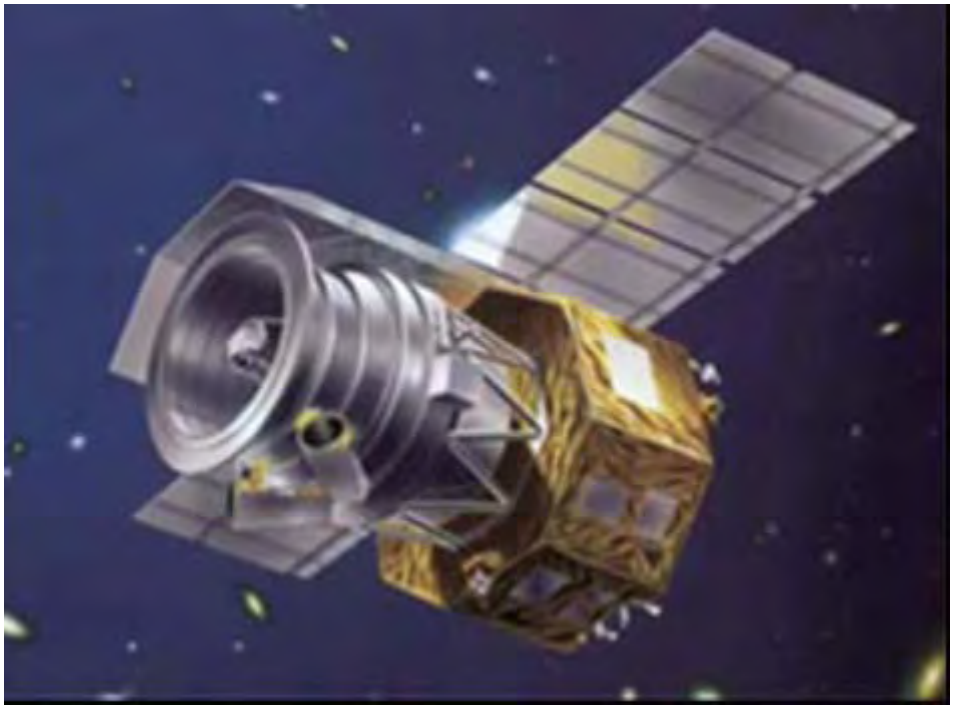
Some satellites have secret laser capabilities along with their known telecommunication abilities.

ESA is sending up Proba-2 as soon as possible and it has secret items aboard. NASA has the Solar Dynamics Observatory “SDO” scheduled for launch in August 2008.

More probes and telescopes pointed away from Earth. In August 2003, NASA launched the Spitzer Space Telescope.



Spitzer is the largest infrared telescope ever launched into space. NASA sent up the Hubble Space Telescope which was due to quit in 2007, but now it has been retro-fitted to continue to work until 2013 and all live feed from it is scrambled.



NASA has a space mission planned for 28th August 2008 to “service” the Hubble with secret hardware and software, plus special **heat shields**. The cost of the trip is US $1.16 trillion, the Hubble repair cost about US $900 million.

Hubble will take images of Nibiru as it comes closer. Not to be outdone, Japan joined in the fun. JAXA launched ASTRO-F, aka AKARI, aka IRIS, InfraRed Imaging Surveyor.

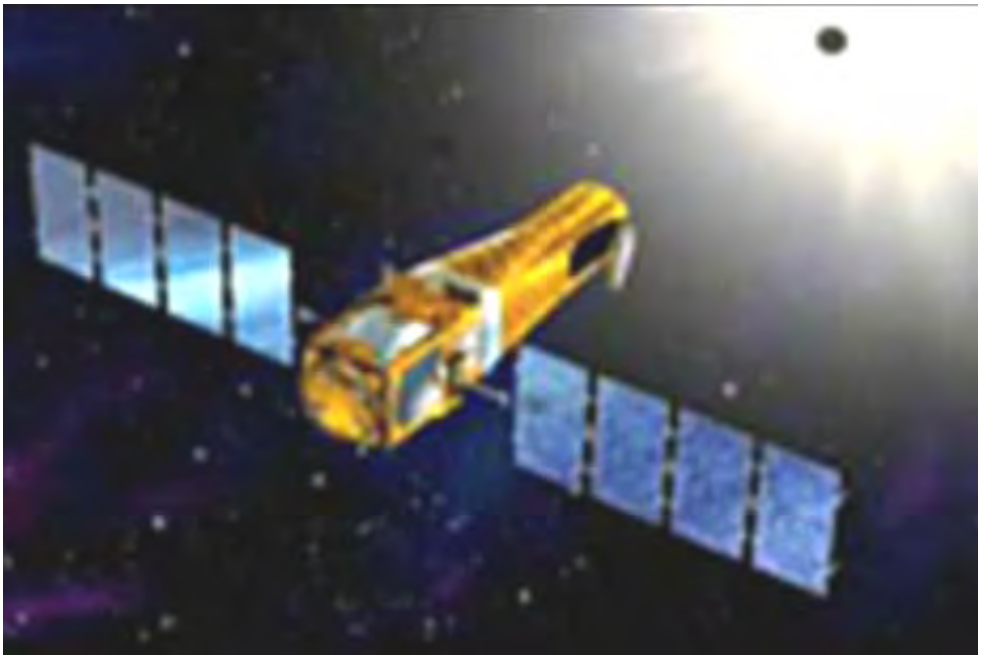
This is the second space mission for infrared astronomy in Japan as a joint venture with the UK, the US and the Netherlands.

This is the Herschel Space Observatory:

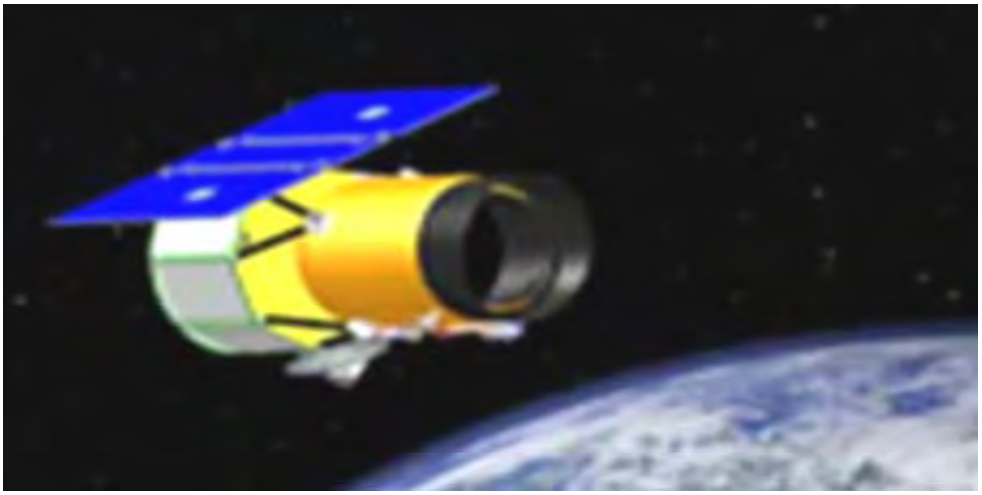
The ESA plans to launch the Herschel Space Observatory in October 2008.

NASA has for their own use, the Sophia Observatory Project:

The primary mirror being lifted into the Telescope Assembly inside the plane (July 2003)



These telescopes have been pointed at the heavens since their launch. In February 2007, NASA installed the South Pole Telescope "SPT" in Antarctica:



The South Pole Telescope is a secret project to study the “dark forces” . Not to be outdone, France announced the Concordia Observatory located in Antarctica, opened in 2005 and seeking Nibiru.

ESA launched CNES: COROT in December 2006, to search for habitable planets:

NASA’s Wide-Field Infrared Survey explorer has got approval for it’s construction and it is due for launch in 2009:

The powers that watch for this sort of thing are watching closely, but silently. The **reason** why all these satellites have very distinctive **infra-red technologies** is very important. Because of the dwarf star heat signature the easiest way to track Nibiru is by watching it's infrared images.

So, to recap:

All of the Space Agencies of the World have spent billions of tax payer's dollars to watch for the solar problems to increase because of a planetary body not formally known to our Astronomical bodies before the 1980's. As this planetary body known as Nibiru, or Planet X, comes into our solar system to perturb our nearby planets and disturb our own Earth, we can anticipate this planet's trajectory based on it's current location compared to where it was previously. They know that it is coming.

2. The second problem which faces us is the orbit of our Solar System which it is said will cross the plane of our galaxy late in the year 2012. This is an event which takes place once every 25,800 years. At first glance, this would seem to be harmless, but that may well be an uninformed assessment. Every sun emits radiation, most of it seriously harmful. Most of the suns in our local galaxy are so far away that we get very little radiation from them, certainly a low enough level to get by.

Unfortunately, the people who study these things say that there is very much intensified radiation along the plane of the galaxy and a concentrated gravitational field with so many astronomical bodies all lined up, and that when we cross that plane, then things will be different. Recently, astronomers were able to watch another solar system crossing the plane of the galaxy and see what happened to it, and in that case, there were massive solar flares.

Observations of another solar system which did that recently, showed that their sun flared up and created major radiation. If that happens to our Sun, which seems distinctly possible, then the effect may well be devastating for life on earth and will most definitely take out all communications. It is interesting to note that the US is investigating non-electronic methods of communications.

3. We are overdue a planetary magnetic pole shift and nobody knows what effect that will have as we weren't around when it happened the last time. It is suggested that the shift will take place over a period of just eleven days and the magnetic poles have already started to shift in a way which is somewhat unusual

4. All of Yellowstone Park in the USA is one super-volcano and when it blows, ash and gas will kill all Americans on the west side of North America within twenty minutes. It will also create an upper atmosphere dust cloud which will cause darkness and winter for some years continuously. This is not a case of "if" but a case of "when" as it will definitely happen. It last happened 640,000 years ago and on average it happens every 600,000 so geological terms, it is 40,000 years overdue. In theory, we need not worry as it could be another thousand years before it goes. A mainstream UK television documentary some years ago demonstrated how the Yellowstone ground is bulging upwards progressively. There is an unpublished report created for the US government which says that they believe that it will blow in the next five years, but it must be assumed that the conclusions of that report are a matter of opinion since, as far as I am aware, at this time there is no proven and reliable way of predicting an eruption of any kind.

Best case: Nibiru passes without causing any really major problem, and, the Solar System crosses the plane of the galaxy with no significant effect, and, the magnetic pole shift does not take place or does take place with no

major problems resulting from it, and, Yellowstone Park does not blow in our lifetime. Overall result: apart from losing all communications for a period of time, life continues as it is doing now.

Worst case: Nibiru passing causes major sun flares which kill a really major percentage of the world's population, 4,500,000,000 being mentioned as the probable number of people killed. The stresses caused by Nibiru trigger the Yellowstone Park eruption, pushing large quantities of dust into the upper atmosphere, blanking out the Sun and causing a 'nuclear' winter which lasts for two or three years, possibly causing another ice age but probably offset by massive amounts of volcanic carbon dioxide emissions.

Nobody can do anything to prevent these catastrophic things happening, no matter what level of technology we have. There is, of course, far more information on these things, not all of which will be reliable. If you want to follow up on it, you could try:

It is possible that the earth's crust could slip round under the stress of a very close pass by Nibiru while the planet's core remains in position. There are detailed and accurate maps, many hundreds of years old, showing the coastline of Antarctica in great detail and interestingly, due to the very thick ice layer covering the land, we have only been able to confirm that coastline very recently with satellite images. This seems to lend some weight to the old legend of Atlantis, located near the Med, populated by a high-tech population, suddenly upset when the island moved position. It might be that there was a planetary crust shift which moved it to the present position of Antarctica, and inundated with an ice sheet. Not by any means certain, but there is usually some truth in old legends, and often a high degree of accuracy.

The most powerful people on earth have been aware of this problem for several decades. So far, they have established more than 130 deep underground bases of massive size and peopled them with individuals of their choice. Two underground grain repositories have been established quite openly and stocked with 2,000 varieties of grain. The reason stated is that they were set up to protect against 'any catastrophic earth event'. Many wealthy individuals have bought land in South America (and are probably digging in there). Bases have also been established on both the Moon and Mars in order to have a greater level of resilience.

This secret operation has been going on for several decades, while running the window-dressing acts of the Moon landing and the Space Shuttle much lower-tech operations, while having much more effective technology. The US, UK, Canadian and USSR governments are definitely in on this combined operation.

If you feel that all this is just too far-fetched to be real, then consider the description in the Bible of the ten "plagues" at the time of the Exodus of the people of Israel from slavery under the Egyptians. This story is told in other literature of the time as well, and the Egyptian documentation confirms the Bible record in all essential details as well as adding additional details. It is suggested, with a great deal of evidence, that these "plagues" were caused by a close fly-by of Nibiru or one of its satellites. The details as suggested in the book "Planet X Forecast and 2012 Survival Guide" by Jacco van der Worp, Marshall Masters and Janice Manning ISBN 1-59772-075-5.

Plagues:

1. "Water turned into blood". Iron-rich meteorites from the fly-by stain river water red with iron oxide and phosporus-rich Schreibersite.

2. “Frogs”. Schreibersite fed blue-green algae growth. This is deadly to life and takes the oxygen from the water, creating a deadly neurotoxin called microcystin which is a skin irritant, driving the frogs out of the water.

3. “Lice”. Toads were also driven out of the water so their main food - lice, grew to plague level with their predators gone.

4. “Flies”. More specifically, blood-sucking flies. With animals no longer able to stand submerged in water to protect themselves from these flies, there was a major expansion in the number of these flies.

5. “Cattle deaths”. The blood-sucking flies carry malaria and other diseases and the bites are often sites for secondary diseases and these caused cattle fatalities.

6. “Boils”. The Nile also served as a source for bathing water and the microcystin would have turned any minor scrapes on hands or feet into boils.

7. “Hail mixed with fire”. This will have been the first plague chronologically and it is assigned to the Destroyer’s “fire, hot stones and a vile smoke”. Almost certainly material drawn in from the fly-by.

8. “Locusts”. These eat well in excess of 80,000 tons of vegetation per day and when food gets scarce and they start bumping repeatedly into each other when feeding, a genetic swarm spot on the back leg causes them to swarm.

9. “Darkness for three days”. The Destroyer or it’s satellites filled the atmosphere with so many particles that they blocked the sunlight for three days and “midday was no brighter than night”.

10. “Death of firstborn sons”. The algae bloom in the rivers eventually produce sulphur dioxide which stays low in the air. The firstborn slept on the ground floor where it was cooler while the others slept on the roof - the second coolest place. The firstborn sons were subjected to more of the SO2 and as well as that, they collected the daily grain allowance from the grain stores which would have been underground and so heavily contaminated with SO2.

Do you feel that the plagues listed in the documentation of that time are just co-incidentally the same as would occur from a close fly-by? I don’t.

The Human Angle:

Unfortunately, it is now becoming ever clearer that we will be lucky to reach 2012 unscathed as human factions are, quite deliberately, creating even bigger problems for us.

Please assume the following to be wholly unsubstantiated and highly dubious opinions. There is a lot of ‘nut case’ statements on the internet, so please understand that I might well be one of those ‘nut cases’. However, I suggest that you consider and further research the following things:

1. There are a several powerful players on the world scene, who are at present engaged in a power struggle, based primarily around the USA. These include:

   a. The Russians
   b. The Chinese
   c. The Japanese
   d. Israel
   e. The illuminati
   f. The Rothschild faction
   g. The Rockefeller faction
   h. The US military “white hat” good-guys faction.
   i. (Possibly) one or more non-human groups.

2. The present situation has become critical because the US, via the Rothschild’s Federal Reserve, have been printing US money without having real assets to give value to those ‘promissory note’ dollar bills and that has effectively bankrupted the US, which now owes trillions to Japan and China. When the US economy fails it is liable to destroy or damage the entire world economy. Mind you, the world economy is actually a scam intended to enslave the world as a whole, holding everybody in economic slavery imposed by corruption and violence. This is given in detail later on.

Japan and China have offered the US three trillion in gold assets to keep everything going, but with the requirement that the US joins the EEC with 22 out of 90 votes, the US military coming under EEC control. Not surprisingly the US did not accept that proposal. The US has just sent China 800 billion in 'Amero' currency, worth about 50 cents per Amero as they expect the US dollar to halve in value very soon, so this is supposed to be repayment of US $400 billion of their debt. The Amero is currency for a combined US-Canada-Mexico conglomeration, so where is that amalgamation coming from? Diplomacy? Invasion? Some cunning ploy? Try listening to the interview at
http://www.lewrockwell.com/podcast/?p=episode&name=2008-10-05_041_thanks_for_the_inflationary_depression.mp3

The present manoeuvre of having national governments using public money to take over the debts of banks around the world is just the first step in establishing a visible world government under the group of people who are called "The New World Order" and so it should not be seen as a way out of our problems, but instead, the start of even greater problems.

3. The Rockefeller faction has been collecting and suppressing high-tech patent applications for at least fifty years now. Vast sums have been siphoned off in 'black ops' projects and it is reliably reported that they are at least fifty years, and possibly even a thousand years ahead of the technology seen publicly. They, and several other governments have had flying saucers for decades now. They also have equipment which can make a person hear what you say inside his head directly, without sound waves being used. With repeated use, this can control the actions of an individual.

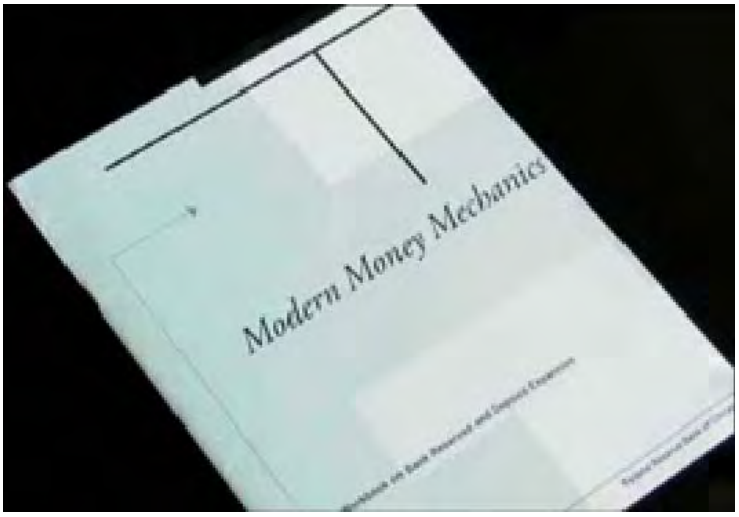
4. The Rockefeller faction is allied with Israel and has already made two separate attempts to nuke Iran. The first attempt was foiled by the 'white hat' military in Iraq who refused to allow them to refuel the bombing aircraft. They then, very recently, tried to bypass that obstacle by refuelling in Georgia, but the Russians invaded very promptly, destroying the armed forces of Georgia and blocking the attack. This explains the seemingly incomprehensible sudden Russian attack on Georgia.

5. The Rockefeller faction want to reduce the world population by 90% as it would then be easier to control the remaining people. They are working solidly on this and have built more than a hundred concentration camps all over the USA. These camps can hold a million people and they are said to have 190,000 mercenaries on standby. Large crematoriums have been built and vast numbers of plastic containers made, each of which, it is alleged, is intended to be used as a temporary coffin holding the remains of three or four people prior to cremation. Recently, the 'Feds' bought up every last can of canned butter and every freeze-dried meal that they could lay their hands on, which suggests that they believe that this situation may come about very soon.

6. George Bush has just been replaced. It is highly likely that every Presidential candidate is also NWO so that it does not really matter who supposedly wins the election. In October, economic pre-election stunts were carried out designed to manipulate and weaken various countries, pick up many assets at knock-down prices, boost oil revenues and then drop the oil price just ahead of the election. The main objective here was another step towards a world government based on economic ties more than anything else.

7. It is said that the Rockefeller faction has built more than a hundred and thirty bases deep underground in the US. The existence of some of the US bases has been confirmed by independent sources. It seems likely that these bases are to keep them out of harm's way while violent activities take place. The US Congress has been assured in closed session, that there is shelter for them and their families when this activity starts. The Rockefeller faction believes that their raising of food and oil prices should already be sufficient to make one billion people die of starvation - the first step towards their goal of killing about five billion people and at this moment, 967,000,000 are faced with starvation. However, the number of bases was 131 in 1995 with an additional two per year being added, which would suggest that the present number is likely to be at least 145, each being two cubic miles on average and located at a depth of 5,000 feet down or more. Details of these have been given by Phil Schneider who was involved in the construction of thirteen of the interconnecting tunnels which are some twenty feet wide and twenty-eight feet tall. Every base is connected to every other base by these tunnels. The bases in Mexico and in Canada are not included in the count of 145.

8. Another weapon which is being used in this power struggle is the HAARP system based in Alaska. It is said, with considerable justification, that the Christmas tsunami, the China and Japan earthquakes were caused deliberately. There is absolutely no question that the hurricane which destroyed New Orleans was being steered by a one billion watt beam and that steering beam was looked for and detected by one of the EVGRAY forum members. Remember that "Weather Engineering" was specifically excluded from SALT -- the Strategic Arms Limitation Treaty. "Weather Engineering" is used as a weapon, and from the Rockefeller faction viewpoint, it can also help by killing large numbers of people.



9. I gather that China and Japan have made it clear that if Iran is nuked, then they will nuke Israel out of existence. Generally speaking, predicting what will happen in the immediate future is not a simple matter by any means, though it is distinctly possible that the Nibiru fly-by will be left to take out those people not taken into the underground bases.

There is a great deal of information on this subject and much of it is difficult to believe. If you want to research further, the try the http://www.projectcamelot.org/2008.html website, and perhaps, pay some attention to the information at http://www.projectcamelot.org/audio_interviews.html, although, as already mentioned, it is distinctly possible that much of the web-based information is not wholly reliable.

While I do not agree with the conclusions reached in the video presentation which can be seen on the internet at http://video.google.com/videoplay?docid=7065205277695921912, here are some of the relevant facts quoted in that video:

In a world where 1% of the population owns 40% of the planet's wealth, in a world where 34,000 children die every single day through poverty and preventable diseases, and where 50% of the world's population lives on less than US $2 per day, one thing is clear: something is very wrong.

And whether we are aware of it or not, the lifeblood of all of our institutions, and therefore this society itself, is money. Therefore, understanding this institution of monetary policy is critical in understanding why our lives are the way that they are. Unfortunately, economics is often viewed with confusion and boredom. Endless streams of financial jargon coupled with intimidating mathematics, quickly deters people from attempts to understand it. However, the complexity associated with the financial system is a mere mask intended to conceal one of the most socially paralysing structures which man has ever endured.

A number of years ago, the Central Bank of the United States of America, "the Federal Reserve", produced a document entitled "Modern Money Mechanics". This publication detailed the institutionalised practice of money creation as utilised by the Federal Reserve and the web of global banks which it supports. On the opening page, the document states it's objectives: "The purpose of this booklet is to describe the basic process of money creation in a 'fractional reserve' banking system". It then proceeds to describe this practice through various banking practice terminologies. A translation of it goes something like this:

The United States government decides it needs some money, so it calls up the Federal Reserve and requests, say, $10,000,000,000. The Fed replies saying "Sure, we will buy $10 billion in government Bonds from you". So the government takes some pieces of paper, paints some official-looking designs on them and calls them "Treasury Bonds". Then it puts a value on them of $10 billion and sends them over to the Feds. In turn, the people in the Fed draw up a series of impressive looking pieces of paper themselves, only, this time, calling them Federal Reserve notes, also designated with a value of $10 billion. The Feds then take these notes and trades them for the Treasury Bonds. Once this trade is complete, the government than takes the $10 billion in Federal Reserve notes and deposits them in a bank account, and on doing this, the $10 billion becomes legal tender money, adding $10 billion to the US money supply. And there it is: $10 billion in new money has been created. Of course, this example is a generalisation because in reality, this transaction would occur electronically, with no paper used at all. In fact, only 3% of the US money supply exists in physical currency and the other 97% exists in computers alone.

Now, Government Bonds are by design, instruments of debt, and when the Fed buys these bonds with money which essentially it created out of thin air, the government is actually undertaking to pay back that money to the Fed - in other words, the money was created out of debt.

This mind-numbing paradox that money or value can be created out of debt or liability, will become more clear as we continue this exercise. So, the exchange has been made and $10 billion sits in a commercial banking account. Here, is where it gets really interesting, for as based on the fractional reserve practice, that $10 billion deposit instantly becomes part of that bank's reserves, just as all deposits do. And as regarding the fractional reserve requirements, as stated in Modern Money Mechanics, a bank must maintain legally required reserves equal to a prescribed percentage of it's deposits. It then quantifies this by stating "under current regulations, the reserve requirement against most transaction accounts is 10%". This means that with the $10 billion deposit, 10% or $1 billion is held as the required reserve, while the other $9 billion is considered as an excessive reserve and can be used as the basis for new loans. Now it is logical to assume that this $9 billion is literally coming out of the original $10 billion deposit, however, this is actually not the case. What really happens is that the $9 billion is actually created out of thin air on top of the original $10 billion deposit. This is how the money supply is expanded, as stated in Modern Money Mechanics, "of course they (the banks) do not really pay out loans from the money they receive as deposits. If they did this, no additional money would be created. What they do when they make loans is to accept promissory notes in exchange for credits in the borrower's transaction accounts". In other words, the $9 billion is created out of nothing simply because they have a demand for that loan and there is a $10 billion deposit to satisfy the reserve requirements.

Now, let's assume that somebody walks into this bank and borrows the newly-available $9 billion, they will then most probably take that money and deposit into their own bank account. The process then repeats, as that deposit becomes part of that bank's reserve, and while 10% is held as a reserve, the remaining 90% or $8.1 billion is now available for more newly created loans. And of course, that $8.1 billion can be lent out, creating a further $7.2 billion which in turn can create a further $6.56 billion, ... This money deposit/loan-creation cycle can technically go on to infinity. The average mathematical result is that $90 billion can be created on top of the original $10 billion. In other words, for every deposit that ever occurs in the banking system, nine times that amount can be created out of thin air.

So, now that we understand how money is created by this fractional-reserve banking system, a logical, yet elusive, question might come to mind: "What is actually giving this newly traded money value?". The answer: "the money which already exists". The new money essentially steals value from the existing money supply. The total money pool is being expanded irrespective for the demand for goods and services, and as the demand and supply balance finds equilibrium, prices rise, diminishing the purchasing power of each individual dollar. This is generally referred to as **Inflation** and inflation is essentially a hidden tax on the public.

The fractional-reserve banking system is inherently inflationary. One dollar in 1913 had the equivalent value of $21.60 in 2007. That is a 96% devaluation since the Federal Reserve came into existence. If this reality of perpetual and continuous inflation seems absurd and economically self-defeating, then hold that thought as "absurd" is an understatement with regard to how the US financial system really operates. For, in that financial system, money is debt, and debt is money. The more money there is, the more debt there is and the more debt there is, the more money there is.

To put it a different way, every single dollar in your wallet is owed to somebody by somebody. Remember, the only way that money can come into existence is from loans, therefore is everyone in the country, including the government, were able to pay off all debts then there would not be one dollar in circulation. In September 1941, the Governor of the Federal Reserve stated: "If there were no debts in our money system, there wouldn't be any money".

In fact, the last time in American history the National Debt was paid off in full was in 1835 when President Andrew Jackson shut down the Central Bank which preceded the Federal Reserve. He stated: "The bold efforts the present bank has made to control the Government ... are but premonitions of the fate that awaits the American people should they be deluded into a perpetuation of this institution or the establishment of another like it". Unfortunately, this message was short-lived and the bankers installed another Central Bank in 1913, calling it the Federal Reserve, and as long as this institution exists, perpetual debt is guaranteed.

We now have the added factor of **Interest**. Every single dollar which exists has to be repaid to a bank with interest added as well. But, if all money is borrowed from the Central Bank, and is expanded by commercial banks through loans, only what would be referred to as "the principal" is being created in the money supply. So, from where does the money needed to pay this interest come? Nowhere. It doesn't exist. The ramification of this are staggering. The amount of money owed back to the banks will always exceed the amount of money in circulation. This is why inflation is a constant in the economy. New money is always needed to cover the perpetual deficit built in to the system, caused by the need to pay the interest. This ensures that defaults and bankruptcy are guaranteed to occur and there will be foreclosures. This always transfers true assets from the individual to the banks. If you are unable to pay your mortgage, then they will take your property. This is particularly annoying as the money which the bank lent you in the first place, didn't even legally exist.

In 1969, there was a Minnesota court case involving a man named Jerome Daly who was challenging the foreclosure of his home by the bank which provided the loan to purchase it. His argument was that the mortgage contract required both parties (he and the bank) to put up a legitimate form of property for the exchange. In legal language, this is called "consideration". Mr Daly explained that the money was, in fact, not the property of the bank as it was created out of nothing as soon as the loan agreement was signed. Remember what Modern Money Mechanics stated about loans: "What they do when they make loans is to accept promissory notes in exchange for credits ... reserves are unchanged by the loan transactions, but the deposit credits constitute new additions to the total deposits of the banking system". In other words, the money doesn't come out of their existing assets, the bank is simply inventing it, putting up nothing of it's own, except for a theoretical liability on paper. As the court case progressed, the bank's President, Mr Morgan, took the stand and the judges memorandum records that the "Plaintiff admitted that it, in combination with the Federal Reserve Bank ... did create the entire $14,000 in money in credit upon it's own books by bookkeeping entry ... the money and credit first came into existence when they created it. Mr Morgan admitted that no United States Law or Statute existed which gave him the right to do this. A lawful consideration must exist and must be tendered to support the Note" ... The jury found that there was no lawful consideration, and I agree, only God can create something of value out of nothing." On this finding, the court rejected the bank's application for foreclosure and Mr Daly kept his home.

The implications of this court decision are immense. Every time you borrow money from the bank, whether it is a mortgage loan or a credit card charge, the money given to you is not only counterfeit, but it is an illegitimate form of 'consideration' and hence voids the contract to repay as the bank never had the money as property to begin with. Unfortunately, such legal realisations are suppressed and ignored and perpetual wealth transfer and perpetual debt continues. This brings us to the ultimate question: "**Why?**"

During the American Civil War, President Lincoln bypassed the high-interest loans offered by the European banks and decided to do what the Founding Fathers advocated, which was to create an independent and inherently

debt-free currency. It was called the “greenback”. Shortly after this measure was taken, a private document circulated between British and American banking interests stated “... slavery is but the owning of labour and carries with it the care of the labourers, while the European plan ... is that capital shall control labour by controlling wages. This can be done by controlling the money. It will not do to allow the greenback as we cannot control that”. - The Hazard Circular, July 1862.

The fractional reserve policy perpetrated by the Federal Reserve which has spread in practice to the great majority of banks in the world, is, in fact, a system of modern slavery. Think about it: money is created out of debt. What do people do when they earn debt? They submit to employment to pay it off. But if money can only be created out of loans, how can society ever be debt-free? It can’t, and that’s the point. And it is the fear of losing assets coupled with the struggle to keep up with the perpetual debt and inflation in the system, compounded by the inescapable scarcity in the money supply itself, created by the interest which can never be repaid, that keeps the wage slave in line, powering the pyramid which only benefits the elite at the top of the pyramid. At the end of the day, for whom are you really working? The banks. Money is created in a bank and inevitably ends up in a bank. They are the true masters along with the corporations and governments which they support. Physical slavery requires people to be housed and fed, economic slavery requires people to house and feed themselves.

It is one of the most ingenious scams for social manipulation ever invented, and at it’s core, it is an invisible war waged against the population. Debt is the weapon used to conquer and enslave societies and interest is its prime ammunition. As the majority walks around, oblivious to this reality, banks in collusion with governments and corporations continue to expand and perfect their tactics of economic warfare, spawning new bases such as the World Bank and the International Monetary Fund and introducing a new kind of soldier - the economic hitman.

****

Here is the testimony of one of those economic hitmen, John Perkins:

We, the economic hitmen, are the ones really responsible for creating the first really global empire, and we work many different ways. Perhaps the most common is that we will identify a country which has resources which our corporations covet, such as oil, and then arrange a huge loan to that country from the World Bank or one of it’s sister organisations. But the money never actually goes to the country, instead, it goes to our big construction corporations to build infrastructure projects in that country, like industrial power plants, things which benefit a few rich people in that country (in addition to our corporations), but really don’t help the people involved, however those people and the whole country are left holding a huge debt so big that they can’t repay it, which is the whole plan - that they can’t repay it. So we economic hitmen go back to them and say “listen, you owe us a lot of money, you can’t repay it, so sell your oil real cheap to our oil companies, allow us to build a military base in your country or send troops to some place in the world to support our troops in somewhere like Iraq, or vote with us in the UN to have their electric utility company privatised, or their sewage system privatised and sold to US corporations or other multinational corporations, so there is a whole mushrooming thing and it’s the way that the World Bank and the International Monetary Fund operate to put a whole country in debt with such a big debt that it can’t pay it, so you then offer to refinance that debt and get them to pay even more interest and you demand this ‘quid pro quo’ or ‘conditionality’ or ‘good governance’ which means basically that they have to sell off their resources, including their social services and utility companies, their school systems sometimes, their penal systems, their insurance systems to foreign corporations. So, it’s a double, triple, quadruple whammy.

Examples:

Iran 1953: The precedent for economic hitmen began back in the early 1950s when the democratically elected President of Iran, Dr Mohammad Mossadegh, was considered to be a hope for democracy - Time Magazine's Man of the Year. One of the policies which he ran on was the idea that the oil companies needed to pay the Iranian people a lot more for the oil which they were taking out of Iran. We didn't like that, of course, but we were afraid to do what we would normally do, which is to send in the military. Instead, we sent in one CIA agent, a relative of President Roosevelt. He went in with a few million dollars and was very efficient and effective and in a short amount of time he managed to get Mossadegh overthrown and brought in the Shah of Iran to replace him. It was extremely effective. So back here in the United States, people in Washington looked around and said "wow - that was easy and cheap !" So this established the whole new way of manipulating countries and creating empire. The only problem with Roosevelt was that he was a card-carrying CIA agent and if he had been caught, the ramifications would have been pretty serious. So, very quickly at that point a decision was made to use private 'consultants', to channel the money through the World Bank, the IMF or one of the other such agencies, bring in people like me who worked for private companies, so that if we got caught, there would be no government ramifications.

Guatemala 1954: When Arbenz (Jacobo Arbenz Guzman) became President of Guatemala, the country was very much under the thumb of the United Fruit Company, the big international corporation and Guzman ran under the strategy of giving the land back to the people. When he was elected he started implementing those policies of giving the land back to the people. United Fruit didn't like that so much, so they hired a Public Relations company in the United States mounted a huge campaign to convince the people of the US, the press of the US and the Congress of the US that Arbenz was a Soviet puppet and if we allowed him to stay in power the Soviets would have a foothold in this hemisphere, which, at that time, was a huge fear on everybody's minds, so to make a long story short, out of this public relations campaign came a commitment on the part of the CIA and the military to take this man out, and in fact, we did. We sent in planes, we sent in soldiers, we sent in jackals, we sent in everything to take him out, and we did take him out. And as soon as he was removed, his successor reinstated the links to the big corporations including United Fruit.

Ecuador 1981: Ecuador for many, many years was ruled by pro-US dictators, often relatively brutal. Then it was decided that they were going to have a truly democratic election Jaime Roldos (Aguilera) ran for office and his main goal, he said, as President was to make sure that Ecuador's resources were used to help the people. And he won, overwhelmingly, by more votes than anyone has ever won anything in Ecuador and he began to implement these policies to make sure that the profits from oil went to help the people. Well, we didn't like that in the United States. I was sent down as one of several economic hitmen to change Roldos, to corrupt him, to bring him around, to let him know "you know, you and your family can get very rich if you play our game but if you but if you continue to try and keep these policies you promised, then you are going to go". He wouldn't listen. He was assassinated "Ecuadorian Leader Dies in Plane Crash". As soon as the plane crashed, the whole area was cordoned off. The only people allowed in were the US military from a nearby base and some of the Ecuadorian military. When an investigation was launched, two of the key witnesses died in car accidents before they had a chance to testify. A lot of very, very strange things went on around the assassination of Roldos. I, like most of the people who really looked at this case had absolutely no doubt that it was an assassination and of course, in my position of an economic hitman, I was expecting something to happen to Jaime, whether a coup or an assassination I was sure that he would be taken down as he was not being corrupted, he would not allow himself to be corrupted the way we wanted to corrupt him.

Panama 1981: Omar Tarrijas President of Panama was one of my favourite people. I really, really liked him, he was very charismatic and he really wanted to help his country. When I tried to bribe him, to corrupt him, he said "look, John, he called me Juanita, look Juanita, you know, I don't need the money, what I really need is for my country to be treated fairly. I need the United States to replay the debts which you owe my people for all the destruction you have done here. I need to be in a position to help other Latin American countries with their independence and be free of this terrible presence from the North. You people are exploiting us so badly. I need to have the Panama Canal back in the hands of the Panamanian people. That's what I want. So leave me alone, don't try to bribe me". It was in 1981 and in May Jaime Roldos was assassinated and Omar was very aware of this. He got his family together and said "I'm probably next, but it is ok because I've done what I came here to do, I've renegotiated the Canal, the Canal will now be in our hands". He had been renegotiating the treaty with Jimmy Carter:

In June of that same year, just a couple of months later, he also went down in an aeroplane crash which there is no question was executed by CIA jackals. There is a tremendous amount of evidence, one of Tarrijas' security guards handed him, at the last moment as he was getting on the plane, a small tape recorder which contained a bomb.

Venezuela 2002: It is interesting to me how this system has continued pretty much the same way for years and years and years except the economic hitmen get better and better and better. Then we come up with, very recently, what happened in Venezuela in 1998 when (Hugo Rafael) Chavez gets elected, following a long line of Presidents who were very corrupt and who basically destroyed the economy of the country, and Chavez was elected following all of that. Chavez stood up to the United States demanding that Venezuela oil be used to help the Venezuelan people. Well we didn't like that in the United States, so in 2002, a coup was staged, and there is no question in my mind or in most other people's minds, that the CIA was behind that coup. The way that coup was fermented was very effective, like Colonel Roosevelt had done in Iran - paying people to go out into the streets to riot, to protest and say that Chavez is very unpopular. You know, if you can get a few thousand people to do that, television can make it look like the whole country and things start to mushroom, except in the case of Chavez, he was smart enough and the people were so strongly behind him that they overcame it, which was a phenomenal moment in the life of Latin America.

Iraq 2003: Iraq, actually, is a perfect example of the way the whole system works. We economic hitmen are the first line of defence. We go in and try to corrupt governments and get them to accept these huge loans which we then use as leverage to basically own them. If we fail, as I failed in Panama with Omar Tarrijas, and in Ecuador with Jaime Roldos, men who refused to be corrupted, then the second line of defence is we send in the jackals

and the jackals either overthrow governments or they assassinate and when that happens and a new government comes in, boy, it's going to toe the line as the new President knows what will happen if he doesn't. And in the case of Iraq, both of those things failed and the economic hitmen were not able to get through to Saddam Hussein although they tried very hard. We tried very hard to get him to accept a deal but he wouldn't accept it and so the jackals went in to take him out but they couldn't do it as his security was very good. After all, he had at one time worked for the CIA and been hired to assassinate a former President of Iraq and failed, but he knew the system. So, in 1991 we send in the troops and we take out the Iraqi military, assuming that at that point that Saddam is going to come around. We could, of course, have taken him out at that time, but we didn't want to as he is the kind of strong man that we like, able to control his people and keep pumping oil for us. But when we took out his military he didn't come around so the economic hitmen go back in in the 90s without success. If they had had success, he'd still be running the country - we'd be selling him all the fighter jets he'd want, but they didn't have success. The jackals couldn't take him out again, so we sent the military in once again and took him out, and created for ourselves very lucrative reconstruction deals to rebuild a country which we had essentially destroyed - which is a very good deal if you own a construction company - a really big one. So, Iraq shows the three stages: the economic hitmen - failed there, the jackals failed there, so as the final measure, the military goes in.

And in that way, we have really created an empire, but we have done it very, very subtly, it's clandestine. All the empires in the past were built by the military and everybody knew they were building them. The British knew they were building it, the French, the Germans, the Romans, the Greeks - they were all proud of it and they always had some excuse like "spreading civilisation", or spreading some religion, something like that, but they knew they were doing it. We don't. The majority of the people in the United States have no idea that we are living off the benefits of a clandestine empire, that today there is more slavery in the world than ever before.

You may have to ask yourself if it's an empire, then who's the Emperor? Obviously, our Presidents in the United States are not Emperors. An Emperor is someone who is not elected, does not serve a limited term, and who doesn't report to anyone. So you can't classify Presidents that way. But we do have what I consider to be the equivalent of the Emperor in what I call the "Corporatocracy". The Corporatocracy is this group of individuals who run our biggest corporations and they really act as the Emperor of this empire. They control our media (either by direct ownership or by advertising), they control most of our politicians because they finance their campaigns, either through corporations or through personal donations. They are not elected, they don't serve a limited term, they don't report to anybody, and at the very top of the Corporatocracy, we can't tell if the person is working for a corporation or for the government as they are always moving back and forth, so you get a guy who is one moment the president of a big company like Halliburton and the next moment he's the Vice President of the United States, or the President who is in the oil business and this is true whether you get Democrats or Republicans in the office, you have them moving back and forth through the revolving door, and in a way, our government is invisible a lot of the time as it's policies are carried out by a corporation on one level or another, and then again, the policies of the government are basically forged by the Corporatocracy and then presented to the government and become government policies. So, it is an incredibly cosy relationship. This isn't a "conspiracy theory" kind of thing, these people don't have to get together and plot to do things, they all basically work under one primary assumption, and that is that they must maximise profits regardless of the social and environmental costs.

****

This process of manipulation by the Corporatocracy, through the use of debt, bribery and political overthrow, is called "Globalisation". Just as the Federal Reserve keeps the American people in a position of indentured servitude, through perpetual debt, inflation and interest, the World Bank and International Monetary Fund fulfil this role on a global scale.

At the present time, the price of oil has dropped from $145 per barrel to under $50 per barrel. This seemed to be an impossibility just a few weeks ago, but the price is being manipulated by the people who are known as "The New World Order". A man who claims to have access to the agenda of these people, announced the drop to $50 per barrel oil price back in June 2008 and was laughed at. Now that it has happened, people are not laughing any longer. He is now supplying substantial further information and he states that the New World Order people who effectively run the US government, Federal Reserve, Stock Exchange, banks, etc. have the following agenda for the immediate future:

1. They intend to hold the price of oil down to around $50 per barrel for the next 6 to 12 months and then raise it to a very high level. The present wholesale oil price is $1.15 per US gallon delivered to the filling stations. The objective of this price drop is to bankrupt the Arab oil-producing nations. This is a deliberate act of economic warfare.

2. They intend to boost the US stock market to a level of 14,000 over the next 12 months and then drop it suddenly. The objective is to try to destroy the American middle-class by creating a financial collapse that will take years to overcome. If you think that this is impossible, then consider the present position of the people of

Iceland. Iceland declared bankruptcy recently and it's currency fell from 65 krona per US dollar to 130 krona per US dollar. Iceland's monetary inflation is now 16% and rising. People lost their savings overnight. Prices are soaring. Banks are limiting borrowing. Salaries have been cut. Working hours have been cut and there have been mass layoffs of workers. Doing business abroad is very difficult and Icelandic people no longer holiday abroad.

If you think that it is impossible for that to happen in the USA, then think again. The USA was the very bottom country in the list of World Trade Imbalances for 2007, that being the most recent completed trading year. In 2007, the US had a trade deficit of US $816,000,000,000 plus a Federal Debt of $9,700,000,000 to other countries, plus a Federal Debt to Americans which raises that figure to $53,000,000,000. This situation has been deliberately manoeuvred by the New World Order people in preparation for their planned financial attack on the American people, so please don't think that what happened to Iceland can't happen to the USA. The New World Order people are planning exactly that and their timetable is for US financial collapse within a year or so. Becoming self-sufficient would be a very good idea.

If you live outside the USA and think that a US economic collapse will not affect you, then I suggest that you think again as all of the financial systems worldwide are interlinked and there will be a chain reaction across the world.

If you want to check the source of this information, then try:

http://www.youtube.com/watch?v=MzO8av9ey6I&feature=related

http://www.youtube.com/watch?v=gJhOC3iCvTk&feature=channel

http://www.youtube.com/watch?v=Yic_knhoC1Q&feature=related

One other thing which you should perhaps note in connection with this is the World Trade Imbalances for the last available full trading year, namely 2007. The source of this information is the CIA World Fact Book which lists

The 2007 World Trade Imbalances (Source: the CIA World Fact Book)

This lists 224 countries in the world, showing the relative values of their total imports and exports for the year. Only 64 of these countries have a positive balance with exports outweighing imports. I found some of the results to be startling, and here are some of the entries:

1. China	$315,700,000,000
2. Germany	$245,000,000,000
3. Saudi Arabia	$148,830,000,000
4. Russia	$104,600,000,000
5. Japan	$104,500,000,000
6. Norway	$61,290,000,000
7. U.A.E.	$55,000,000,000
8. Singapore	$54,600,000,000
9. Netherlands	$52,900,000,000
10. Canada	$46,200,000,000
11. Kuwait	$42,090,000,000
12. Brazil	$40,000,000,000
13. Malaysia	$39,500,000,000
14. Indonesia	$33,070,000,000
15. Angola	$32,030,000,000
16. Algeria	$32,000,000,000
17. Ireland	$31,400,000,000
18. Iran	$30,260,000,000
19. Taiwan	$27,400,000,000
20. Libya	$26,000,000,000
21. Thailand	$26,000,000,000
22. Venezuela	$23,710,000,000
23. Chile	$23,650,000,000
24. Nigeria	$23,590,000,000
25. Finland	$23,360,000,000
26. Sweden	$19,600,000,000
27. Qatar	$18,090,000,000
28. Switzerland	$17,900,000,000

29. Puerto Rico $17,800,000,000
30. Azerbaijan $15,225,000,000
31. Kazakhstan $15,140,000,000
32. South Korea $14,700,000,000
33. Iraq $13,300,000,000
34. Ivory Coast $12,363,000,000
35. Argentina $12,010,000,000

……

217. Turkey -$46,800,000,000
218. France -$52,100,000,000
219. Greece -$56,880,000,000
220. India -$79,400,000,000
221. Spain -$121,200,000,000
222. The E.U. -$136,000,000,000
223. The U.K. -$175,400,000,000
224. The U.S.A. -$816,000,000,000

You will notice that Saudi Arabia is third of the list with a very satisfactory trade balance. What is not immediately seen is that they have major undertakings in hand which leave them vulnerable and the vast bulk of their sales is oil. The price of a barrel of oil on the international market needs to be US $80 for Saudi Arabia to be financially viable, which is why the New World Order people want to hold that price down to $50 per barrel for a long period. Charming people, aren't they?

The Economic Techniques

The following is an excerpt from a document, dated May 1979, and which appears to be a statement of the methods and techniques used in the economic warfare which is being waged against all ordinary people at this time. Let me emphasise that these are not my words but that I am quoting the contents of an old and unverified document of unknown origin. Anonymous documents are a standard method of spreading disinformation, however, the statements quoted below are included because they have every appearance of being factual.

Top Secret
Silent Weapons for Quiet Wars, An introductory programming manual, Operations Research Technical Manual TM-SW7905.1 This publication marks the 25th anniversary of the Third World War, called the "Quiet War", being conducted using subjective biological warfare, fought with "silent weapons." May 1979

Security
It is patently impossible to discuss social engineering or the automation of a society, i.e., the engineering of social automation systems (silent weapons) on a national or worldwide scale without implying extensive objectives of social control and destruction of human life, i.e., slavery and genocide. Whenever any person or group of persons in a position of great power and without full knowledge and consent of the public, uses such knowledge and methodologies for economic conquest - it must be understood that a state of domestic warfare exists between that person, or group of persons, and the public. The solution of today's problems requires an approach which is ruthlessly candid, with no agonizing over religious, moral or cultural values.

Historical Introduction
Silent weapon technology has evolved from Operations Research ("OR"), a strategic and tactical methodology developed under the Military Management in England during the Second World War. The original purpose of Operations Research was to study the strategic and tactical problems of air and land defence with the objective of effective use of limited military resources against foreign enemies (i.e., logistics). It was soon recognised by those in positions of power that the same methods might be useful for totally controlling a society, but better tools were needed.

Social engineering (the analysis and automation of a society) requires the correlation of great amounts of constantly changing economic information (data), so a high-speed computerised data-processing system was necessary which could predict when society would arrive at the point of capitulation. Mechanical computers were too slow, but the electronic computer fills the bill. The next breakthrough was the development of the simplex method of linear programming in 1947 by the mathematician George B. Dantzig. Then in 1948, the transistor, promised great expansion of the computer field by reducing space and power requirements.

With these three inventions, those in positions of power strongly suspected that it was possible for them to control the whole world. Immediately, the Rockefeller Foundation got in on the ground floor by making a four-year grant to Harvard College, funding the Harvard Economic Research Project for the study of the structure of the American Economy. One year later, in 1949, The United States Air Force joined in. In 1952 the grant period terminated, and a high-level meeting of the Elite was held to determine the next phase of social Operations Research. The Harvard project had been very fruitful, as is borne out by the publication of some of its results in 1953 suggesting the feasibility of economic (social) engineering. (Studies in the Structure of the American Economy - copyright 1953 by Wassily Leontief, International Science Press Inc., White Plains, New York).

Engineered during the last half of the 1940's, by 1954 the new Quiet-War machine was ready. With the creation of the maser in 1954, the promise of unlocking unlimited sources of fusion atomic energy from the heavy hydrogen in sea water and the consequent availability of unlimited social power was a possibility only decades away. The combination was irresistible. The Quiet War was quietly declared by the International Elite at a meeting held in 1954. Although the silent weapons system was nearly exposed 13 years later, the evolution of the new weapon-system has never suffered any major setbacks. This year of 1979 marks the 25th anniversary of the beginning of the Quiet War. Already this domestic war has had many victories on many fronts throughout the world.

Political Introduction

In 1954 it was well recognised by those in positions of authority, that it would be only a few decades, before the general public would be able to grasp and upset the cradle of power, for the elements of the new silent-weapon technology were as accessible for use in providing a public utopia as they were for providing a private utopia. So, the issue of primary concern, namely that of dominance, revolved around the subject of the energy sciences.

Energy

Energy is recognised as the key to all activity on earth. Natural science is the study of the sources and control of natural energy, and social science (theoretically expressed as economics) is the study of the sources and control of social energy. Both are bookkeeping systems based on mathematics. Therefore, mathematics is the primary energy science and the bookkeeper can be king if the public can be kept ignorant of the methodology of the bookkeeping.

All science is merely a means to an end. The means is knowledge. The end is control. Beyond this remains only one issue: Who will be the beneficiary? In 1954 this was the issue of primary concern. Although the so-called "moral issues" were raised, in view of the law of natural selection it was agreed that a nation or world of people who will not use their intelligence are no better than animals who do not have intelligence. Such people are beasts of burden and steaks on the table by choice and consent.

Consequently, in the interest of future world order, peace, and tranquillity, it was decided to wage a private quiet war against the American public with an ultimate objective of permanently shifting the natural and social energy (wealth) of the undisciplined and irresponsible many into the hands of the self-disciplined, responsible, and "worthy" few.

In order to implement this objective, it was necessary to create, secure, and apply new weapons which, as it turned out, were a class of weapons so subtle and sophisticated in their principle of operation and public appearance as to earn for themselves the name of "silent weapons." In conclusion, the objective of economic research, as conducted by the magnates of capital (banking) and the industries of commodities (goods and services), is the establishment of an economy which is totally predictable and which can be manipulated.

In order to achieve this totally predictable economy, the low-class elements of society must be brought under total control, i.e., They must be housebroken, trained, and assigned a yoke and long-term social duties from a very early age, before they have an opportunity to question the propriety of the matter. In order to achieve such conformity, the lower-class family unit must be disintegrated by a process of increasing preoccupation of the parents and the establishment of government-operated day-care centres for the occupationally orphaned children.

The quality of education given to the lower class must be of the poorest sort, so that the moat of ignorance isolating the inferior class from the superior class is and always remains, incomprehensible to the inferior class. With such an initial handicap, even bright lower class individuals have little if any hope of extricating themselves from their assigned lot in life. This form of slavery is essential to maintain some measure of social order, peace, and tranquillity for the ruling upper class.

Descriptive Introduction to the Silent Weapon

Everything which can be expected from an ordinary weapon is also expected from a silent weapon by its creators, but only in its own manner of functioning. It shoots situations, instead of bullets; it's propellant is data processing, instead of the conventional chemical explosion. The power originates from bits of data in a computer, instead of grains of gunpowder inside a gun. The operator is a computer programmer, instead of a military marksman, and

the orders are issued by a banking magnate, instead of a military general. It makes no obvious explosive noises, causes no obvious physical or mental injuries, and does not interfere in an obvious way with anyone's daily social life.

However, it makes an unmistakable "noise," causes unmistakable physical and mental damage, and interferes unmistakably with daily social life, that is, in ways which are unmistakable to a trained observer who knows what to look for. The public cannot comprehend this weapon, and therefore cannot believe that they are being attacked and subdued by a weapon. The public might instinctively feel that something is wrong, but because of the technical nature of the silent weapon, they cannot express their feeling in any rational way, or handle the problem with intelligence. Therefore, they do not know how to call for help, nor do they know how to associate with others to defend themselves against it.

When a silent weapon is applied gradually, the public adjusts and adapts to its presence and learns to tolerate its encroachment on their lives until the psychological pressure (applied via economic methods) becomes too great and they crack up. Therefore, in a way, the silent weapon can be considered to be a type of biological weapon. It attacks the vitality, options, and mobility of the individuals of a society by knowing, understanding, manipulating, and attacking their sources of natural and social energy, and their physical, mental, and emotional strengths and weaknesses.

Theoretical Introduction

"Give me control over a nation's currency, and I care not who makes its laws." - Mayer Amschel Rothschild (1743 - 1812). Today's silent weapons technology is an outgrowth of a simple idea discovered, succinctly expressed, and effectively applied by Mr. Mayer Amschel Rothschild. Mr. Rothschild discovered the missing passive component of economic theory known as economic inductance. He, of course, did not think of his discovery in these twentieth century terms, and, to be sure, mathematical analysis had to wait for the Second Industrial Revolution, the rise of the theory of mechanics and electronics, and finally, the invention of the electronic computer before it could be effectively applied in the control of the world economy.

General Energy Concepts

In the study of energy systems, there always appears three elementary concepts. These are:
Potential Energy,
Kinetic Energy, and
Energy Dissipation.
Corresponding to these concepts, there are three idealised, essentially pure physical counterparts called passive components.

In the science of physical mechanics, the phenomenon of Potential Energy is associated with a physical property called Elasticity or stiffness, and can be represented by a stretched spring. In electronic science, Potential energy is stored in a capacitor instead of a spring. This property is called Capacitance instead of Elasticity.

In the science of physical mechanics, the phenomenon of Kinetic Energy is associated with a physical property called Inertia or Mass, and can be represented by a mass or a flywheel in motion. In electronic science, Kinetic Energy is stored in an inductor (in a magnetic field) instead of a mass. This property is called Inductance instead of Inertia.

In the science of physical mechanics, the phenomenon of Energy Dissipation is associated with a physical property called Friction or Resistance, and can be represented by a dashpot or other device which converts energy into heat. In electronic science, Energy Dissipation is performed by an element called either a Resistor.

In economics the equivalents of these three energy concepts are:
Economic Capacitance - **Capital** (money, stock/inventory, investments in buildings and durables, etc.)
Economic Conductance - **Goods** (production flow coefficients)
Economic Inductance - **Services** (the influence of the industrial population on output)

All of the mathematical theory developed in the study of one energy system (e.g., mechanics, electronics, etc.) can be immediately applied in the study of any other energy system (e.g., economics).

Mr Rothschild's Energy Discovery

What Mr. Rothschild discovered was the basic principle of power, influence, and control over people as applied to economics. That principle is "when you assume the appearance of power, people soon give it to you." Mr. Rothschild had discovered that currency or deposit loan accounts had the required appearance of power that could be used to induce people (inductance, with people corresponding to a magnetic field) into surrendering their real wealth in exchange for a promise of greater wealth (instead of real compensation). They would put up real collateral in exchange for a loan of promissory notes. Mr. Rothschild found that he could issue more notes than

he had backing for, provided he had someone's stock of gold to show his customers as a persuader.

Mr. Rothschild loaned his promissory notes to individual and to governments. These would create overconfidence. Then he would make money scarce, tighten control of the system, and collect the collateral through the obligation of contracts. The cycle was then repeated. These pressures could be used to ignite a war. Then he would control the availability of currency to determine who would win the war. Any government which agreed to give him control of its economic system got his support. Collection of debts was guaranteed by economic aid to the enemy of the debtor. The profit derived from this economic methodology made Mr. Rothschild all the more able to expand his wealth. He found that the public greed would allow currency to be printed by government order beyond the limits (inflation) of backing in precious metal or the production of goods and services.

Apparent Capital as "Paper" Inductor

In this structure, credit, presented as a pure element called "currency," has the appearance of capital, but is in effect, negative capital. Hence, it has the appearance of service, but it is, in fact, indebtedness or debt. It is therefore an economic inductance instead of an economic capacitance, and if balanced in no other way, will be balanced by the negation of population (war, genocide). The total sum of goods and services represents real capital and it is called the **Gross National Product**, and currency may be printed up to this level and still represent economic capacitance; but currency printed beyond this level is subtractive, represents the introduction of economic inductance, and so becomes notes of indebtedness.

War is therefore the balancing of the system by killing the true creditors (the public which has been taught to exchange true value for inflated currency) and falling back on whatever is left of the resources of nature and regeneration of those resources. Mr. Rothschild had discovered that currency gave him the power to rearrange the economic structure to his own advantage, to shift economic inductance to those economic positions which would encourage the greatest economic instability and oscillation.

The final key to economic control had to wait until there was sufficient data and high-speed computing equipment to keep close watch on the economic oscillations created by price shocking and excess paper energy credits - paper inductance/inflation.

Breakthrough

The aviation field provided the greatest evolution in economic engineering by way of the mathematical theory of shock testing. In this process, a projectile is fired from an airframe on the ground and the impulse of the recoil is monitored by vibration transducers connected to the airframe and wired to chart recorders. By studying the echoes or reflections of the recoil impulse in the airframe, it is possible to discover critical vibrations in the structure of the airframe which either vibrations of the engine or aeolian vibrations of the wings, or a combination of the two, might reinforce resulting in a resonant self-destruction of the airframe in flight. From the standpoint of engineering, this means that the strengths and weaknesses of the structure of the airframe in terms of vibrational energy can be discovered and manipulated.

Application in Economics

To use this method of airframe shock testing in economic engineering, the prices of commodities are shocked, and the public consumer reaction is monitored. The resulting echoes of the economic shock are interpreted theoretically by computers and the psycho-economic structure of the economy is thus discovered. It is by this process that partial differential and difference matrices are discovered that define the family household and make possible its evaluation as an economic industry (dissipative consumer structure). Then the response of the household to future shocks can be predicted and manipulated, and society becomes a well-regulated animal with its reins under the control of a sophisticated computer-regulated social energy bookkeeping system. Eventually every individual element of the structure comes under computer control through a knowledge of personal preferences, such knowledge guaranteed by computer association of consumer preferences (universal product code - the striped bar codes on packages) with identified consumers (initially identified through the use of a credit card and later through a permanent "tattooed" body number invisible under normal ambient illumination).

The Economic Model

The Harvard Economic Research Project (1948-1952) was an extension of World War II Operations Research. Its purpose was to discover the science of controlling an economy: at first the American economy, and then the world economy. It was felt that with sufficient mathematical foundation and data, it would be nearly as easy to predict and control the trend of an economy as to predict and control the trajectory of a projectile. Such has proven to be the case. Moreover, the economy has been transformed into an accurately targeted guided missile.

The immediate aim of the Harvard project was to discover the economic structure, what forces can change that structure, how the behaviour of the structure can be predicted, and how it can be manipulated. What was needed was a well-organised knowledge of the mathematical structures and interrelationships of investment, production,

distribution, and consumption. Briefly, it was discovered that an economy obeyed the same laws as electricity and that all of the mathematical theory and practical and computer know-how developed for the electronic field could be directly applied in the study of economics. This discovery was not openly declared, and its more subtle implications were, and are, kept as a closely guarded secret, for example, in an economic model, human life is measured in dollars, and that the electric spark generated when opening a switch connected to an active inductor is mathematically the same as starting a war.

The greatest hurdle which theoretical economists faced was the accurate description of the household as an industry. This is a challenge because consumer purchases are a matter of choice which in turn is influenced by family income, purchase price, and other economic factors. This hurdle was cleared in an indirect and statistically approximate way by an application of shock testing to determine the current characteristics, called current technical coefficients, of a household industry. Finally, because problems in theoretical electronics can be translated very easily into problems of theoretical economics, and the solution translated back again, it follows that only a book of language translation and concept definition needed to be written for economics. The remainder could be got from standard works on mathematics and electronics. This makes the publication of books on advanced economics unnecessary, and greatly simplifies the silent war project security.

Industrial Diagrams

An ideal industry is defined as a device which receives value from other industries in several forms and converts them into one specific product for sales and distribution to other industries. It has several inputs and one output. What the public normally thinks of as one industry is really an industrial complex, where several industries under one roof produce one or more products.

Three Industrial Classes

Industries fall into three categories or classes by type of output:
Class 1 - **Capital** (resources)
Class 2 - **Goods** (commodities or use - dissipative)
Class 3 - **Services** (action of population).

Class 1 industries exist at three levels:
(a) Nature - sources of energy and raw materials.
(b) Government - printing of currency equal to the gross national product (GNP), and extension of currency in excess of GNP.
(c) Banking - loaning of money for interest, and extension (inflation/counterfeiting) of economic value through deposit loan accounts.

Class 2 industries exist as producers of tangible or consumer (dissipated) products. This sort of activity is usually recognised and labelled by the public as "industry."

Class 3 industries are those which have service rather than a tangible product as their output. These industries are called
(a) Households, and
(b) Governments. Their output is human activity of a mechanical sort, and their basis is population.

Aggregation

The whole economic system can be represented by a three-industry model if one allows the names of the outputs to be:
(1) Capital,
(2) Goods, and
(3) Services.

The problem with this representation is that it would not show the influence of, say, the textile industry on the steel industry. This is because both the textile industry and the steel industry would be contained within a single classification called the "goods industry" and by this process of combining or aggregating these two industries under one system block they would lose their economic individuality.

The E- Model

A national economy consists of simultaneous flows of production, distribution, consumption, and investment. If all of these elements including labour and human functions are assigned a numerical value using common units of measure, say, US dollars at their 1939 value, then this flow can be further represented by a current flow in an electronic circuit, and its behaviour can be predicted and manipulated with useful precision.

The three ideal passive energy components of electronics, the capacitor, the resistor, and the inductor correspond to the three ideal passive energy components of economics called the pure industries of capital, goods, and

services.

Economic Capacitance represents the storage of capital in one form or another.

Economic Conductance represents the level of conductance of materials for the production of goods.

Economic Inductance represents the inertia of economic value in motion. This is a population phenomenon known as services.

Economic Inductance
An electrical inductor (e.g., a coil or wire) has an electric current as its primary phenomenon and a magnetic field as its secondary phenomenon (inertia). Corresponding to this, an economic inductor has a flow of economic value as its primary phenomenon and a population field as its secondary field phenomenon of inertia. When the flow of economic value (e.g., money) diminishes, the human population field collapses in order to keep the economic value (money) flowing (extreme case - war). This public inertia is a result of consumer buying habits, expected standard of living, etc., and is generally a phenomenon of self-preservation.

Inductive Factors to Consider
(1) Population
(2) Magnitude of the economic activities of the government
(3) The method of financing these government activities
(See Peter-Paul Principle - inflation of the currency.)

Translation
(a few examples will be given.)
Charge - coulombs - dollars (1939).
Current Flow - amperes (coulombs per second) - dollars of flow per year.
Motivating Force - volts - dollars (output) demand.
Conductance - amperes per volt - dollars of flow per year per dollar demand.
Capacitance - coulombs per volt - dollars of production inventory/stock per dollar demand.

Time-Flow Relationships and Self-Destructive Oscillations
An ideal industry may be symbolised electronically in various ways. The simplest way is to represent a demand by a voltage and a supply by a current. When this is done, the relationship between the two becomes what is called an admittance, which can result from three economic factors:

(1) **Hindsight flow**,
(2) **Present flow**, and
(3) **Foresight flow**.

Foresight flow is the result of that property of living entities to cause energy (food) to be stored for a period of low energy (e.g., a winter season). It consists of demands made upon an economic system for that period of low energy (winter season). In a production industry it takes several forms, one of which is known as production stock or inventory. In electronic symbology this specific industry demand (a pure capital industry) is represented by capacitance and the stock or resource is represented by a stored charge. Satisfaction of an industry demand suffers a lag because of the loading effect of inventory priorities.

Present flow ideally involves no delays. It is, so to speak, input today for output today, a "hand to mouth" flow. In electronic symbology, this specific industry demand is represented by a conductance which is then a simple economic valve (a dissipative element).

Hindsight flow is known as habit or inertia. In electronics this phenomenon is the characteristic of an inductor (economic analogue = a pure service industry) in which a current flow (economic analogue = flow of money) creates a magnetic field (economic analogue = active human population) which, if the current (money flow) begins to diminish, will collapse (war) to maintain the current (flow of money - energy).

Other large alternatives to war as economic inductors or economic flywheels are an open-ended social welfare program, or an enormous (but fruitful) open-ended space program. The problem with stabilising the economic system is that there is too much demand on account of:
(1) Too much greed and
(2) Too much population.
This creates excessive economic inductance which can only be balanced with economic capacitance (true resources or value - e.g., in goods or services).

The social welfare program is nothing more than an open-ended credit balance system which creates a false capital industry to give non-productive people a roof over their heads and food in their stomachs. This can be useful, however, because the recipients become state property in return for the "gift," and form a standing army for the Elite - as he who pays the piper picks the tune. Those who get hooked on the economic drug, must go to the Elite for a fix. In this, the method of introducing large amounts of stabilising capacitance is by borrowing on the future "credit" of the world. This is a fourth law of motion - **onset**, and consists of performing an action and leaving the system before the reflected reaction returns to the point of action - a delayed reaction.

The means of surviving the reaction is by changing the system before the reaction can return. By this means, politicians become more popular in their own time and the public pays later. In fact, the measure of such a politician is the delay time. The same thing is achieved by a government by printing money beyond the limit of the gross national product, and economic process called inflation. This puts a large quantity of money into the hands of the public and maintains a balance against their greed, creates a false self-confidence in them and, for a while, stays the wolf from the door.

They must eventually resort to war to balance the account, because war ultimately is merely the act of destroying the creditor, and the politicians are the publicly hired hit men that justify the act to keep the responsibility and blood off the public conscience. If the people really cared about their fellow man, they would control their appetites (greed, procreation, etc.) so that they would not have to operate on a credit or welfare social system which steals from the worker to satisfy the bum. Since most of the general public will not exercise restraint, there are only two alternatives to reduce the economic inductance of the system.

(1) Let the populace bludgeon each other to death in war, which will only result in a total destruction of the living earth.

(2) Take control of the world by the use of economic "silent weapons" in a form of "quiet warfare" and reduce the economic inductance of the world to a safe level by a process of benevolent slavery and genocide.

The latter option has been taken as the obviously better option. At this point it should be crystal clear to the reader why absolute secrecy about the silent weapons is necessary. The general public refuses to improve its own mentality and its faith in its fellow man. It has become a herd of proliferating barbarians, and, so to speak, a blight upon the face of the earth. They do not care enough about economic science to learn why they have not been able to avoid war despite religious morality, and their religious or self-gratifying refusal to deal with earthly problems, places the solution of the earthly problem beyond their reach.

It is left to those few who are truly willing to think and survive, as the fittest to survive, to solve the problem for themselves as the few who really care. Otherwise, exposure of the silent weapon would destroy our only hope of preserving the seed of the future true humanity.

The Household Industry

The industries of finance (banking), manufacturing, and government, real counterparts of the pure industries of capital, goods, and services, are easily defined because they are generally logically structured. Because of this their processes can be described mathematically and their technical coefficients can be easily deduced. This, however, is not the case with the service industry known as the household industry.

Household Models

The problem which a theoretical economist faces is that the consumer preferences of any household are not easily predictable and the technical coefficients of any one household tend to be a non-linear, very complex, and variable function of income, prices, etc. Computer information derived from the use of the universal product code in conjunction with credit-card purchase as an individual household identifier, could change this state of affairs, but the Universal Product Code method is not yet available on a national or even a significant regional scale. To compensate for this data deficiency, an alternate indirect approach of analysis has been adopted known as economic shock testing. This method, widely used in the aircraft manufacturing industry, develops an aggregate statistical sort of data.

Applied to economics, this means that all of the households in one region or in the whole nation are studied as a group or class rather than individually, and the mass behaviour rather than the individual behaviour is used to discover useful estimates of the technical coefficients governing the economic structure of the hypothetical single-household industry. One method of evaluating the technical coefficients of the household industry depends upon shocking the prices of a commodity and noting the changes in the sales of all of the commodities.

Economic Shock Testing

In recent times, the application of Operations Research to the study of the public economy has been obvious for anyone who understands the principles of shock testing. In the shock testing of an aircraft airframe, the recoil impulse of firing a gun mounted on that airframe causes shock waves in that structure which tell aviation

engineers the conditions under which some parts of the airplane or the whole airplane or its wings will start to vibrate or flutter like a guitar string, a flute reed, or a tuning fork, and disintegrate or fall apart in flight. Economic engineers achieve the same result in studying the behaviour of the economy and the consumer public by carefully selecting a staple commodity such as beef, coffee, gasoline, or sugar, and then causing a sudden change or shock in its price or availability, thus kicking everybody's budget and buying habits out of shape. They then observe the shock waves which result by monitoring the changes in advertising, prices, and sales of that and other commodities.

The objective of such studies is to acquire the know-how to set the public economy into a predictable state of motion or change, even a controlled self-destructive state of motion which will convince the public that certain "expert" people should take control of the money system and re-establish security (rather than liberty and justice) for all. When the subject citizens are rendered unable to control their financial affairs, they, of course, become totally enslaved, and a source of cheap labour. Not only the prices of commodities, but also the availability of labour can be used as the means of shock testing. Labour strikes deliver excellent tests shocks to an economy, especially in the critical service areas of trucking (transportation) , communication, public utilities (energy, water, garbage collection), etc. By shock testing, it is found that there is a direct relationship between the availability of money flowing in an economy and the real psychological outlook and response of masses of people dependent upon that availability. For example, there is a measurable quantitative relationship between the price of gasoline and the probability that a person would experience a headache, feel a need to watch a violent movie, smoke a cigarette, or go to a tavern for a mug of beer.

It is most interesting that, by observing and measuring the economic models by which the public tries to run from their problems and escape from reality, and by applying the mathematical theory of Operations Research, it is possible to program computers to predict the most probable combination of created events (shocks) which will bring about a complete control and subjugation of the public through a subversion of the public economy (by shaking the plum tree).

Introduction to Economic Amplifiers

Economic Amplifiers are the active components of economic engineering. The basic characteristic of any amplifier (mechanical, electrical, or economic) is that it receives an input control signal and delivers energy from an independent energy source to a specified output terminal in a predictable relationship to that input control signal. The simplest form of an economic amplifier is a device called advertising. If a person is spoken to by a T.V. advertiser as if he were a twelve-year-old, then, due to suggestibility, he will, with a certain probability, respond or react to that suggestion with the uncritical response of a twelve-year-old and will reach into his economic reservoir and deliver its energy to buy that product on impulse when he passes it in the store.

An Economic Amplifier may have several inputs and output. Its response might be instantaneous or delayed. Its circuit symbol might be a rotary switch if its options are exclusive, qualitative, "go" or "no-go", or it might have its parametric input/output relationships specified by a matrix with internal energy sources represented. Whatever its form might be, its purpose is to govern the flow of energy from a source to an output sink in direct relationship to an input control signal. For this reason, it is called an active circuit element or component. Economic Amplifiers fall into classes called strategies, and, in comparison with electronic amplifiers, the specific internal functions of an economic amplifier are called logistical instead of electrical. Therefore, economic amplifiers not only deliver power gain but also, in effect, are used to cause changes in the economic circuitry.

In the design of an economic amplifier we must have some idea of at least five functions ,which are:

(1) The available input signals,
(2) The desired output-control objectives,
(3) The strategic objective,
(4) The available economic power sources,
(5) The logistical options.

The process of defining and evaluating these factors and incorporating the economic amplifier into an economic system has been popularly called "game theory". The design of an economic amplifier begins with a specification of the power level of the output, which can range from personal to national. The second condition is accuracy of response, i.e., how accurately the output action is a function of the input commands. High gain combined with strong feedback helps to deliver the required precision. Most of the error will be in the input data signal. Personal input data tends to be specified, while national input data tends to be statistical.

Short List of Inputs

General sources of information:
(1) Telephone taps

(2) Surveillance
(3) Analysis of garbage
(4) Behaviour of children in school

Standard of living by:
(1) Food
(2) Clothing
(3) Shelter
(4) Transportation

Social contacts:
(1) Telephone - itemized record of calls
(2) Family - marriage certificates, birth certificates, etc.
(3) Friends, associates, etc.
(4) Memberships in organizations
(5) Political affiliation

The Personal Paper Trail

Personal buying habits, i.e., personal consumer preferences:
(1) Bank accounts
(2) Credit-card purchases
(3) "Tagged" credit-card purchases - those with a Universal Product Code

Assets:
(1) Bank accounts
(2) Savings accounts
(3) Property
(4) Business
(5) Vehicles, etc.
(6) Safety deposit at a bank
(7) Stock market purchases

Liabilities:
(1) Creditors
(2) Enemies (see - legal)
(3) Loans
(4) Consumer credit

Government sources (ploys)*:
(1) Welfare
(2) Social Security
(3) U.S.D.A. surplus food
(4) Dole
(5) Grants
(6) Subsidies

*Principle of this ploy - the citizen will almost always make the collection of information easy if he can operate on the "free sandwich principle" of "eat now, and pay later."

Government sources (via intimidation) :
(1) Internal Revenue Service
(2) OSHA
(3) Census
(4) etc.

Other government sources - surveillance of U.S. mail.

Habit Patterns - Programming

Strengths and weaknesses:
(1) Activities (sports, hobbies, etc.)

(2) See "legal" (fear, anger, etc. - crime record)
(3) Hospital records (drug sensitivities, reaction to pain, etc.)
(4) Psychiatric records (fears, angers, disgusts, adaptability, reactions to stimuli, violence, suggestibility or hypnosis, pain, pleasure, love, and sex)

Methods of coping - of adaptability - behaviour:
(1) Consumption of alcohol
(2) Consumption of drugs
(3) Entertainment
(4) Religious factors influencing behaviour
(5) Other methods of escaping from reality

Payment modus operandi (MO) - pay on time, etc.:
(1) Payment of telephone bills
(2) Energy purchases (electrical, gas,...)
(3) Water purchases
(4) Repayment of loans
(5) House payments
(6) Vehicle payments
(7) Payments on credit cards

Political sensitivity:
(1) Beliefs
(2) Contacts
(3) Position
(4) Strengths/weaknesses
(5) Projects/activities

Legal inputs - behavioural control (Excuses for investigation, search, arrest, or use of force to modify behaviour):
(1) Court records
(2) Police records - NCIC
(3) Driving record
(4) Reports made to police
(5) Insurance information
(6) Anti-establishment acquaintances

National Input Information

Business sources (via I.R.S., etc.):
(1) Prices of commodities
(2) Sales
(3) Investments in
  (a) stocks/inventory
  (b) production tools and machinery
  (c) buildings and improvements
  (d) the stock market

Banks and credit bureaus:
(1) Credit information
(2) Payment information

Miscellaneous sources:
(1) Polls and surveys
(2) Publications
(3) Telephone records
(4) Energy and utility purchases

Short List of Inputs
Outputs - create controlled situations - manipulation of the economy, hence society - control of compensation and income.
Sequence:

(1) Allocates opportunities.
(2) Destroys opportunities.
(3) Controls the economic environment.
(4) Controls the availability of raw materials.
(5) Controls capital.
(6) Controls bank rates.
(7) Controls the inflation of the currency.
(8) Controls the possession of property.
(9) Controls industrial capacity.
(10) Controls manufacturing.
(11) Controls the availability of goods (commodities) .
(12) Controls the prices of commodities.
(13) Controls services, the labour force, etc.
(14) Controls payments to government officials
(15) Controls the legal functions.
(16) Controls the personal data files - uncorrectable by the party slandered.
(17) Controls advertising.
(18) Controls media contact.
(19) Controls material available for T.V. viewing.
(20) Disengages attention from real issues.
(21) Engages emotions.
(22) Creates disorder, chaos, and insanity.
(23) Controls design of more probing tax forms.
(24) Controls surveillance.
(25) Controls the storage of information.
(26) Develops psychological analyses and profiles of individuals.
(27) Controls sociological factors.
(28) Controls health options.
(29) Preys on weakness.
(30) cripples strengths.
(31) leaches wealth and substance.

Table of Strategies

Do This	To Get This
Keep the public ignorant	Less public organisation
Maintain access control	Required reaction to output (prices, sales)
Create preoccupation	Lower defences
Attack the family unit	Control the education of the young
Give less cash and more credit and dole	More self-indulgence and more data
Attack the privacy of the church	Destroy faith in this sort of government
Social conformity	Computer programming simplicity
Minimise tax protests	Maximum economic data, minimum enforcement problems
Stabilise the consent	Simplicity coefficients
Tighten control of variables	Simpler computer input data - greater predictability
Establish boundary conditions	Problem simplicity / solutions of differential and difference equations
Proper timing	Less data shift and blurring
Maximise control	Minimum resistance to control
Collapse of currency	Destroy the faith of the American people in each other

Diversion, the Primary Strategy

Experience has shown that the simplest method of securing a silent weapon and gaining control of the public is to keep the public undisciplined and ignorant of the basic system principles on the one hand, while keeping them confused, disorganised, and distracted with matters of no real importance on the other hand. This is achieved by:

(1) Disengaging their minds; sabotaging their mental activities; providing a low-quality program of public education in mathematics, logic, systems design and economics; and discouraging technical creativity.
(2) Engaging their emotions, increasing their self-indulgence and their indulgence in emotional and physical activities, by:
(a) Unrelenting emotional affronts and attacks (mental and emotional rape) by way of constant barrage of sex, violence, and wars in the media - especially the T.V. and the newspapers.

(b) Giving them what they desire - in excess - "junk food for thought" - and depriving them of what they really need.
(3) Rewriting history and law and subjecting the public to the deviant creation, thus being able to shift their thinking from personal needs to highly fabricated outside priorities.

These preclude their interest in, and discovery of, the silent weapons of social automation technology. The general rule is that there is a profit in confusion; the more confusion, the more profit. Therefore, the best approach is to create problems and then offer solutions.

Diversion Summary
Media: Keep the adult public attention away from the real social issues, and captivated by matters of no real importance.

Schools: Keep the young public ignorant of real mathematics, real economics, real law, and real history.

Entertainment: Keep the public entertainment below a sixth-grade (12 year old) level.

Work: Keep the public busy, busy, busy, with no time to think; back on the farm with the other animals.

Consent, the Primary Victory
A silent weapon system operates upon data obtained from a docile public by legal (but not always lawful) force. Much information is made available to silent weapon systems programmers through the Internal Revenue Service. (See Studies in the Structure of the American Economy for an I.R.S. source list). This information consists of the enforced delivery of well-organised data contained in federal and state tax forms, collected, assembled, and submitted by slave labour provided by taxpayers and employers. Furthermore, the number of such forms submitted to the I.R.S. is a useful indicator of public consent, an important factor in strategic decision making. Other data sources are given in the Short List of Inputs.

Consent Coefficients - numerical feedback indicating victory status. Psychological basis: When the government is able to collect tax and seize private property without just compensation, it is an indication that the public is ripe for surrender and is consenting to enslavement and legal encroachment. A good and easily quantified indicator of harvest time is the number of public citizens who pay income tax despite an obvious lack of reciprocal or honest service from the government.

Amplification Energy Sources
The next step in the process of designing an Economic Amplifier is discovering the energy sources. The energy sources which support any primitive economic system are, of course, a supply of raw materials, and the consent of the people to labour and consequently assume a certain rank, position, level, or class in the social structure, i.e., to provide labour at various levels in the pecking order. Each class, in guaranteeing its own level of income, controls the class immediately below it, hence preserves the class structure. This provides stability and security, but also government from the top. As time goes on and communication and education improve, the lower-class elements of the social labour structure become knowledgeable and envious of the good things that the upper-class members have. They also begin to attain a knowledge of energy systems and the ability to enforce their rise through the class structure. This threatens the sovereignty of the Elite.

If this rise of the lower classes can be postponed long enough, the Elite can achieve energy dominance, and labour by consent no longer will hold a position of an essential energy source. Until such energy dominance is absolutely established, the consent of people to labour and let others handle their affairs must be taken into consideration, since failure to do so could cause the people to interfere in the final transfer of energy sources to the control of the Elite. It is essential to recognise that at this time, public consent is still an essential key to the release of energy in the process of economic amplification. Therefore, consent as an energy release mechanism will now be considered.

Logistics
The successful application of a strategy requires a careful study of inputs, outputs, the strategy connecting the inputs and the outputs, and the available energy sources to fuel the strategy. This study is called "Logistics". A logistical problem is studied at the elementary level first, and then levels of greater complexity are studied as a synthesis of elementary factors. This means that a given system is analysed, i.e., broken down into its sub-systems, and these in turn are analysed, until by this process, one arrives at the logistical "atom," the individual.

The Artificial Womb

From the time a person leaves his mother's womb, his every effort is directed towards building, maintaining, and withdrawing into artificial wombs, various sorts of substitute protective devices or shells. The objective of these artificial wombs is to provide a stable environment for both stable and unstable activity; to provide a shelter for the evolutionary processes of growth and maturity - i.e., survival; to provide security for freedom and to provide defensive protection for offensive activity. This is equally true of both the general public and the Elite. However, there is a definite difference in the way each of these classes go about the solution of problems.

The Political Structure of a Nation - Dependency

The primary reason why the individual citizens of a country create a political structure is a subconscious wish or desire to perpetuate their own dependency relationship of childhood. Simply put, they want a human god to eliminate all risk from their life, pat them on the head, kiss their bruises, put a chicken on every dinner table, clothe their bodies, tuck them into bed at night, and tell them that everything will be all right when they wake up in the morning. This public demand is incredible, so the human god, the politician, meets incredibility with incredibility by promising the world and delivering nothing. So who is the bigger liar? The public? or The "godfather"? This public behaviour is surrender born of fear, laziness, and expediency. It is the basis of the welfare state as a strategic weapon, useful against a disgusting public.

Action / Offence

Most people want to be able to subdue and/or kill other human beings who disturb their daily lives, but they do not want to have to cope with the moral and religious issues which such an overt act on their part might raise. Therefore, they assign the dirty work to others (including their own children) so as to keep the blood off their hands. They rave about the humane treatment of animals and then sit down to a delicious hamburger from a whitewashed slaughterhouse down the street and out of sight. But even more hypocritical, they pay taxes to finance a professional association of hit men collectively called politicians, and then complain about corruption in government.

Responsibility

Again, most people want to be free to do the things (to explore, etc.) but they are afraid of failing. The fear of failure is manifested in irresponsibility, and especially in delegating those personal responsibilities to others where success is uncertain or carries possible or created liabilities (law) which the person is not prepared to accept. They want authority (root word - "author"), but they will not accept responsibility or liability. So they hire politicians to face reality for them.

Summary

The people hire the politicians so that the people can:
(1) Obtain security without managing it.
(2) Obtain action without thinking about it.
(3) Inflict theft, injury, and death upon others without having to contemplate either life or death.
(4) Avoid responsibility for their own intentions.
(5) Obtain the benefits of reality and science without exerting themselves or learning either of these things.

They give the politicians the power to create and manage a war machine:
(1) Provide for the survival of the nation/womb.
(2) Prevent encroachment of anything upon the nation/womb.
(3) Destroy the enemy who threatens the nation/womb.
(4) For the sake of stability of the nation/womb, destroy those citizens of their own country who do not conform.

Politicians hold many quasi-military jobs, the lowest being the police who are soldiers, the attorneys and C.P.A.s next who are spies and saboteurs (licensed), and the judges who shout orders and run the closed union military shop for whatever the market will bear. The generals are industrialists. The "presidential" level of commander-in-chief is shared by the international bankers. The people know that they have created this farce and financed it with their own taxes (consent), but they would rather knuckle under than be the hypocrite. Thus, a nation becomes divided into two very distinct parts, a docile sub-nation [great silent majority] and a political sub-nation. The political sub-nation remains attached to the docile sub-nation, tolerates it, and leaches its substance until it grows strong enough to detach itself and then devour its parent.

System Analysis

In order to make meaningful computerized economic decisions about war, the primary economic flywheel, it is

necessary to assign concrete logistical values to each element of the war structure - personnel and material alike. This process begins with a clear and candid description of the subsystems of such a structure.

The Draft (military service)

Few efforts of human behaviour modification are more remarkable or more effective than that of the socio-military institution known as the draft. A primary purpose of a draft or other such institution is to instil, by intimidation, in the young males of a society the uncritical conviction that the government is omnipotent. He is soon taught that a prayer is slow to reverse what a bullet can do in an instant. Thus, a man trained in a religious environment for eighteen years of his life can, by this instrument of the government, be broken down, be purged of his fantasies and delusions in a matter of mere months. Once that conviction is instilled, all else becomes easy to instil.

Even more interesting is the process by which a young man's parents, who purportedly love him, can be induced to send him off to war to his death. Although the scope of this work will not allow this matter to be expanded in full detail, nevertheless, a coarse overview will be possible and can serve to reveal those factors which must be included in some numerical form in a computer analysis of social and war systems. We begin with a tentative definition of the draft. The draft (selective service, etc.) is an institution of compulsory collective sacrifice and slavery, devised by the middle-aged and elderly for the purpose of pressing the young into doing the public dirty work. It further serves to make the youth as guilty as the elders, thus making criticism of the elders by the youth less likely (Generational Stabilizer). It is marketed and sold to the public under the label of "patriotic = national" service.

Once a candid economic definition of the draft is achieved, that definition is used to outline the boundaries of a structure called a Human Value System, which in turn is translated into the terms of game theory. The value of such a slave labourer is given in a Table of Human Values, a table broken down into categories by intellect, experience, post-service job demand, etc. Some of these categories are ordinary and can be tentatively evaluated in terms of the value of certain jobs for which a known fee exists. Some jobs are harder to value because they are unique to the demands of social subversion, for an extreme example: the value of a mother's instruction to her daughter, causing that daughter to put certain behavioural demands upon a future husband ten or fifteen years hence; thus, by suppressing his resistance to a perversion of a government, making it easier for a banking cartel to buy the State of New York in, say, twenty years.

Such a problem leans heavily upon the observations and data of wartime espionage and many types of psychological testing. But crude mathematical models (algorithms, etc.) can be devised, if not to predict, at least to predetermine these events with maximum certainty. What does not exist by natural cooperation is thus enhanced by calculated compulsion. Human beings are machines, levers which may be grasped and turned, and there is little real difference between automating a society and automating a shoe factory. These derived values are variable. (It is necessary to use a current Table of Human Values for computer analysis). These values are given in true measure rather than U.S. dollars, since the latter is unstable, being presently inflated beyond the production of national goods and services so as to give the economy a false kinetic energy ("paper" inductance). The silver value is stable, it being possible to buy the same amount with a gram of silver today as it could be bought in 1920. Human value measured in silver units changes slightly due to changes in production technology.

Factor 1 - Enforcement

As in every social system approach, stability is achieved only by understanding and accounting for human nature (action/reaction patterns). A failure to do so can be, and usually is, disastrous. As in other human social schemes, one form or another of intimidation (or incentive) is essential to the success of the draft. Physical principles of action and reaction must be applied to both internal and external subsystems. To secure the draft, individual brainwashing/programming and both the family unit and the peer group must be engaged and brought under control.

Factor 2 - Father

The man of the household must be housebroken to ensure that junior will grow up with the right social training and attitudes. The advertising media, etc., are engaged to see to it that father-to-be is pussy-whipped before or by the time he is married. He is taught that he either conforms to the social notch cut out for him or his sex life will be hobbled and his tender companionship will be zero. He is made to see that women demand security more than logical, principled, or honourable behaviour. By the time his son must go to war, father (with jelly for a backbone) will slam a gun into junior's hand before father will risk the censure of his peers, or make a hypocrite of himself by crossing the investment he has in his own personal opinion or self-esteem. Junior will go to war or father will be embarrassed. So junior will go to war, the true purpose not withstanding.

Factor 3 - Mother

The female element of human society is ruled by emotion first and logic second. In the battle between logic and imagination, imagination always wins, fantasy prevails, maternal instinct dominates so that the child comes first and the future comes second. A woman with a newborn baby is too starry-eyed to see her child as a wealthy

man's cannon fodder or a cheap source of slave labour. A woman must, however, be conditioned to accept the transition to "reality" when it comes, or even sooner. As the transition becomes more difficult to manage, the family unit must be carefully disintegrated, and state-controlled public education and state-operated child-care centres must be become more common and legally enforced so as to begin the detachment of the child from the mother and father at an earlier age. Inoculation of behavioural drugs [Ritalin] can speed the transition for the child (mandatory). Caution: A woman's impulsive anger can override her fear. An irate woman's power must never be underestimated, and her power over a pussy-whipped husband must likewise never be underestimated. It got women the vote in 1920.

Factor 4 - Junior
The emotional pressure for self-preservation during the time of war and the self-serving attitude of the common herd that have an option to avoid the battlefield - if junior can be persuaded to go - is all of the pressure finally necessary to propel Johnny off to war. Their quiet blackmailings of him are the threats: "No sacrifice, no friends; no glory, no girlfriends".

Factor 5 - Sister
And what about junior's sister? She is given all the good things of life by her father, and taught to expect the same from her future husband regardless of the price.

Factor 6 - Cattle
Those who will not use their brains are no better off than those who have no brains, and so this mindless school of jelly-fish, father, mother, son, and daughter, become useful beasts of burden or trainers of the same.

Please note that the section of text above, shown in blue, is not an expression of my own personal opinion, but comes from an anonymous document. However, sections of it describe clearly what is without question being applied to the people in many nations of the world today, so it is difficult to discount any of what is said. At the present time, economic warfare is most definitely being waged against normal, innocent people in most countries of the world, and there is every appearance that a major offensive against us is in progress, instigated and orchestrated by the few "Elite" New World Order people who have already caused so much unnecessary death and suffering.

So who are the New World Order people whose aims are to disadvantage and destroy ordinary people through their "Quiet War"? Well, there are several major branches of them, each presenting a benign and caring face to the world and most with large numbers of sincere adherents who have not the slightest idea of the aims and policies of the few people at the top who actually direct and control those organisations. While most operations are carried out in complete secrecy, the most visible people in the ruling bodies form the Bilderberg Group. This comprises 13 Freemasons, 13 Vatican representatives, and 13 Black Mobility people. These 39 people of the Bilderberg Group have offices in Switzerland (the only European country which was never invaded or bombed during World War One or World War Two) answer to the 13 people who form the Policy Group, which in turn answers to the 9 people of the Round Table. The individuals concerned are typically, powerful financiers, industrialists, statesmen and intellectuals.

The power and influence of these people should not be underestimated. They have infiltrated and subverted the US Congress and Senate, rendering ineffective the checks and balances intended when the Constitution was originally set up. At 3:30 am on Saturday 4th August 1990, a minority of US Senators, maybe ten at most, passed the Senate Intelligence Authorisation Act for Fiscal Year 1991 (S.B. 2834). This bill is not widely known. It was brought to a vote by Senator Sam Nunn in the dead of night when the opposition was gone. It effectively transfers most authority of the United States Government directly into the hands of the President. It gives him the power to initiate war, appropriate public funds, define foreign policy goals, and decide what is important to US national security. It gives the President the power to initiate covert actions (a power never before given to any President) and prevents Congress from stopping the President's initiation of covert actions. It allows the President to use any federal "departments, agencies or entities" to operate or finance a covert operation. It empowers the President to use any other nation or private contractor or person to fund or operate a covert action. It redefines covert actions as operations "necessary to support foreign policy objectives of the United States" which is a definition which is so broad and vague as to be essentially unlimited. It, for the first time ever, officially claims the right of the United States to interfere secretly in the internal "political, economic or military affairs" of other countries in direct and flagrant violation of international law. It requires the President to prepare and deliver a written finding to the Intelligence committees of Congress, but it allows the President to omit "extremely sensitive matters" and authorises the President to claim Executive Privilege if Congress asks too many questions.

Further, there are no penalties in the Bill for violating any of its provisions, including the provision for requiring a finding. That Bill effectively handed all the powers of government to the President, effectively making him the sole ruler of the USA without accountability to anyone.

I suggest that the New World Order people have sufficient influence to ensure that every candidate for President of the USA is a member of the New World Order. That way, they are assured that they have full control of the whole of the USA at all times no matter what the outcome of the "democratic" voting. It is said that Henry Ford stated that customers could have a new Model T car in any colour they wanted, provided that the colour was black. Well, the equivalent is now in place, where the American people can have any President they want, provided that the President is a New World Order man. This information is not even considered secret any more. For example:

"... Some even believe we (the Rockefellers) are part of a secret cabal working against the best interests of the United States, characterising my family and me as 'internationalists' and of conspiring with others around the world to build a more integrated global political and economic structure - one world, if you will. If that's the charge, I stand guilty, and I am proud of it. "

—David Rockefeller, Memoirs (2002, Random House publishers), page 405

It should not be imagined that the events in the USA have no effect elsewhere. The New World Order people are working on expanding the EU, blurring the identities of individual countries through legislation, reducing the effects of borders and generally moving towards a single entity with one central government. They are actually aimed at producing ten unified areas of the world which they then intend to amalgamate into a single world state governed by them. This is judged to be easier if there are fewer people, so one of their major aims is to reduce the number of people living at the present time. They also need the remaining people to be wholly dependent on them for the essentials of life, which is one reason why they oppose the introduction of any free-energy device, since having an independent source of power would put people outside their direct control and so will not be allowed.

Patent US 6,867,514 B2 **15th March 2005** **Inventor: Frank J. Fecera**

PERMANENT MAGNET MOTOR

This patent application shows the details of a permanent magnet motor. It should be noted that while in this text, Frank states that permanent magnets store a finite amount of magnetism, in actual fact, the magnet poles form a dipole which causes a continuous flow of energy drawn from the quantum foam of our universe, and that flow continues until such time as the dipole is destroyed. The energy which powers any permanent magnet motor comes directly from the zero-point energy field and not actually from the magnet itself. A piece of iron can be converted into a magnet by a single nanosecond magnetic pulse. It makes no sense that a pulse of that duration could provide months of continuous power from anything stored in the magnet itself, but it makes perfect sense if that brief pulse created a magnetic dipole which acts as a gateway for the inflow of zero-point energy from the environment.

ABSTRACT

A motor providing unidirectional rotational motive power is provided. The motor has a generally circular stator with a stator axis, an outer surface, and a circumferential line of demarcation at about a midpoint of the outer surface. The motor also includes one or more stator magnets attached to the outer surface of the stator. The stator magnets are arranged in a generally circular arrangement about the stator axis and generate a first magnetic field. An armature is attached to the stator so that it rotates with it, the armature having an axis parallel to the stator axis. One or more rotors, are spaced from the armature and coupled to it by an axle to allow each rotor to rotate around an axis, each rotor rotating in a plane generally aligned with the axis of the armature. Each rotor includes one or more rotor magnets, with each rotor magnet generating a second magnetic field. The second magnetic field generated by each rotor magnet interacts with the first magnetic field, to cause each rotor to rotate about the rotor axis. A linkage assembly drive connects each rotor to the stator to cause the armature to rotate about the armature axis thereby providing the unidirectional rotational motive power of the motor.

BACKGROUND OF THE INVENTION

This invention relates to dynamo electric motor structures and more particularly to rotary and linear permanent magnet motors. Conventional electric motors rely on the interaction of magnetic fields to produce a force which results in either rotary or linear motion. The magnetic fields in conventional electric motors providing rotary power, are generated by passing an externally provided electric current through conductors in either a stator (i.e. stationary portion of the motor), a rotor (i.e. rotary portion) or both the stator and the rotor. The rotary power of the motor arises from a rotating magnetic field which is created by commutating the electric current, either by a switching the current through different conductors, as in a direct current motor or by a polarity reversal of the electric current as in an alternating current motor.

It is well known that a class of materials known as ferromagnetic materials are also capable of generating a magnetic field having once been energised. Ferromagnetic materials with high coercivity are known as permanent magnets. Permanent magnets are capable of storing a finite amount of energy and retaining the ability to generate a substantial magnetic field until the stored energy is depleted.

There are electric motors which use permanent magnets in either the stator portion of the motor or the rotor portion of the motor. These motors achieve a small size for the amount of power delivered by the motor because the motors avoid having current carrying conductors to produce the magnetic field which is otherwise produced by the permanent magnets. However, these conventional permanent magnet motors still require a source of external power to produce a rotating magnetic field.

There have also been developed permanent magnet motors which use permanent magnets for both the stator and the rotor. For example, U.S. Pat. No. 4,598,221 discloses a permanent magnet motor which relies on an external source of power to rotate the magnetic fields of a rotor by ninety degrees with respect to the interacting stator magnetic fields to eliminate the counterproductive magnetic repulsion and attraction between the rotor and the stator magnets. In another example, U.S. Pat. No. 4,882,509 discloses a permanent magnet motor which relies on an external source of power to position a shield which does not permit coupling between the rotor and the stator magnets at times when attraction or repulsion would drag down the strength of the motor.

There are many instances where a motor action is required and no source of external power is available. Accordingly, a motor which relies solely on the energy stored in permanent magnets would be useful.

BRIEF SUMMARY OF THE INVENTION

Briefly stated, the present invention comprises a rotor for use in a permanent magnet motor and for providing motive power by rotation of the rotor about a rotor axis. The rotor comprises at least one first U-shaped magnet having a rear side and generating a first magnetic field. The rotation of the rotor about the rotor axis is caused by an interaction of a portion of the first magnetic field directly adjacent to the rear of the at least one U-shaped magnet with a stationary second magnetic field.

Another aspect of the present invention comprises a rotor providing motive power by a rotation of the rotor about the rotor axis and by a translation of the rotor in a direction of the rotor axis. The rotor comprises: a first U-shaped magnet having a north pole, a south pole and a rear side, the first U-shaped magnet generating a first magnetic field; a second U-shaped magnet having a north pole and a south pole, the south pole of the second U-shaped magnet abutting the north pole of the first U-shaped magnet; and a third U-shaped magnet having a north pole and a south pole, the north pole of the third U-shaped magnet abutting the south pole of the first U-shaped magnet. A portion of the first magnetic field generated by the first U-shaped magnet directly adjacent to the rear of the first U-shaped magnet interacts with a stationary fourth magnetic field to cause the rotor to rotate. A second magnetic field generated by the north pole of the second U-shaped magnet and a third magnetic field generated by the south pole of the third U-shaped magnet interact with the fourth magnetic field to cause the rotor to translate in the direction of the rotor axis.

A further aspect of the present invention comprises a rotor including a rotor axis, and a thruster axis in a plane of the rotor and intersecting the rotor axis. The rotor provides motive power by a rotation of the rotor about the rotor axis and by a translation of the rotor in a direction of the rotor axis. The rotor comprises: a first U-shaped magnet having a north pole and a south pole and a rear side, the north pole and the south pole being generally aligned with the thruster axis, the first U-shaped magnet generating a first magnetic field; a first thruster magnet having a direction of magnetisation generally aligned with the thruster magnet axis, the first thruster magnet being proximate to and spaced from the north pole of the first U-shaped magnet; and a second thruster magnet having a direction of magnetisation generally aligned with the thruster magnet axis, the second thruster magnet being near to and spaced from the south pole of the first U-shaped magnet, the first U-shaped magnet being interposed between the first and the second thruster magnets. A portion of the first magnetic field generated by the first U-shaped magnet directly adjacent to the rear side of the first U-shaped magnet interacts with a stationary fourth magnetic field to cause the rotor to rotate, a second magnetic field generated by the first thruster magnet and a third magnetic field generated by the second thruster magnet respectively interact with a stationary fifth magnetic field to cause the rotor to translate in the direction of the rotor axis.

Another aspect of the present invention comprises a rotor providing motive power by rotation of the rotor about a rotor axis and translation of the rotor in the direction of the rotor axis. The rotor has at least one rotor magnet generating a first magnetic field, the first magnetic field being generated by the rotor magnet interacting with at least one stationary U-shaped magnet, the U-shaped magnet having a rear side and generating a second magnetic field. The rotational and translational motive power of the rotor is provided by an interaction of a portion of the second magnetic field directly adjacent to the rear of the U-shaped magnet with the first magnetic field.

A further aspect of the present invention comprises a motor providing unidirectional rotational motive power. The motor includes a generally circular stator having a stator axis, an outer surface, and a circumferential line of demarcation at about a midpoint of the outer surface; at least one stator magnet attached to the outer surface of the stator, the at least one stator magnet being arranged in a generally circular arrangement about the stator axis and generating a first magnetic field; an armature attached to the stator for rotation with it; the armature having an axis parallel to the stator axis; at least one rotor, the rotor being spaced from the armature and coupled to it by an axle to allow rotation about an axis of the rotor, the rotor rotating in a plane generally aligned with the armature axis, the rotor, including at least one magnet generating a second magnetic field, where the second magnetic field generated by the rotor magnet interacts with the first magnetic field to cause the rotor to rotate about it's axis; and a drive linkage assembly connecting the rotor to the stator to cause the armature to rotate about it's axis as the rotor rotates about it's axis, thereby providing the unidirectional rotational motive power of the motor.

In another aspect, the present invention is directed to a motor providing unidirectional rotational motive power comprising: a generally circular stator having an axis, an outer surface, and a circumferential line of demarcation around the outer surface, the line of demarcation having a pre-determined direction around the stator axis and separating a first side of the outer surface and a second side of the outer surface, wherein at least one pair of stator magnets is attached to the outer surface generating a first magnetic field, the pair of magnets comprising a first stator magnet having a north pole and a south pole and a second stator magnet having a north pole and a south pole, the south pole of the first stator magnet being located on the first side of the outer surface and the north pole of the first stator magnet being closest to the line of demarcation, the north pole of the second stator magnet being located on the second side of the outer surface and the south pole of the second stator magnet being closest to the line of demarcation, wherein the at least one pair of stator magnets is spaced along the line of demarcation so that a first inter-magnet distance measured along the line of demarcation between the north pole of the first stator magnet and the south pole of the second stator magnet of an adjacent pair of the at least one pair of stator magnets is generally equal to a second inter-magnet distance measured along the line of

demarcation between the south pole of the first stator magnet and the north pole of the second stator magnet; an armature attached to the stator, the armature having an axis parallel to the stator axis and attached to the stator for rotation therewith; and at least one rotor attached to the armature, the at least one rotor being spaced from the armature and coupled to it by an axle for rotation about an axis of the rotor, the rotor rotating in a plane generally aligned with the armature axis, the rotor comprising at least one rotor magnet, the rotor magnet generating a second magnetic field which interacts with the first magnetic field to cause the rotor to rotationally oscillate about the axis of the rotor and to generate a force in a direction of the rotor axis, thereby causing the armature to rotate in the pre-determined direction around the armature axis to provide the unidirectional rotational motive power of the motor.

In a further aspect, the present invention is directed to a motor providing unidirectional linear motive power comprising: a linear stator having a generally curved cross-section and a longitudinal line of demarcation perpendicular to the cross-section extending on about a midpoint of a surface of the stator between a first end and a second end of the stator, the stator including at least one magnet arranged between the first end and the second end, the magnet having a direction of magnetisation at about a right angle to the line of demarcation and generating a first magnetic field, the magnitude of the first magnetic field being generally uniform along the line of demarcation except in a pre-determined number of null regions, wherein the first magnetic field is substantially zero a rail connected to the stator, the rail having a longitudinal axis generally parallel to the line of demarcation and a helical groove with a pre-determined pitch running around a periphery of the rail; at least one rotor having a rotor axis aligned with the axis of the rail, the rotor being connected to the rail so that the rotor is free to rotate about the axis of the rail and slide along the rail, the rotor including at least one U-shaped magnet having a rear side and generating a second magnetic field, where a portion of the second magnetic field directly adjacent to the rear of the U-shaped magnet interacts with the first magnetic field to cause the rotor to rotate about the axis of the rail; a bearing assembly connecting the rotor to the helical groove, the bearing assembly converting the rotary motion of the rotor about the axis of the rail to linear motion along the rail; and a cross-link connecting the bearing assembly of a first rotor to a second rotor, thereby adding together the linear motion along the rail of the first rotor and the second rotor to provide the unidirectional linear motive power.

In yet another aspect, the present invention is directed to a motor providing unidirectional motive power comprising: a rail having a longitudinal axis and at least one helical groove having a pre-determined pitch running around a periphery of the rail; at least one first helical stator concentrically surrounding the rail, the first helical stator having the pre-determined pitch of the groove and a longitudinal axis generally parallel to the axis of the rail, at least one first stator magnet being attached to the first helical stator, the first stator magnet generating a first magnetic field; at least one rotor having an axis generally aligned with the axis of the rail, the rotor being connected to the rail so that the rotor is free to rotate about the axis of the rail and slide along the rail, the rotor comprising at least one rotor magnet generating a second magnetic field, the second magnetic field interacting with the first magnetic field generated by the first stator magnet to cause the rotor to rotate about the axis of the rail; and a bearing assembly connecting the rotor to the helical groove around the periphery of the rail, the bearing assembly converting the rotational motion of the rotor about the rail to unidirectional linear motion along the rail.

A further aspect of the present invention is directed to a motor providing unidirectional motive force comprising: a rail having a longitudinal axis and a helical groove running around the rail, the groove having a predetermined pitch; at least one first helical stator comprising a plurality of discontinuous spaced apart first ribs, each first rib partially surrounding the rail at a generally uniform distance from the rail, the first helical stator having the pre-determined pitch of the groove and a longitudinal axis generally aligned with the rail, at least one first stator magnet being attached to each rib, each first stator magnet generating a first magnetic field; at least one rotor having an axis generally aligned with the axis of the rail, the rotor being connected to the rail so that the rotor is free to rotate about the axis of the rail and to slide along the rail, the rotor comprising at least one rotor magnet generating a second magnetic field, the second magnetic field interacting with the first magnetic field generated by the first stator magnet to cause the rotor to rotate about the axis of the rail; and a bearing assembly connecting the rotor to the helical groove around the rail, the bearing assembly converting the rotary motion of the rotor about the rail to linear motion along the rail.

The present invention is further directed to a motor providing unidirectional motive power comprising: a rail having a longitudinal axis and a generally sinusoidal groove running around a periphery of the rail, the sinusoidal groove having a pre-determined period; at least one stator having a generally curved cross-section and a longitudinal line of demarcation perpendicular to the cross-section located at about a midpoint of a surface of the stator, the surface of the stator being disposed generally equidistant from and parallel to the axis of the rail; at least one stator magnet attached to the surface of the stator generating a first magnetic field, the stator magnet having a magnetisation which is displaced sinusoidally from the line of demarcation, the sinusoid having a pre-determined period and a pre-determined maximum amplitude and being divided into a plurality of alternating first and second sectors, with a boundary between the alternating first and second sectors occurring at the maximum amplitude of the sinusoid, the direction of magnetisation of the stator magnet being opposite in direction in the first and second segments; at least one rotor having an axis aligned with the axis of the rail, the rotor being connected to the rail so that the rotor is free to rotate about the axis of the rail and slide along the rail, the rotor including at least one U-

shaped magnet having a rear side and generating a second magnetic field, the U-shaped magnet being positioned on the rotor so that the rear side of the U-shaped magnet is apposite to the first and the second segments of the stator as the rotor rotates about the rotor axis, wherein an interaction of a portion of the second magnetic field directly adjacent to the rear of the U-shaped magnet with the first magnetic field causes the rotor to rotationally oscillate about the axis of the rail; and a bearing assembly connecting the rotor to the sinusoidal groove around the rail, the bearing assembly converting the oscillatory motion of the rotor about the rail to unidirectional linear motion along the rail.

The present invention is also directed to a motor providing unidirectional motive power comprising: a rail having a longitudinal axis and a helical groove running around a periphery of the rail, the helical groove having a pre-determined pitch; at least one stator having a generally having a longitudinal line of demarcation located at about a midpoint of a surface of the stator, the surface of the stator being disposed generally equidistant from and parallel to the axis of the rail; at least one stator magnet attached to the surface of the stator, the stator magnet having a direction of magnetisation which rotates about a magnetic axis parallel to the line of demarcation with a predetermined pitch, thereby generating a first magnetic field having a substantially uniform magnitude along the magnetic axis and rotates around the magnetic axis with the pre-determined pitch of the stator magnet rotation; at least one rotor having an axis aligned with the axis of the rail, the rotor being connected to the rail so that the rotor is free to rotate about the axis of the rail and slide along the rail, the rotor including at least one U-shaped magnet generating a second magnetic field, the U-shaped magnet being positioned on the rotor so that a portion of the second magnetic field directly adjacent to the rear side of the U-shaped magnet interacts with the first magnetic field of the stator magnet to cause the rotor to rotate about it's axis; and a bearing assembly connecting the rotor to the helical groove, the bearing assembly converting the rotary motion of the rotor about the rail to unidirectional linear motion along the rail.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWINGS

The foregoing summary, as well as the following detailed description of preferred embodiments of the invention, will be better understood when read in conjunction with the appended drawings. For the purpose of illustrating the invention, there are shown in the drawings embodiments which are presently preferred. It should be understood, however, that the invention is not limited to the precise arrangements and instrumentalities shown. In the drawings:

DETAILED DESCRIPTION OF THE INVENTION

It will be appreciated by those skilled in the art that changes could be made to the embodiments described above without departing from the broad inventive concept thereof. It is understood, therefore, that this invention is not limited to the particular embodiments disclosed, but it is intended to cover modifications within the spirit and scope of the present invention as defined by the appended claims. It should also be understood that the articles "a" and "the" used in the claims to define an element may refer to a single element or to a plurality of elements without a limit as to the number of elements.

Past attempts to construct a working permanent magnet motor have met with difficulties because of the simultaneous attractive and repulsive characteristics of a permanent magnet. A principle has been discovered where, by engaging a magnetic field at the rear of one or more U-shaped magnets mounted on a rotor with a second stationary magnetic field, a torque is created that rotates the rotor about a rotational axis of the rotor. Further, by properly shaping the second magnetic field, the rotor may be caused to also translate in the direction of the rotor axis.

Accordingly, using the aforementioned principle, and referring to **Fig.7A**, one aspect of the present invention is directed to a rotor **12** for use in a motor and which provides motive power by a rotation of the rotor **12** about a rotor axis **16** and by a translation of the rotor **12** in a direction of the rotor axis **16**. In one aspect, the rotor **12** comprises a first U-shaped magnet **20** in which the U-shaped magnet **20** generates a first magnetic field. A rotation of the rotor **12** about the rotor axis **16** is caused by an interaction of a portion of the first magnetic field directly adjacent to a rear **26** of the U-shaped magnet **20** with a stationary second magnetic field. A translation of the rotor **12** in the direction of the rotor axis **16** is caused by an interaction of the first magnetic field adjacent to a north pole **23** and a south pole **25** of the U-shaped magnet **20** with the stationary second magnetic field. As will be appreciated by those skilled in the art, the design of the rotor **12** is not limited to a single U-shaped magnet **12**. A plurality of U-shaped magnets **20**, arranged around a periphery of the rotor **12** is within the spirit and scope of the invention.

Another aspect of the present invention, shown in **Fig.7B** comprises a rotor **12** including a first U-shaped magnet having a north pole and a south pole generating a first magnetic field; a second U-shaped magnet **24** having a north pole and a south pole with the south pole of the second U-shaped magnet **24** abutting the north pole of the first U-shaped magnet **20**; and a third U-shaped magnet **22** having a north pole and a south pole with the north pole of the third U-shaped magnet **22** abutting the south pole of the first U-shaped magnet **20**. A portion of the first magnetic field generated by the first U-shaped magnet **20** directly adjacent to the rear **26** of the first U-shaped magnet **20** interacts with a stationary fourth magnetic field to cause the rotor **12** to rotate. A second magnetic field generated by the north pole of the second U-shaped magnet **24** and a third magnetic field generated by the south pole of the third U-shaped magnet **22** respectively interact with the fourth magnetic field to cause the rotor **12** to translate in the direction of the rotor axis **16**.

A further aspect of the present invention, shown in **Fig.7C**, comprises a first U-shaped magnet **20** having a north pole and a south pole generating a first magnetic field. The north pole and the south pole of the U-shaped magnet **20** are generally aligned with a thruster axis **34** which lies in the plane of the rotor **12** and intersects the rotor axis **16**. A first thruster magnet **36** is located proximate to and spaced from the north pole of the first U-shaped magnet with a direction of magnetisation being generally aligned with the thruster magnet axis **34**. A second thruster magnet **38** is located proximate to and spaced from the south pole of the first U-shaped magnet **20** with a direction of magnetisation also being generally aligned with the thruster magnet axis **34**. A portion of the first magnetic field generated by the first U-shaped magnet **20** directly adjacent to the rear side **26** of the first U-shaped magnet **20** interacts with a stationary fourth magnetic field to cause the rotor **12** to rotate. A second magnetic field generated by both the north pole and the south pole of the first thruster magnet **36** and a third magnetic field generated by both the north pole and the south pole of the second thruster magnet **38** respectively interact with a fifth magnetic field to cause the rotor **12** to translate in the direction of the rotor axis **16**. In one

further aspect of the rotor **12**, as shown in **Fig.7D**, a bar magnet **43** may be substituted for the U-shaped magnet **20** and the fourth magnetic field is formed by one or more U-shaped magnets, where the bar magnet **43** interacts with a portion of the stationary fourth magnetic field adjacent to the rear of a U-shaped magnet.

As will be appreciated by those skilled in the art, the polarities of the magnets shown in **Figs. 7A, 7B, 7C** and **7D** may be reversed and still be within the spirit and scope of the invention.

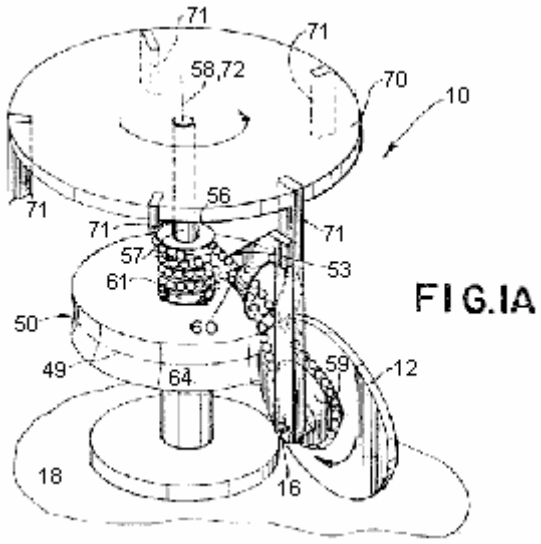

FIG.1A

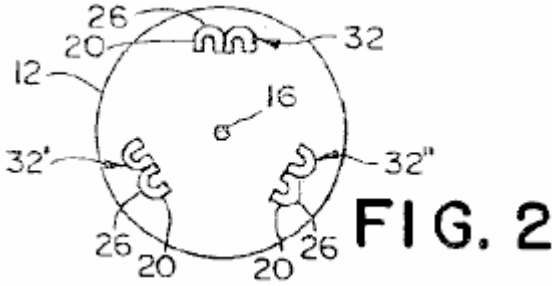

FIG. 2

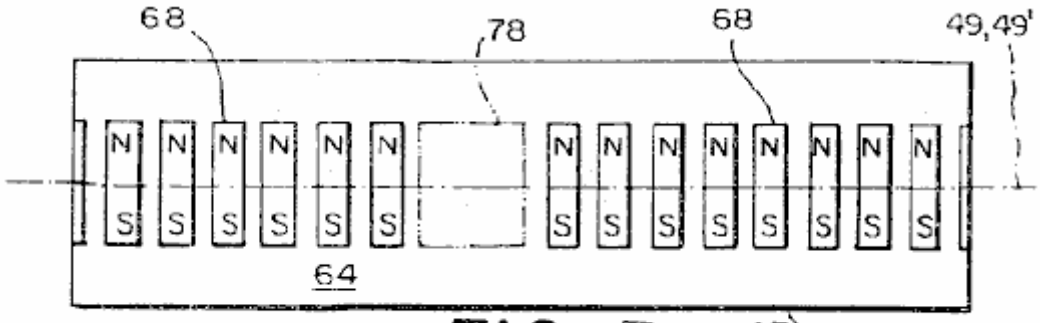

FIG. 3

Referring now to **Fig.1A**, **Fig.2** and **Fig.3** there is shown a first preferred embodiment of a motor **10** using the rotor **12** and providing unidirectional rotational motive power. The first preferred embodiment comprises a generally circular stator **50** having a stator axis **72** and a circumferential surface **64** mounted to a base **18**; an armature **70**, having an armature axis of rotation **58** coincident with the stator axis **72**, attached to the stator **50** by an armature axle **57** for rotation about the armature axis of rotation **58**; and five rotors **12** (only one of which is shown for clarity), the rotors **12** being spaced at intervals of about **72** degrees around the armature **70**. Each rotor **12** is spaced from the armature by an armature strut **71** and attached to the armature strut **71** by an axle, for rotation about an axis **16** of the rotor **12** in a plane generally aligned with the armature axis of rotation **58**. The motor **10** further includes a driving linkage assembly **53** connecting each rotor **12** and the stator **50** together, the linkage **53** urging the armature **70** to rotate about the armature axis of rotation **58** as each rotor **12** rotates about its respective rotor axis **16**. As will be appreciated by those skilled in the art the number of rotors **12** is not limited to the five rotors **12** disclosed in the first embodiment. Any number of rotors **12** from one to as many as there would be space for mounting on the armature **70** is within the spirit and scope of the invention.

Preferably, the surface **64** of the stator **50** is curved, having a curvature conforming to the arc of the rotors **12**. However, it will be appreciated by those skilled in the art that the surface **64** need not be curved but could be planar and still be within the spirit and scope of the invention. As will be appreciated by those skilled in the art the stator **50** is merely intended as a stationary supporting structure for stator magnets and, as such, the shape of the stator **50** is not intended to be controlling of the size and shape of the air gap between the magnets attached to the stator **50** and the magnets attached to the rotors **12**.

Preferably, the stator **50** is made of a material (or a combination of materials) having a magnetic susceptibility less than 10-3, i.e. a material displaying paramagnetic or diamagnetic properties. For example, the stator **50** could be

made of a non-magnetic metal such as aluminium or brass. Also, the rotor **12** could be made of a natural material such as wood, glass, a polymeric material or a combination of any of the aforementioned materials within the spirit and scope of the invention. Further, it should be understood that the aforementioned materials are preferred for the stators and all other parts of the motor **10** that could significantly disrupt the magnetic interaction between the stator and the rotor of all of the disclosed preferred embodiments of the motor **10**.

In the first preferred embodiment, the surface **64** of the stator **50** includes a circumferential line of demarcation **49** at about a midpoint of the surface **64** formed by an intersection with the surface **64** of a plane perpendicular to the armature axis of rotation **58**. As shown in **Fig.3**, the stator **50** includes a plurality of bar magnets **68** attached to the outer surface **64** along the line of demarcation **49**, except in a single null region **78** where the magnitude of the first magnetic field is substantially reduced. The bar magnets **68** have a direction of magnetisation at about a right angle to the line of demarcation **49** thereby creating a first magnetic field adjacent to the outer surface **64**, the magnitude and the direction of which is substantially uniform along the circumferential line of demarcation **49** around the axis **58** of the stator **50**, except within the null region **78**. As will be appreciated by those skilled in the art, the stator axis **72** need not be coincident with the armature axis of rotation **58**. Accordingly, a stator **50** arranged around the armature axis **58** at any location at which the stator axis **72** is parallel to the armature axis **58** and the surface **64** of the stator **50** faces the periphery of the rotors **12** thereby providing for the interaction between the first magnetic field and the second magnetic field around the armature axis **58**, is within the spirit and scope of the invention.

Preferably, as further shown in **Fig.3**, the bar magnets are attached to the surface **64** of the stator **50** so that the direction of magnetisation of the bar magnets **68** are about perpendicular to a radial line of the rotor **12**. However, the bar magnets **68** could also be attached to the surface **64** of the stator so that the direction of magnetisation of the bar magnets **68** is aligned with a radial line of the rotor **12**. The bar magnets **68** are preferably abutting so as to form the substantially uniform first magnetic field. However, it is not necessary for the bar magnets **68** to abut one another. Further, it is not necessary to use a plurality of bar magnets **68** to form the first magnetic field. A single magnet producing a uniform first magnetic field in the region in which the first magnetic field interacts with the second magnetic field of the rotors **12** would provide the required first magnetic field. Also, the number of null regions **78** may be more than one, depending upon the desired speed of the motor, as explained below.

Preferably, the stator magnets **68** are permanent magnets made of a neodymium-iron-boron material. However, as will be appreciated by those skilled in the art, any type of permanent magnet material displaying ferromagnetic properties could be used for the stator magnets **68**. For instance, stator magnets **68** made of samarium cobalt, barium ferrite or AlNiCo are within the spirit and scope of the invention. It should be understood that these permanent magnet materials or their equivalents are preferred for the stator magnets and the rotor magnets of all of the disclosed preferred embodiments of the motor **10**. Also, while the use of permanent magnets is preferred, the use of electro-magnets for some or all of the magnets is within the spirit and scope of the invention.

As discussed above, the stator **50** may include a pre-determined number of null regions **78** on the surface of the stator **64**. In the first preferred embodiment, the single null region **78** is formed by a shield of a ferromagnetic material, such as iron, placed adjacent to the surface **64**. However, as those skilled in the art will appreciate, the null region **78** can also be formed by an absence of the bar magnets **68** in the region coinciding with the null region **78**. The null region **78** of substantially reduced magnetic field magnitude may also be formed by an auxiliary magnetic field suitably generated by one or more permanent magnets or by one or more electromagnets powered by an electric current arranged so that the auxiliary magnetic field substantially cancels the first magnetic field in the null region **78**. In the case of the electromagnets, the electric current may be turned off in synchronism with the rotation of the rotors **12** passing through the null region **78**, in order to conserve power. Preferably, the first magnetic field is reduced to ten percent or less of the magnetic force outside of the null region. However, the motor **10** will operate with a reduction of only fifty percent. Accordingly, a motor **10** having a substantial reduction of the first magnetic field of fifty percent or less is within the spirit and scope of the invention.

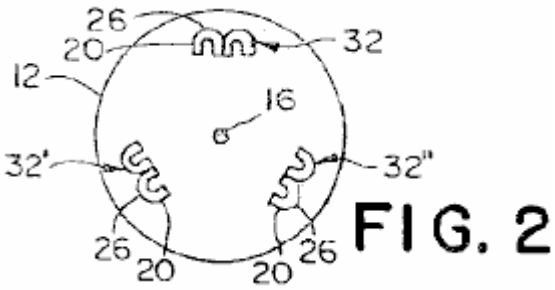

FIG. 2

As shown in **Fig.2**, the rotor **12** of the first preferred embodiment includes three pairs **32**, **32'**, **32''** of abutted U-shaped magnets **20** spaced apart at about 120 degree intervals around the periphery of the rotor **12**. Preferably,

the U-shaped magnets **20** having substantially identical magnetic properties and are arranged to have opposite poles of the abutting each other. The pairs **32**, **32'**, **32''** of abutted U-shaped magnets **20** are positioned so that the north pole and the south poles of each U-shaped magnet **20** face toward the axis of the rotor **16**, and the rear side **26** of each U-shaped magnet **20**, opposite to the north and the south pole of the U-shaped magnet **20**, faces out from the axis of the rotor **16** toward the surface **64** of the stator **50**. The pairs **32**, **32'**, **32''** of the U-shaped magnets **20** are situated on the rotor **12** so that a portion of the second magnetic field directly adjacent to the rear **26** of each U-shaped magnet **20** interacts with a first stationary magnetic field to cause the rotor **12** to rotate about its respective rotor axis **16**. Those skilled in the art will appreciate that it is not necessary to have exactly three pairs **32**, **32'**, **32''** of U-shaped magnets **20** on the rotor **12**. For instance, the number of U-shaped magnets **20** (or groups of abutted U-shaped magnets) spaced apart around the periphery of the rotor **12** may range from merely a single U-shaped magnet **20**, up to a number of magnets limited only by the physical space around the periphery of the rotor **12**. Further, the number of abutted U-shaped magnets **20** within each group of magnets **32** is not limited to two magnets but may also range from 1 up to a number of magnets limited only by the physical space around the periphery of the rotor **12**.

Preferably, the rotor **12** is made of a material (or a combination of materials) having a magnetic susceptibility less than 10-3. Accordingly, the rotor could be made of any of the same materials used to make the stator, such as for instance, a non-magnetic metal, wood, glass, a polymeric or a combination of any of the above as shown in **Fig.1A**, the rotor **12** is preferably disk shaped with the rear **26** of the U-shaped rotor magnets **20** being arranged on the periphery of the rotor **12** in such a way that the U-shaped magnets **20** pass in close proximity to the circumferential line of demarcation **49** on the outer surface **64** of the stator **50** as the rotor **12** rotates. However, as will be clear to those skilled in the art, the structure of the rotor **12** need not be disk shaped. The rotor **12** could be a structure of any shape capable of rotating around the rotor axis **16** and capable of supporting the U-shaped magnets **20** so that, as the rotor **12** rotates, the U-shaped magnets **20** come into close proximity with the outer surface **64** of the stator **50**. For example, a rotor **12** comprised of struts connected to a central bearing, where each strut holds one or more U-shaped magnets **20**, is within the spirit and scope of the invention.

In the first preferred embodiment, the linkage **53** connecting each rotor **12** and the stator **50** comprises a beaded chain drive **60** which meshes with a stator sprocket **61** on the stator **50**, and an eccentric rotor sprocket **59** on each rotor **12** so that, as each rotor **12** rotates about its respective rotor axis **16**, the armature **70** is forced to rotate about the armature axis of rotation **58**. The eccentric rotor sprocket **59** causes the instantaneous angular velocity of the rotor **12** about the rotor axis **16** to increase above the average angular velocity of the rotor **12** as each pair **32**, **32'**, **32''** of U-shaped magnets **20** passes through the null region **78**. As will be appreciated by those skilled in the art, the rotor sprocket **59** could be circular and the stator sprocket **61** eccentric and still cause the angular velocity of the rotor **12** to increase. Further, the beaded chain **60** in combination with the stator sprocket **61** and the eccentric rotor sprocket **59** are not the only means for connecting each rotor **12** to the stator **50**. For instance, the beaded chain **60** could also be a belt. Further, the linkage **53** could comprise a drive shaft between each rotor **12** and the stator **50**, the drive shaft having a bevel gear set at each end of the shaft mating with a bevel gear on the rotor **12** and the stator **50**. An automatic gear shift mechanism would shift gears as each U-shaped magnet pair **32**, **32'**, **32''** entered the null regions **78** to increase the instantaneous angular velocity of the rotor **12** as the pair **32**, **32'**, **32''** of rotor magnets **20** passed through the null region **78**. Alternatively the linkage **53** could comprise a transmission system employing elliptical gears.

While it is preferred that the instantaneous angular velocity of the rotor **12** to increase above the average angular velocity of the rotor **12** as each pair of U-shaped magnets **20** passes through the null region **78**, it is not necessary to provide the increased angular velocity of the rotor **12** to provide motive power from the motor **10**.

Preferably, the diameters of the rotor sprocket **59** and stator sprocket **61** are selected so that the rear **26** of each U-shaped magnet **20** passes through one and only one null region **78** for each full revolution of the rotor **12** about the respective rotor axis **16** as the armature **70** rotates about the armature axis of rotation **58**. Accordingly, the revolution rate of the armature **70** is related to the revolution rate of the rotor **12** by the expression:

Sa = (Nr / Ns) x Sr ..... (1)

Where:
Sa is the angular velocity of the armature **70** (RPM);
Nr is the number of the U-shaped magnets **20** (or groups of abutted U-shaped magnets **32**) on a rotor **12**;
Ns is the number of null regions **12** on the stator **50**; and
Sr is the angular velocity of the rotor **12** (RPM).

The timing of the rotation of the rotor **12** around its respective rotor axis **16**, and the armature **70** about the armature axis of rotation **58** is such that each U-shaped magnet **20** (or U-shaped magnet pair **32**, **32'**, **32''**) on each rotor **12** enters into a null region **78** at a point where the magnetic interaction between the first magnetic field

and the second magnetic field is substantially reduced, thus providing a commutation of the second magnetic field. As each rotor **12** continues to rotate about the rotor axis **16** and the armature **70** rotates about the armature axis of rotation **58**, the U-shaped magnet **20** traces a slanted path through the null region **78**. As the U-shaped magnet emerges from the null region **78**, the U-shaped magnet **20** encounters the strong first magnetic field, which urges the U-shaped magnet **20** to continue the rotation of the rotor **12** about the rotor axis **16**.

As previously discussed, the first preferred embodiment of the motor **10** comprises a single null region **78** and five rotors **12**, each rotor **12** having three pairs **32**, **32'**, **32"** of abutted U-shaped magnets **20**. Preferably, the rotors **12** are uniformly spaced around the armature axis of rotation **58** and the pairs **32**, **32'**, **32"** of U-shaped magnets **20** are uniformly spaced around the periphery of each respective rotor **12**. Further, the pairs **32**, **32'**, **32"** of U-shaped magnets **20** on each rotor **12** are phased with respect to each other by one-fifth of a revolution of the rotor **12** (i.e. the reciprocal of the number of rotors) so that the pairs **32**, **32'**, **32"** of U-shaped magnets **20** of all the rotors **12** enter the null region at substantially uniform intervals to provide a more or less continuous magnetic interaction between the first magnetic field of the stator **50** and the second magnetic field of the rotors **12**. As will be appreciated by those skilled in the art, the motive power provided by the motor is proportional to the number of rotors **12** and the number of magnets **20** on each rotor **12** as well as the strength of the rotor **12** magnets **20** and the stator **50** magnets **68**. Accordingly, the number of rotors **12** and the number of pairs **32**, **32'**, **32"** of U-shaped magnets **20** are not limited to five rotors **12** and three pairs of U-shaped magnets **32**. Similarly, the number of null regions **78** is not limited to one. The number of U-shaped magnets **20** and the number of null regions **78** are limited only by adherence to the rule established by **Equation (1)**.

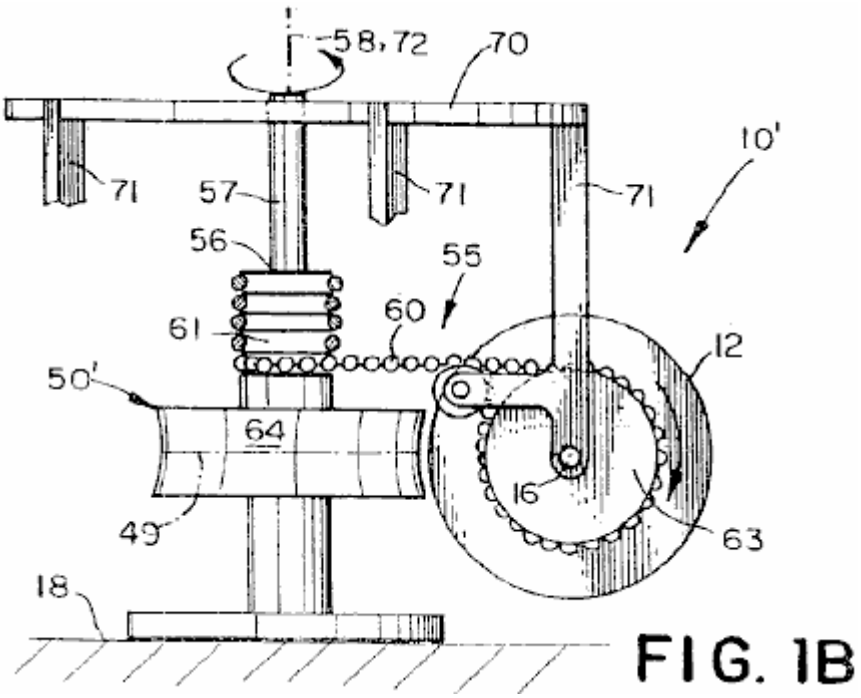

FIG. 1B

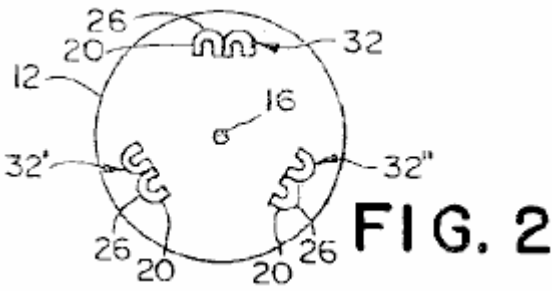

FIG. 2

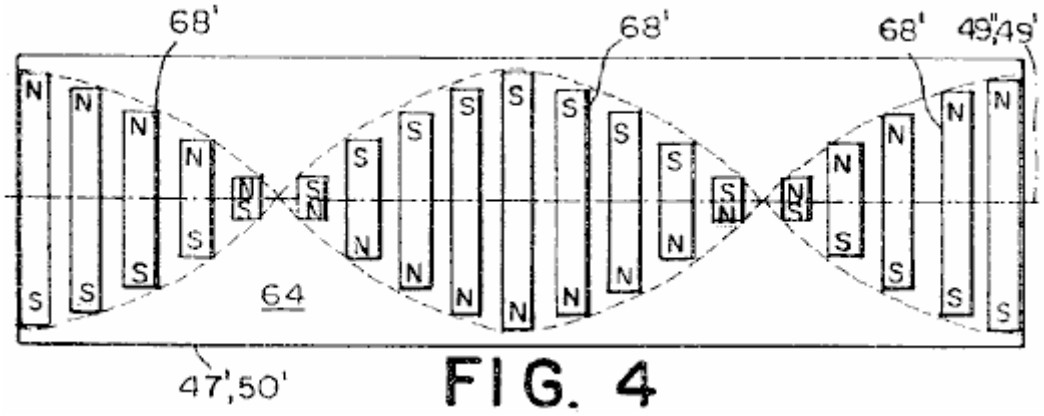

FIG. 4

Referring now to **Fig.1B**, **Fig.2 and** Fig.4 there is shown a second preferred embodiment of a motor **10** providing unidirectional rotational motive power. The second preferred embodiment comprises a generally circular stator **50'** having a stator axis **72** with magnets **68'** attached to a surface **64** of the stator **50'**; an armature **70** attached to the stator **50'** by an armature axle **57** for rotation about an armature axis of rotation **58** coincident with the stator axis **72**; and five rotors **12** (for clarity, only one of which is shown) having three pairs **32**, **32'**, **32''** of abutted U-shaped magnets **20**, the rotors **12** being spaced at intervals of about **72** degrees around the armature **70**. Each rotor **12** is spaced from the armature by a strut **71** and attached to the strut **71** by an axle for rotation in the plane of the armature axis of rotation **58** about a rotor **12** axis of rotation **16**. The motor **10** further includes a driving linkage **55** connecting each rotor **12** and the stator **50** together to cause the armature **70** to rotate about the armature axis of rotation **58** as each rotor **12** rotates about its respective rotor axis **16**.

The second preferred embodiment is identical to the first preferred embodiment except for two differences. First, instead of the first magnetic field being uniform in both magnitude and direction along the circumferential line of demarcation **49** (except in one or more null regions **78** as in the first preferred embodiment), the direction of the first magnetic field rotates about a magnetic axis parallel to the circumferential line of demarcation **49** with a pre-determined periodicity along the line of demarcation **49**. Preferably, the first magnetic field is formed from one or more stator magnets **68'** attached to the outer surface **64** of the stator **50'**, each magnet **68'** having a direction of magnetisation which causes the first magnetic field to rotate about the magnetic axis. In the second preferred embodiment, as shown in **Fig.4**, the stator magnets **68'** are equally sized bar magnets, attached to the stator **50'** so that the bar magnets **68'** spiral on the stator **50'** with the pre-determined periodicity. However, as would be apparent to those skilled in the art, the first magnetic field need not be formed by bar magnets but could be formed from a single magnet (or groups of magnets) such that the direction of magnetisation of the single magnet rotates around the magnetic axis.

The second difference between the first preferred embodiment and the second preferred embodiment is that the linkage **55** of the second preferred embodiment does not include a component for increasing the angular velocity of the rotor **12** above the average velocity of the rotor **12**. Accordingly, in the second preferred embodiment, a circular rotor sprocket **63** is used in place of the eccentric rotor socket **59**, thereby providing a constant rate of rotation of the rotor **12** about the rotor axis **16** as the armature **70** rotates about the stator **50'**.

As will be clear to those skilled in the art, the rotation of the direction of the first magnetic field around the circumferential line of demarcation **49** commutates the second magnetic field, overcoming the need for the null regions **78**. In all other respects, the operation of the second embodiment is the same as that of the first embodiment. That is, the revolution rate of each rotor **12** is related to the revolution rate of the armature **70** by **Equation (1)**, where the parameter **Ns** is the number of rotations around the line of demarcation **49** of the first magnetic field along the line of demarcation **49**. In the second preferred embodiment, as shown in **Fig.4**, the number of rotations of the first magnetic field is one. Accordingly, since there are three pairs **32**, **32'**, **32''** of U-shaped magnets **20**, each of the five rotors **12** makes one-third revolution for each full revolution of the armature **70** around the armature axis **58**. However, as will be appreciated by those skilled in the art, the motor **10** could be designed for the first magnetic field to have any number of whole periods of rotation about the armature axis **58** provided that the revolution rate of the rotors **12** was adjusted to conform to **Equation (1)**.

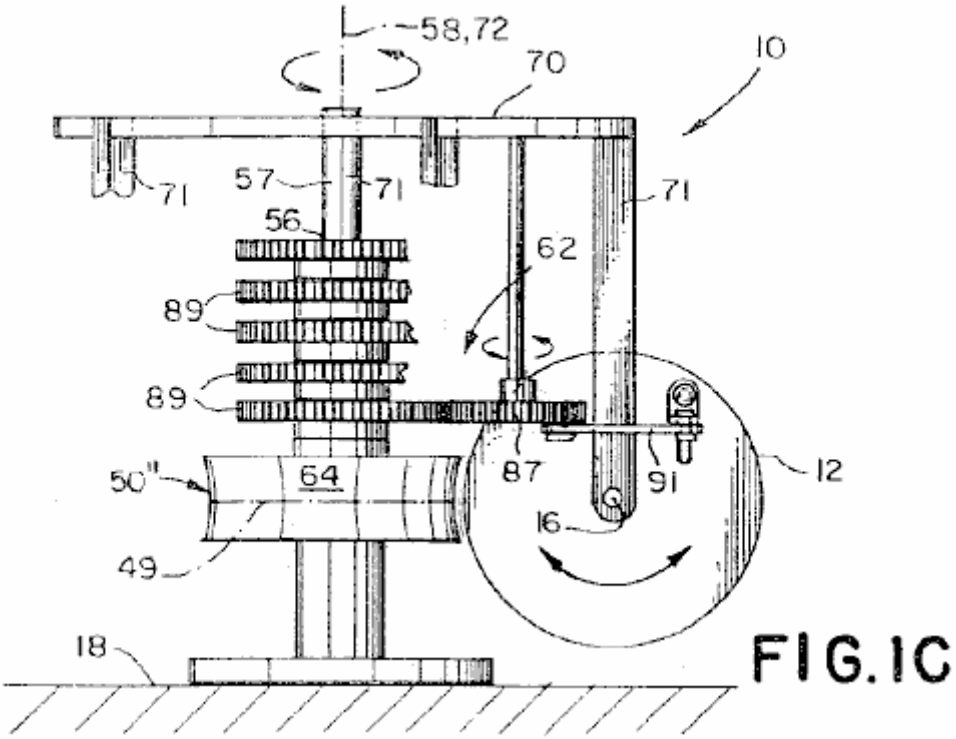

FIG. 1C

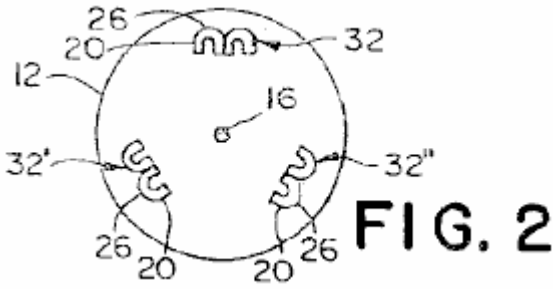

FIG. 2

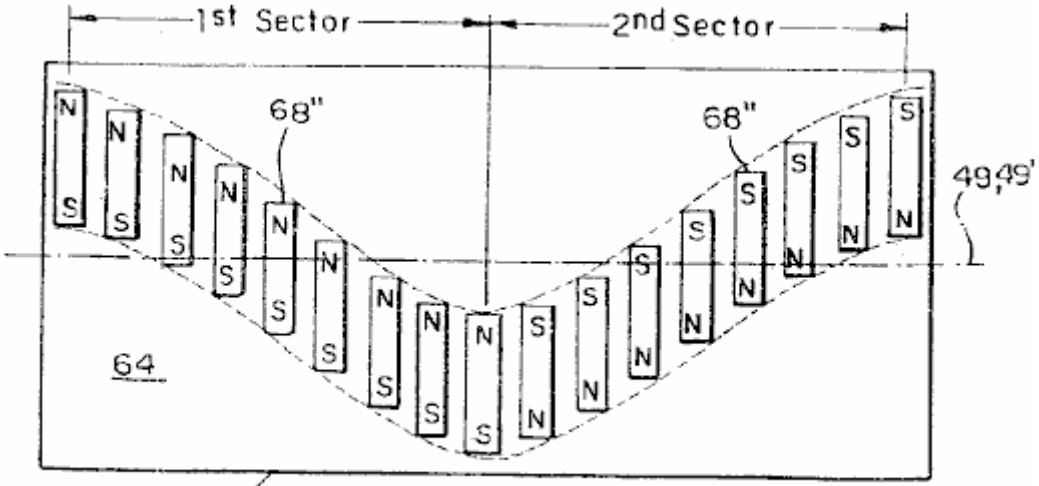

FIG. 5

Referring now to **Fig.1C**, **Fig.2** and **Fig.5** there is shown a third preferred embodiment of a motor **10** providing unidirectional rotational motive power. The third preferred embodiment comprises a generally circular stator **50"** mounted to a base **18** and having an axis **72**, with magnets **68"** attached to the surface **64** of the stator **50"**, an armature **70** attached to the stator **50"** by an axle **57** for rotation about an armature axis of rotation **58** coincident with the stator axis **12**, and five rotors **12** (for clarity, only one of which is shown) having three pairs **32**, **32'**, **32"** of abutted U-shaped magnets **20**, the rotors **12** being spaced at intervals of about **72** degrees around the armature **70**. Each rotor **12** is spaced from the armature by an armature strut **71** and attached to the armature strut **71** by an axle for rotation about an axis **16** of the rotor **12** in a plane generally aligned with the armature axis **58** about

an axis **16** of the rotor **12**. The motor **10** further includes a driving linkage **62** connecting each rotor **12** and the stator **50** together to cause the armature **70** to rotate about the armature axis of rotation **58** as each rotor **12** oscillates about its respective rotor axis **16**.

The third preferred embodiment is identical to the first preferred embodiment except for three differences. First, instead of the first magnetic field being uniform in both magnitude and direction around the circumferential line of demarcation **49** (except in the null zone **78**), the first magnetic field is displaced by a sinusoidal pattern having a pre-determined peak amplitude and a pre-determined period along the circumferential line of demarcation **49**, with the direction of the first magnetic field alternating in opposite directions along the line of demarcation **49** between each peak amplitude of the sinusoidal pattern.

Preferably, as shown in **Fig.5** the first magnetic field is formed by a plurality of bar magnets **68''** arranged on the surface **64** of the stator **50''** so that the magnetisation of the bar magnets **68''** is displaced in the sinusoidal pattern from the line of demarcation **49** around the circumferential line of demarcation **49**. The sinusoidal pattern of the bar magnets **68''** is divided into first and second sectors, the boundary of which occurs at the peaks of the sinusoidal pattern. The direction of magnetisation of the bar magnets **68''** is opposite in direction in the first and the second sectors providing a commutation of the second magnetic field and causing the rotors **12** to reverse in rotational direction as the rotor **12** oscillates around the rotor axis **16** and rotates around the armature axis of rotation **58**.

Preferably, the sinusoidal pattern of the magnets has a predetermined peak amplitude so that each rotor **12** oscillates approximately +/-thirty (30) degrees from a neutral position. However, the value of the peak amplitude is not critical to the design of the motor **10**. Further, the predetermined period of the sinusoidal pattern may be selected to be any value for which the number of cycles of the sinusoidal pattern around the surface **64** of the stator **50''** is an integer value.

As will be apparent to those skilled in the art, the first magnetic field need not be formed by the bar magnets **68''** but could be formed from a single magnet (or groups of magnets) so that the first magnetic field would be sinusoidally displaced around the armature axis of rotation **58** and would alternate in opposite directions between each peak of the sinusoidal pattern. Further, as will be appreciated by those skilled in the art, the displacement of the first magnetic field need not be precisely sinusoidal. For instance the displacement may be in a shape of a sawtooth or in a shape having a portion with constant plus and minus amplitude values, within the spirit and scope of the invention.

As a result of the first magnetic field being sinusoidally displaced and alternating each one-half period, each rotor **12** oscillates through an angle corresponding to approximately the peak amplitude of the sinusoid as the rotor **12** follows the stator magnets **68''**. Accordingly, a second difference between the third embodiment and the first embodiment is in the structure of the linkage **62**. In the third preferred embodiment, shown in **Fig.1C**, the linkage **62** comprises a reciprocating rod **91** connecting each rotor **12** to a respective first gear **87** rotationally attached to the armature **70**. The reciprocating rod **91** is pivotally mounted to each rotor **12** and to each first gear **87** so that the oscillating motion of the rotor **12** is converted to rotary motion of the first gear **87**. Each first gear **87** is coupled to a single second gear **89**, attached to the stator **50** in a fixed position. The rotary motion of each first gear **87** causes the armature **70** to rotate about the armature axis of rotation **58** as the rotors **12** oscillate about the rotor axis **16**. As will be appreciated by those skilled in the art, the speed of the motor **10** is fixed by the ratio of the first gear **87** to the second gear **89** in accordance with the expression:

Sa = (1 / Ns) x Sr ..... (2)

Where:
Ss is the angular velocity of the armature **70** (RPM);
Ns is the number of first magnetic field periods around the stator **50''**; and
Sr is the angular velocity of the rotor **12** (RPM).

Because each rotor **12** oscillates instead of continually rotating, only a single rotor magnet. (or group of magnets) on a given rotor **12** interacts with the single stator **50''**. Accordingly, a third difference between the third preferred embodiment and the first preferred embodiment arises because of the oscillatory motion of each rotor **12** whereby each rotor **12** of the third preferred embodiment has only a single pair of magnets **32**. However, as will be appreciated by those skilled in the art, additional stators **50''** may be added around the periphery of the rotors **12** and additional pairs of U-shaped magnets **20** may be included on each rotor 12 to interact magnetically with each additional stator **50''**, thus providing additional motive power.

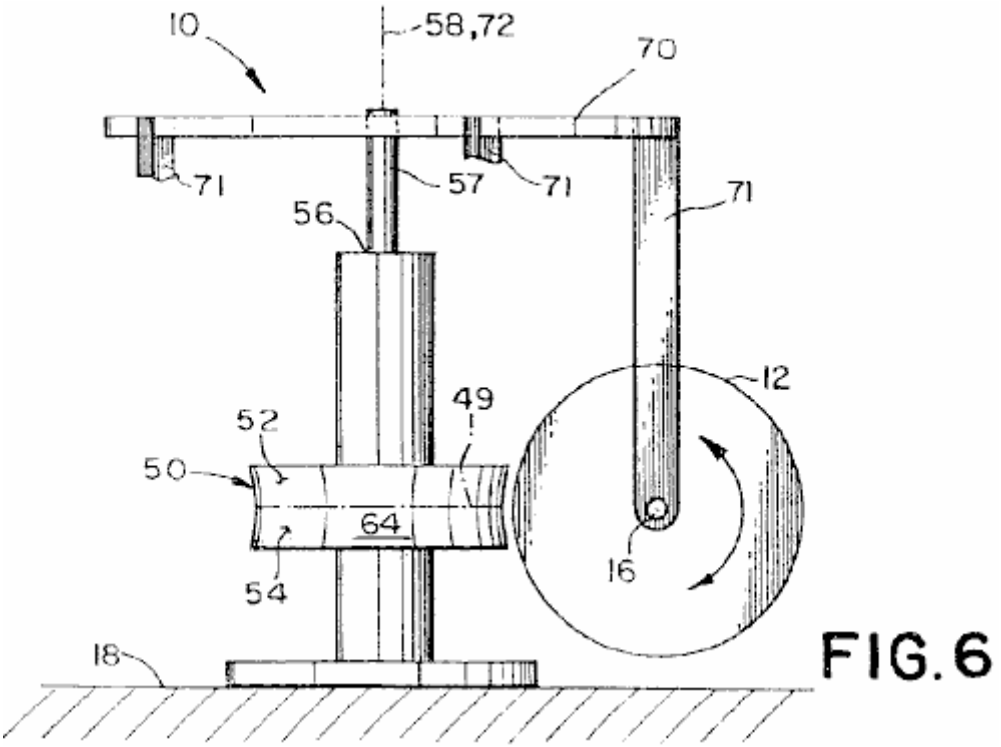

FIG. 6

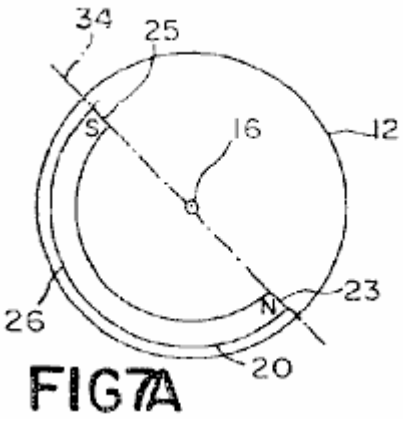

FIG 7A

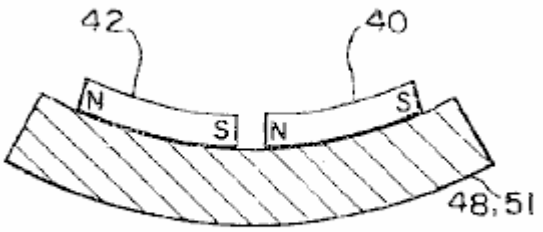

FIG. 8B

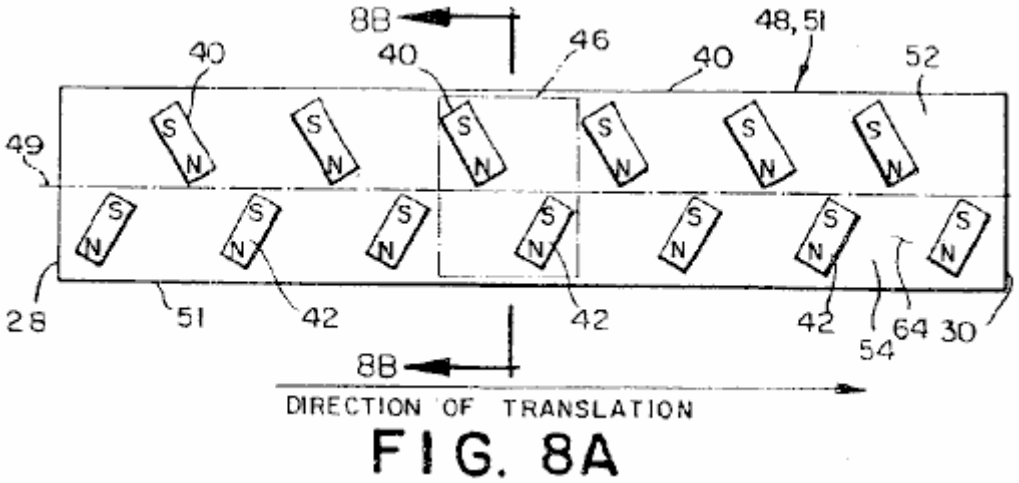

FIG. 8A

Referring now to **Figs. 6, 7A, 8A and 8B**, there is shown a fourth preferred embodiment of the permanent magnet motor **10** for providing unidirectional rotational motive power. The fourth preferred embodiment comprises a generally circular stator **51** having a stator axis **72**, attached to a base **18**. The stator **51** includes an outer surface **64** divided into a first side **52** and a second side **54** by a circumferential line of demarcation **49**, having a pre-determined direction around the stator axis **72**, at about a midpoint of the outer surface **64**.

Preferably, the surface **64** of the stator **51** is curved, having a curvature conforming to the arc of the rotors **12**. However, it will be appreciated by those skilled in the art that the surface **64** need not be curved but could be planar and still be within the spirit and scope of the invention. As will be appreciated by those skilled in the art the stator **51** is merely intended as a stationary supporting structure for stator magnets and, as such, the shape of the stator is not intended to be controlling of the size and shape of the air gap between the magnets attached to the stator and the magnets attached to the rotors.

As shown in **Fig.8A**, one or more pairs of stator magnets **46** are attached to the outer surface **64** spaced along the line of demarcation **49**. Each pair of stator magnets **46** comprises a first stator magnet **40** having a north pole and a south pole and a second stator magnet **42** having a north pole and a south pole. The south pole of each first stator magnet **40**, is located on the first side **52** of the outer surface **64**, and the north pole of the first stator magnet **40** is closest to the line of demarcation **49**. The north pole of each second stator magnet **42** is located on the second side **54** of the outer surface **64** and the south pole of each second stator magnet **42** being closest to the line of demarcation **49**. The first and the second stator magnets **40**, **42** are spaced along the line of demarcation **49** so that a first inter-magnet distance measured along the line of demarcation **49** between the north pole of the first stator magnet **40** and the south pole of the second stator magnet **42** of an adjacent pair of magnets **46** is generally equal to a second inter-magnet distance measured along the line of demarcation **49'** between the south pole of the first stator magnet **40** and the north pole of the second stator magnet **42**.

In the fourth preferred embodiment, the stator magnets **40**, **42** are bar magnets. Preferably, the north pole of each first stator magnet **40** and the south pole of each second stator magnet **42** are inclined toward the pre-determined direction. Also, the bar magnets are preferably oriented on the surface **64** of the stator **50** so that the south pole of each first magnet **40** and the north pole of each second magnet **42** are nearer to the periphery of each rotor **12** than the opposite polarity pole of each of the magnets **40**, **42**. As will be appreciated by those skilled in the art, the stator magnets **40**, **42** need not be bar magnets. For instance, each stator magnet **40**, **42** could be a U-shaped magnet, or could be made up of separate magnets, as long as the first magnetic field generated by the magnets was generally equivalent to that produced by the bar magnets.

In the fourth preferred embodiment, an armature **70** having an armature axis of rotation **58** coincident with the stator axis **72** is attached to the stator **51** by an armature axle **57**, which armature axle **57** allowing the armature **70** to freely rotate about the stator axis **72**. Each rotor **12** is spaced from the armature **70** by an armature strut **71** and is mounted to the armature strut **71** so as to be free to rotate about the rotor axis **16**. The rotor axis **16** is oriented so that the rotor **12** rotates in a plane generally aligned with the armature axis of rotation **58**. In the fourth preferred embodiment, five rotors **12** are attached to the armature **70**. Preferably, the rotors **12** are uniformly spaced around the circumference of the stator **50** with a spacing of the rotors **12** as measured at the surface **64** of the stator **51** about equal to an integer multiple of twice the inter-magnet distance. However, as those skilled in the art will appreciate, it is not necessary to have the rotors **12** uniformly spaced. Further, the number of rotors **12** can be as few as one and as large as size and space constraints allow. As will be appreciated by those skilled in the art, the stator axis **72** need not be coincident with the armature axis of rotation **58**. Accordingly, a stator **50** arranged around the armature axis **58** at any location at which the stator axis **72** is parallel to the armature axis **58** and the surface of the stator **50** faces the periphery of the rotors **12**, thereby providing for the interaction between the first magnetic field and the second magnetic field around the armature axis **58**, is within the spirit and scope of the invention.

Referring now to **Fig.7A**, each rotor **12** comprises a first U-shaped magnet **20** generating a second magnetic field. The first U-shaped magnet **20** is positioned on the rotor **12** so that the north pole and the south pole of the first U-shaped magnet **20** faces toward the axis **16** of the rotor **12**, and the rear side **26** of the first U-shaped magnet **20** faces the periphery of the rotor **12**. When the rear **26** of the first U-shaped magnet **20** is adjacent to the north pole of one of the first stator magnets **40** along the line of demarcation **49**, a portion of the second magnetic field directly adjacent to the rear **26** of the first U-shaped magnet **20** interacts with a portion of the first magnetic field generated by the north pole of the first stator magnet **40** to cause the rotor **12** to rotate in a counterclockwise direction. As the rotor **12** rotates in the counterclockwise direction, a portion of the second magnetic field associated with the south pole of the first U-shaped magnet **20** interacts with a portion of the first magnetic field associated with the south pole of the first stator magnet **40**, giving rise to a force in the direction of the rotor axis **16**, repelling the U-shaped magnet **20**, and causing the rotor **12** to translate in the pre-determined direction around the stator axis. As the rotor **12** moves away from first stator magnet **40** in the pre-direction the second magnetic field adjacent to the rear **26** of the U-shaped magnet **20** interacts with the portion of the first magnetic field associated with the south pole of the second stator magnet **42** of the pair of magnets **46**, causing the rotor **12** to reverse direction and rotate in the clockwise direction. The portion of the second magnetic field associated with the north pole of the U-shaped magnet **20** then interacts with the portion of the first magnetic field associated with the north pole of the second stator magnet **42**, again giving rise to a force in the direction of the rotor axis **16**, repelling the U-shaped magnet **20** and causing the rotor **12** to translate in the pre-determined direction. An

oscillation cycle is then repeated with the second magnetic field of the rotor **12** interacting with the first magnetic field of the adjacent pair of magnets **46**. Accordingly, the rotor **12** rotationally oscillates about the respective rotor axis **16** and generates a force in the direction of the rotor axis **16**, causing the armature **70** to rotate in the pre-determined direction around the armature axis of rotation **58** to provide the unidirectional rotational motive power of the motor. As would be appreciated by those skilled in the art, the fourth embodiment is not limited to a single stator **51** and a single U-shaped magnet **20**. Additional stators having first and second stator magnets **40**, **42** arranged identically to the stator **51** to interact with corresponding U-shaped magnets spaced around the periphery of each rotor are with in the spirit and scope of the invention.

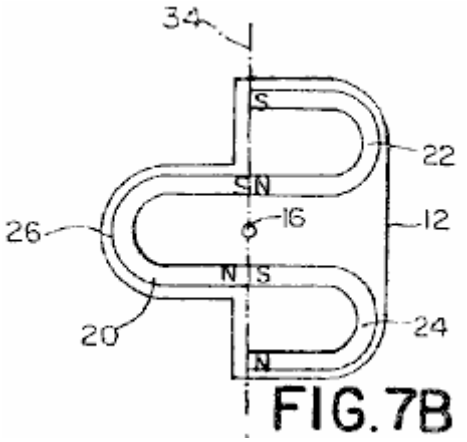

FIG.7B

Referring now to **Fig.6**, **Fig.7B** and **Fig.8A** there is shown a fifth preferred embodiment of the permanent magnet motor **10** for providing unidirectional rotary motive force. The structure and operation of the fifth preferred embodiment is similar to that of the fourth preferred embodiment except that each rotor **12** further includes a second U-shaped magnet **24** having a north pole and a south pole with the south pole of the second U-shaped magnet **24** abutting the north pole of the first U-shaped magnet **20**, and a third U-shaped magnet **22** having a north pole and a south pole, with the north pole of the third U-shaped magnet **22** abutting the south pole of the first U-shaped magnet **20**. As the rotor **12** rotates due to interaction of the portion of the second magnetic field adjacent to the rear of the U-shaped magnet **20** with the first magnetic field, a third magnetic field generated by the north pole of the second U-shaped magnet **24** and a fourth magnetic field generated by the south pole of the third U-shaped magnet **22** each interact with the first magnetic field generated by each stator magnet pair **46** to cause each rotor **12** to generate a force in the direction of the rotor axis **16**, thereby causing the armature **70** to rotate in the pre-determined direction around the axis **58** of the stator **51** to provide the unidirectional rotational motive power of the motor.

In the fifth preferred embodiment, the portion of the second magnetic field adjacent to the rear **26** of the first U-shaped magnet **20** serves to rotate the rotor **12** while the second and third U-shaped magnets **24**, **22** generate the magnetic fields providing the force in the direction of the rotor axis **16**. Accordingly, the fifth preferred embodiment is potentially more powerful than the fourth preferred embodiment. As will be appreciated by those skilled in the art, the stator magnets **40**, **42** need not be bar magnets. For instance, each stator magnet **40**, **42** could be replaced by a U-shaped magnet or could be made up of separate magnets, as long as the first magnetic field generated by the magnets was generally equivalent to that produced by the bar magnets.

FIG. 8C

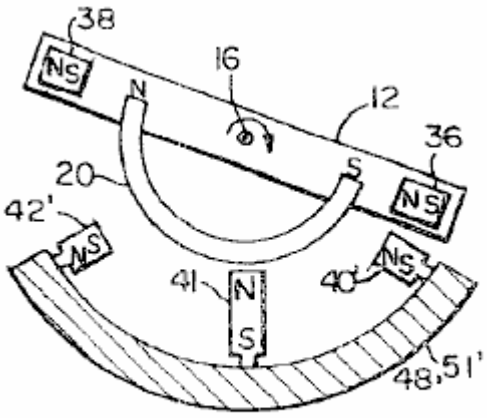

FIG. 8D

Referring now to **Fig.6** and **Fig.8C** and **Fig.8D** there is shown a sixth preferred embodiment of the motor **10**. The structure and operation of the sixth preferred embodiment is identical to that of the fifth preferred embodiment except that:
(1) The stator magnets **40'**, **42'** on the surface **64** of the stator **51'** are in a slightly different orientation;
(2) an additional stator magnet **41** is added to each pair of stator magnets **46** and
(3) the U-shaped magnets **22**, **24** attached to each rotor **12** are replaced with bar magnets **36**, **38**.

Specifically, and referring now to **Fig.8C**, the direction of magnetisation of each first stator magnet **40'** and each second stator magnet **42'** is aligned to be generally perpendicular to the line of demarcation **49** instead of being inclined in the pre-determined direction around the armature axis of rotation **58** as in the fifth embodiment. Also, the stator **51'** also includes a third stator magnet **41** mounted on the outer surface **64** along the line of demarcation **49** mid-way between each first stator magnet **40'** and each second stator magnet **42'**. As shown in **Fig.8C** and **Fig.8D**, the third stator magnet **41** is oriented so that the direction of magnetisation of the third magnet **41** is aligned with the axis **16** of the rotors **12**.

As shown in **Fig.8C** and **Fig.8D**, the rotor **12** used in the sixth preferred embodiment includes a first U-shaped magnet **20**, similar to that of the fifth preferred embodiment. However, in place of the second and the third U-shaped magnets **24**, **22** used in the fifth preferred embodiments, the sixth preferred embodiment includes a first thruster bar magnet **36**, spaced from and proximate to the south pole of the first U-shaped magnet **20** and generally aligned with a thruster magnet axis **34**, and a second thruster bar magnet **38**, spaced from and proximate to the north pole of the first U-shaped magnet **20** and also generally aligned with the thruster magnet axis **34**. The thruster axis **34** lies in the plane of the rotor **12** and intersects the rotor axis **16**. Similar to the fifth preferred embodiment, the interaction of the portion of the second magnetic field directly adjacent to the rear of the U-shaped magnet **20** with the first magnetic field provides the rotational force for the rotors **12**. As the rotor **12** rotates in the clockwise direction (viewed from the second end **30** of the stator **51'**), a third magnetic field generated by both the north pole and the south pole of the second thruster magnet **36** interacts with the first stator magnet **40'**, again generating a force in the direction of the rotor axis **16**. Similarly, when the rotor **12** rotates in the counterclockwise direction a fourth magnetic field generated by both the north pole and the south pole of the first thruster magnet **38** interacts with second stator magnet **42'**, generating a force in the direction of the rotor axis **16**. The result of the force in the direction of the rotor axis **16** is to cause the armature **70** to rotate in the predetermined direction around the armature axis of rotation **58** to provide the unidirectional rotational motive power of the motor **10**.

In the sixth preferred embodiment, the stator magnets **40'**, **41**, **42'** and the thruster magnets **36**, **38** are bar magnets. However, as will be appreciated by those skilled in the art, the stator magnets **40'**, **41 42'** and the thruster magnets **36**, **38** need not be bar magnets. For instance, each stator magnet **40'**, **42'** could be a U-shaped magnet or could be made up of separate magnets, as long as the first magnetic field generated by the magnets was generally equivalent to that produced by the bar magnets.

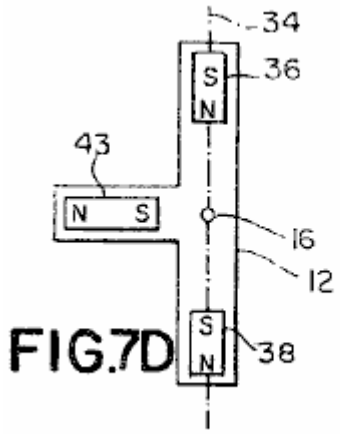

FIG.7D

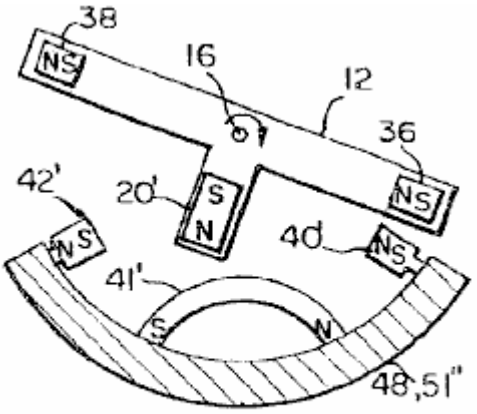

FIG. 8E

Referring now to **Fig.6**, **Fig.7D** and **Fig.8E** there is shown a seventh preferred embodiment of the motor **10**. The structure and operation of the seventh preferred embodiment is similar to the sixth preferred embodiment except that the third stator magnet **41'** located on the surface **64** of the stator **51"** along the line of demarcation **49** is a U-shaped magnet **41'** with the rear of the U-shaped magnet **41'** facing the rotor **12** and the direction of magnetisation being perpendicular to the line of demarcation **49**; and the U-shaped magnet **20** is replaced with a bar magnet **20'** oriented to have the direction of magnetisation aligned with a radial line of the rotor **12**. As in the sixth preferred embodiment, each stator magnet **40'**, **42'** could be a U-shaped magnet or could be made up of separate magnets, as long as the first magnetic field generated by the stator magnets **40'**, **42'** was generally equivalent to that produced by the bar magnets.

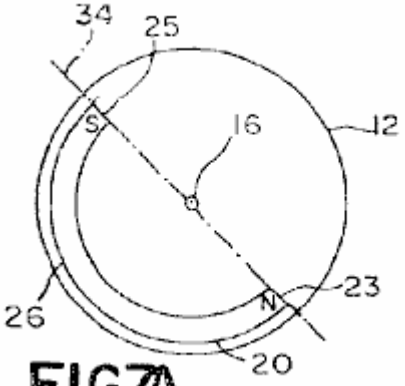

FIG7A

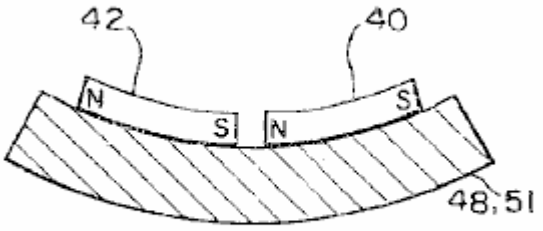

FIG. 8B

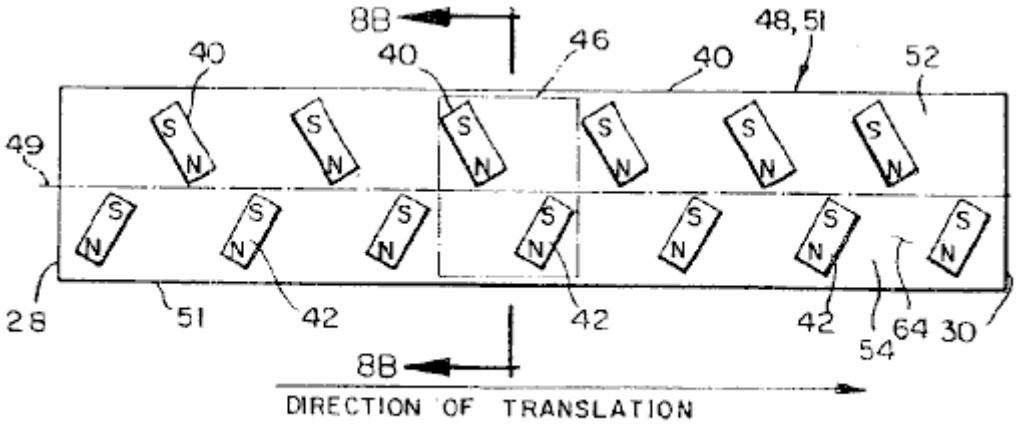

FIG. 8A

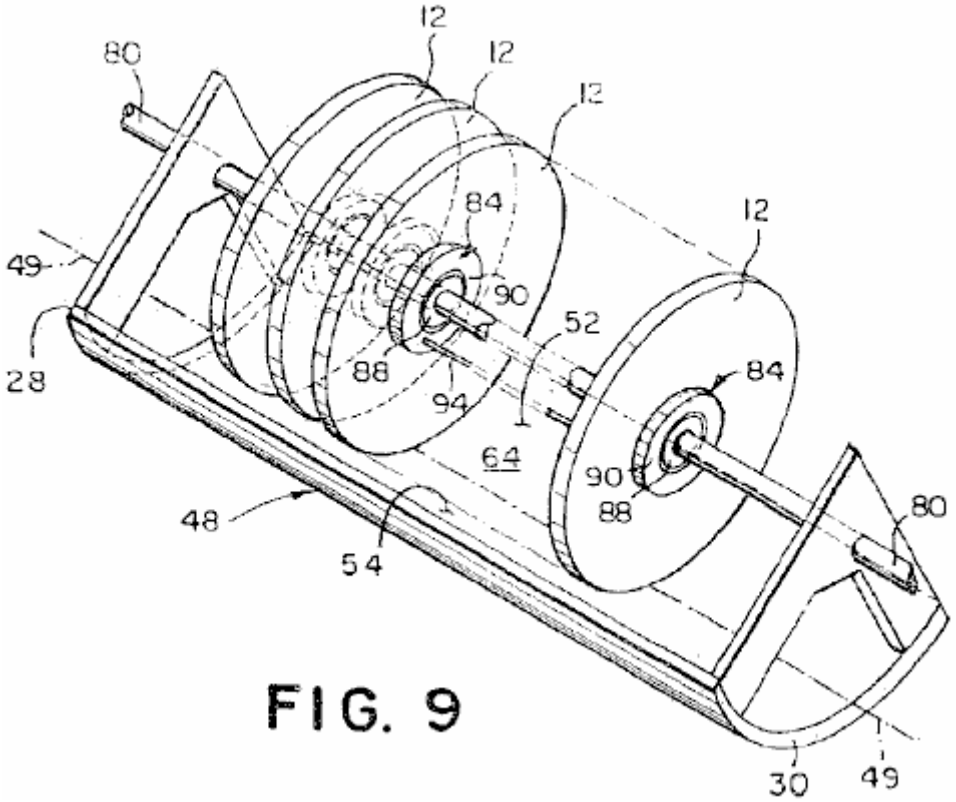

FIG. 9

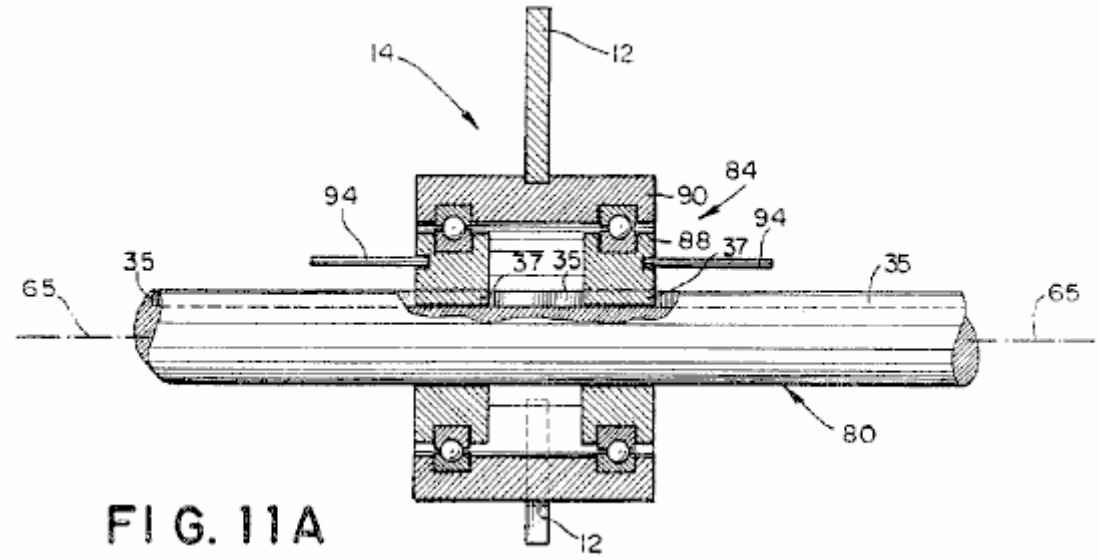

FIG. 11A

Referring now to **Fig.7A**, **Fig.8A**, **Fig.8B**, **Fig.9** and **Fig.11A**, there is shown an eighth preferred embodiment of the motor **10** for providing unidirectional linear motive power. The eighth preferred embodiment comprises a linear stator **48** having a generally curved cross-section perpendicular to a longitudinal line of demarcation **49** extending on a surface **64** of the stator between a first end **28** and a second end **30** and dividing the surface **64** of the stator **48** into a first side **52** and a second side **54**. Preferably, the generally curved cross-section of the stator **48** is concave. However, it will be appreciated by those skilled in the art that the cross-section need not be concave but could be planar or even convex and still be within the spirit and scope of the invention.

The linear stator **48** is identical to the generally circular stator **51** except for the surface **64** of the stator **48** being linear in the direction of the line of demarcation **49** instead of being circular in the direction of the line of demarcation **49**.

The eighth preferred embodiment includes the first and the second stator magnets **40**, **42** (see **Fig.8A**), the location and orientation of which are virtually identical to the orientation and location of the stator magnets **40**, **42** on the circular stator **51**. Accordingly, attached to the linear stator **48** is one or more pairs of magnets **46**, each pair of stator magnets **46** generating a first magnetic field and comprising a first stator magnet **40** having a north pole and a south pole and a second stator magnet **42** having a north pole and a south pole. The south pole of

each first stator magnet **40**, is located on the first side **52** of the outer surface **64**, with the north pole of the first stator magnet **40** being closest to the line of demarcation **49**. The north pole of each second stator magnet **42** is located on the second side **54** of the outer surface **64** with the south pole of each second stator magnet **42** being closest to the line of demarcation **49**. The first and the second stator magnets **40**, **42** are spaced along the line of demarcation **49** so that a first inter-magnet distance measured along the line of demarcation **49** between the north pole of the first stator magnet **40** and the south pole of the second stator magnet **42** of an adjacent pair of magnets **46** is generally equal to a second inter-magnet distance measured along the line of demarcation **49** between the south pole of the first stator magnet **40** and the north pole of the second stator magnet **42**.

In the eighth preferred embodiment, the stator magnets **40**, **42** are bar magnets, the north pole of each first stator magnet **40** and the south pole of each second stator magnet **42** being inclined toward the second end **30** of the linear stator **48**. Also, as shown in **Fig.8A**, the stator magnets **40**, **42** are oriented on the surface **64** of the stator **51** so that the south pole of each first magnet **40** and the north pole of each second magnet **42** are nearer to the periphery of each rotor **12** than the opposite polarity pole of each of the stator magnets **40**, **42**. As will be appreciated by those skilled in the art, the stator magnets **40**, **42** need not be bar magnets. For instance, each stator magnet **40**, **42** could be a U-shaped magnet or could be made up of separate magnets, as long as the first magnetic field generated by the magnets was generally equivalent to that produced by the bar magnets.

The eighth preferred embodiment also includes rail **80** having a longitudinal axis located generally parallel to the line of demarcation **49** of the stator **48**. Five rotor assemblies **14** comprising a rotor **12** and a bearing assembly **84** are slidably attached to the rail **80**.

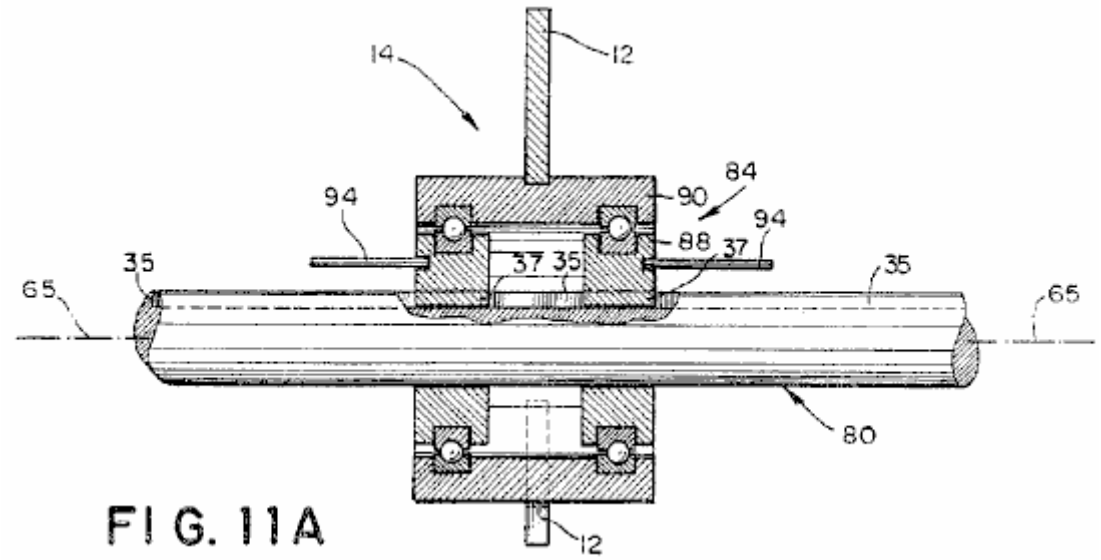

FIG. 11A

Preferably, the bearing assembly **84**, as shown in **Fig.11A**, includes a pair of first bearings **88** slidably mounted to the rail **80** and constrained to slide along the rail without any substantial rotation, by a boss **37** in each first bearing **88**, which is keyed to a longitudinal groove **35** on the rail **80**. A second bearing **90** is connected for rotation to the pair of first bearings **88** by ball bearings. The rotor **12** is attached to the second bearing **90**. Thus, the rotor **12** attached to each bearing assembly **84** is free to oscillate rotationally about the rail **80** and to generate a force along the rail **80** in the direction of the second end of the stator **30**.

Preferably, the eighth preferred embodiment includes a cross-link **94** which ties each bearing assembly **84** together by connecting together the first bearings **88** of each bearing assembly **84**, thereby adding together the linear motion along the rail **80** of each rotor **12**.

Preferably, each rotor **12** comprises one or more one rotor magnets **20**, each rotor magnet **20** generating a second magnetic field which interacts with the first magnetic field to cause the rotor **12** to oscillate rotationally about the axis of the rail **80** and to generate a force in the direction of the axis of the rail **80** to provide the unidirectional linear motive power of the motor. In the eighth preferred embodiment, each rotor **12** is substantially identical to the rotor **12** described for the fourth preferred embodiment. Accordingly, each rotor magnet comprises a first U-shaped magnet **20** having a north pole, a south pole and a rear side **26**, a first portion of the second magnetic field directly adjacent to the rear **26** of the U-shaped magnet **20** interacting with each first magnetic field to cause each rotor **12** to oscillate rotationally about the rail **80**. A second portion of the second magnetic field adjacent to the north and the south poles of the first U-shaped magnet **20** interacts with the first magnetic field to cause the rotor **12** to generate a force in the direction of the axis of the rail **80** thereby providing the unidirectional linear motive power of the motor. As would be clear to those skilled in the art, the operation of the eighth

preferred embodiment is identical to that of the fourth preferred embodiment except that the motion of the cross-linked rotors **12** is linear along the rail **80** instead of being rotational about the armature axis of rotation **58**. Accordingly, for the sake of brevity, a description of the operation of the eighth preferred embodiment is not repeated.

Referring now to **Fig.7B**, **Fig.8A**, **Fig.8B**, **Fig.9** and **Fig.11A** there is shown a ninth preferred embodiment of the motor **10** for providing unidirectional linear motive power. As would be apparent to those skilled in the art, the structure and the operation of the ninth preferred embodiment is virtually identical to that of the fifth preferred embodiment except that the motion of the cross-linked rotors **12** is linear instead of rotational about the armature axis of rotation **58**. Accordingly, for the sake of brevity, a description of the structure and the operation of the ninth preferred embodiment is not repeated.

Referring now to **Figs. 7C, 8C, 8D, 9 and 11A** there is shown a tenth preferred embodiment of the motor **10** for providing unidirectional linear motive power. As would be apparent to those skilled in the art, the structure and the operation of the tenth preferred embodiment is virtually identical to that of the sixth preferred embodiment except that the motion of the cross-linked rotors **12** is linear instead of rotational about the armature axis of rotation **58**. Accordingly, for the sake of brevity, the operation of the tenth preferred embodiment is not repeated.

Referring now to **Figs. 7D, 8C, 8E, 9 and 11A** there is shown an eleventh preferred embodiment of the motor **10** for providing unidirectional linear motive power. The structure and operation of the eleventh preferred embodiment is virtually identical to the seventh preferred embodiment except that the motion of the cross-lined rotors **12** is linear instead of rotational about the armature axis of rotation **58**. Accordingly, for the sake of brevity, the operation of the tenth preferred embodiment is not repeated.

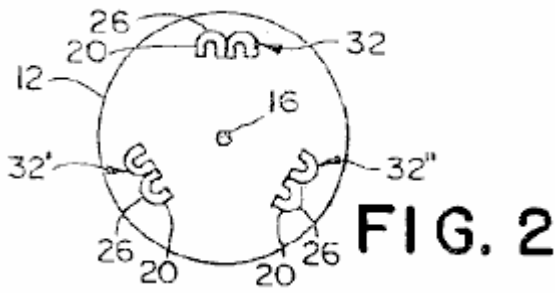

FIG. 2

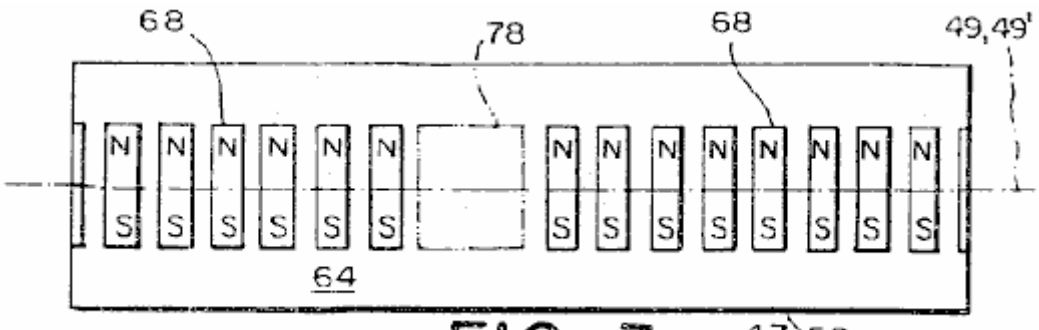

FIG. 3

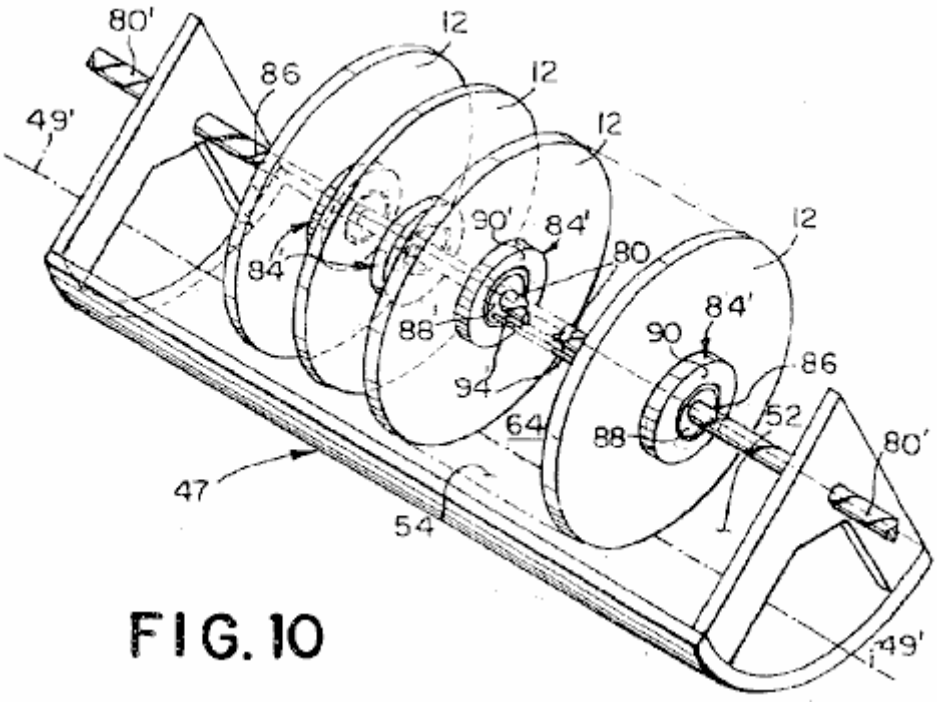

FIG. 10

Referring now to **Fig.2**, **Fig.3**, **Fig.10** and **Fig.11B**, there is shown a twelfth preferred embodiment of the motor **10** for providing linear motive power. As shown in **Fig.10**, the twelfth preferred embodiment comprises a linear stator **47** having a generally curved cross-section perpendicular to a line of demarcation **49'** extending along a midpoint of the stator **47** between a first end **28** and a second end **30** of the linear stator **47**, a rail **80'** connected to the linear stator **47** having an axis generally parallel to the line of demarcation **49'**, one or more rotor assemblies **14'** comprising rotors **12** connected to the rail **80'** by a bearing assembly **84'**, and a cross-link **94'** connecting together the linkages **84'** of adjacent rotors **12**. Preferably, the generally curved cross section of the stator **47** is concave, having a curvature conforming to the arc of the rotors **12**. However, it will be appreciated by those skilled in the art that the generally curved cross-section need not be concave but could be planar or even convex and still be within the spirit and scope of the invention.

As shown in **Fig.3**, the linear stator **47** includes one or more magnets **68** arranged on the surface **64** of the linear stator **47**, each magnet **68** having a direction of magnetisation directed at about a right angle to the line of demarcation **49'** and resulting in a first magnetic field directed generally at a right angle to the line of demarcation **49'**. The magnitude of the first magnetic field is generally uniform except in the null region **78**, in which the magnitude of the first magnetic field is substantially reduced. The linear stator **47** of the twelfth preferred embodiment is virtually identical to the circular stator **50** of the first preferred embodiment except the linear stator **50** is linear in the direction of the line of demarcation **49'** instead of being circular around the armature axis of rotation **58**. Also, the arrangement of the magnets **68** on the surface **64** of the stator **47** and the structure of the null region(s) **78** is the same as for the first preferred embodiment, as shown in **Fig.3** and as fully described in the discussion of the first embodiment. Accordingly, for the sake of brevity, a more detailed description of the structure of the linear stator **47** is not repeated.

The rotors **12** of the twelfth preferred embodiment each have an axis of rotation **16** which is aligned with an axis of the rail **80'**. The rotors **12** are connected to the rail **80'** by the bearing assembly **84'** so that each rotor **12** is free to rotate about the rail **80'** and to slide along the rail **80'.** Preferably, as shown in **Fig.2**, each rotor **12** includes three pairs of U-shaped magnets **32, 32, 32'**, each U-shaped magnet having a rear side **26** and generating a second magnetic field. A portion of the second magnetic field adjacent to the rear-side **26** of each U-shaped magnet **20** interacts with the first magnetic field to cause each rotor **12** to rotate about the axis of the rail **80**. The rotors **12** of the twelfth preferred embodiment are the same as the rotors in the first preferred embodiment, as described in **Fig.2** and fully discussed above. Accordingly, for the sake of brevity, the detailed description of the rotors **12** is not repeated.

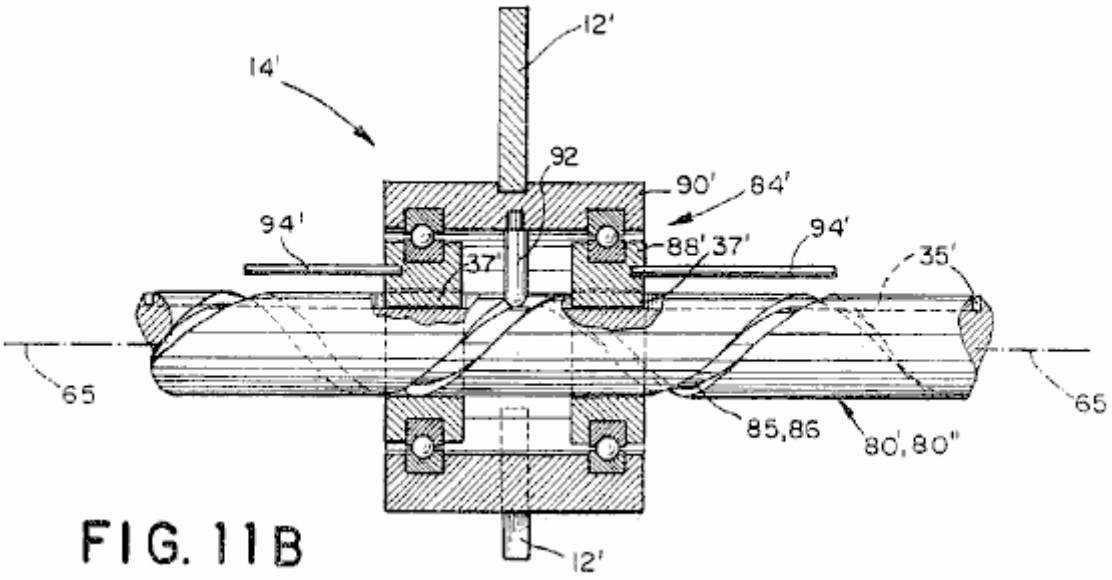

FIG. 11B

As shown in **Fig.11B**, the rail **80'** has a helical groove **86** with a pre-determined pitch (i.e., turns/unit length) running around a periphery of the rail **80'**. The bearing assembly **84'** connects each rotor **12** to the helical groove **86**, converting the rotational motion of each rotor **12** around the rail **80'** to the linear motion along the rail **80'**. As shown in **Fig.11B**, the bearing assembly **84'** comprises a pair of first bearings **88'** mounted to the rail **80'** and constrained to slide along the rail **80'** without any substantial rotation, and a second bearing **90'**, mounted to an outer surface the first bearing **88'** for receiving the rotor **12**. Preferably, each first bearing **88'** has a boss **37** which engages a longitudinal groove **35** so that each first bearing **88'** slides on the rail **80'** without rotation as the second bearing **90'** rotates on the first bearings **88'**. It will be appreciated by those skilled in the art, other methods for securing the first bearings **88'** to the rail **80'** could be employed, as for instance, by making the cross-section of the rail **80'** oblate (flattened at the poles). As in the first preferred embodiment, each rotor **12** must rotate at a rate which results in the rear of each U-shaped magnet **20** on the rotor **12** passing through one of the null regions **78** each full rotation of the rotor **12**. Accordingly, the pre-determined pitch of the helical groove **86** on the rail **80'** preferably equals:

Pg = (1 / Nr) x Pr ..... (3)

Where:
Pr = the pitch of the null regions **78** (null regions/unit length);
Nr = the number of U-shaped magnets (or groups of abutted U-shaped magnets) on a rotor **12**; and
Pg = the pitch of the helical groove **86** (revolutions/unit length).

Preferably, the portions of the helical groove **86** corresponding to each null region **78** have an instantaneous pitch which is greater than the pre-determined pitch of the groove **86** for increasing the angular velocity of the each rotor **12** as each one of the pairs **32, 32', 32"** of U-shaped magnets **20** passes through one of the null regions **78**. However, as will be appreciated by those skilled in the art, it is not necessary to provide the greater instantaneous pitch in order for the motor **10** to provide motive power.

As described above, the cross-link **94'** connects the bearing assembly **84'** of adjacent rotors **12** together. As shown in **Fig.10**, the cross-link **94'** connects the first bearings **88'** of each bearing assembly **84'** to the first bearing **88'** of the adjacent bearing assemblies **84'** so that the linear motion of all the rotor assemblies **14'** are added together to provide the unidirectional linear motive power of the motor **10**.

As previously stated, the first preferred embodiment of the motor **10** comprises a single null region **78** and five rotors **12**, each rotor **12** having three pairs **32, 32', 32"** of abutted U-shaped magnets **20**. Preferably, the rotors **12** are uniformly spaced along the rail **80'** and the pairs **32, 32', 32"** of U-shaped magnets **20** are uniformly spaced around the periphery of each respective rotor **12**. Further, the pairs **32, 32', 32"** of U-shaped magnets **20** are phased with respect to each rotor **12** by one-fifth of a revolution of the rotor **12** so that the pairs **32, 32', 32"** of U-shaped magnets **20** of all the rotors **12** pass through the null region **78** at a substantially uniform rate to provide a more or less continuous interaction between the first magnetic field and the second magnetic field of the rotors **12**, resulting in a more or less continuous urging of the rotor assemblies **14'** toward the second end of the stator **47**. As will be appreciated by those skilled in the art, the motive power provided by the motor **10** is proportional to the number of rotors **12** and the number of U-shaped magnets **20** on each rotor **12**. Accordingly, the number of rotors **12** and the number of pairs **32, 32', 32"** of magnets **20** of the present invention are not limited to five rotors

12 and three pairs **32** of U-shaped magnets **20**. Neither is the number of null regions limited to one. The number of U-shaped magnets **20** and null regions **78** are limited only by adherence to the rule established by **Equation 3**.

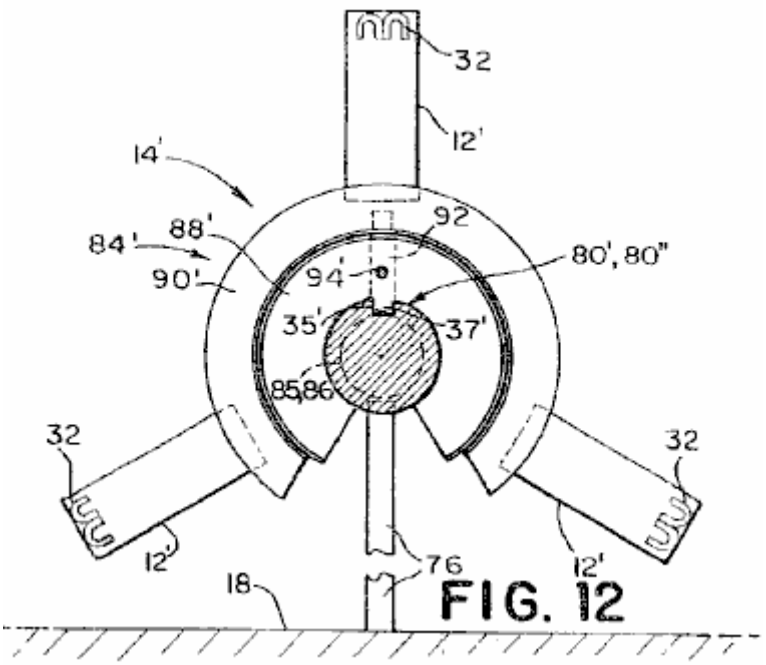

FIG. 12

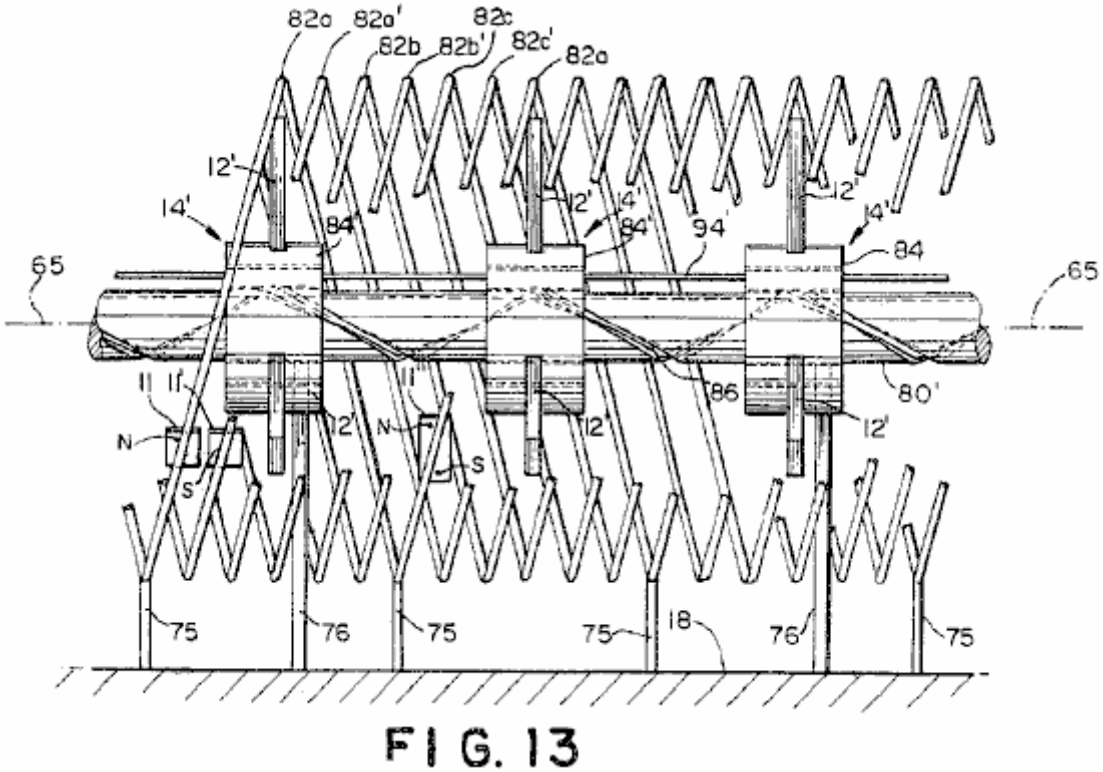

FIG. 13

Referring now to **Fig.2**, **Fig.11B**, **Fig.12** and **Fig.13** there is shown a thirteenth preferred embodiment of the motor **10** comprising a rail **80'** supported by rail mounting posts **76** and having a longitudinal axis **65**. A helical groove **86** having a pre-determined pitch runs around a periphery of the rail **80**.

The thirteenth preferred embodiment also includes three first helical stators **82a, 82b, 82c** (**82**) concentrically surrounding the rail **80'** corresponding to three pairs **32, 32' 32"** of U-shaped magnets **20** mounted on each of five rotors **12**. Preferably, the first helical stators **82** have the same pitch as the pre-determined pitch of the groove **86** and a longitudinal axis generally parallel to the axis **65** of the rail **80'**. A plurality of first stator magnets **11** having a direction of magnetisation aligned with a radial line of each rotor **12** are spaced along each first helical stator **82** with the first stator magnets **11** generating a first magnetic field.

The thirteenth preferred embodiment further includes plurality of second helical stators **82a', 82b', 82c'** (**82'**) alternating with the first helical stators **82'** along the axis **65** of the rail **80'**, and having the pre-determined pitch of the groove **86**. Each second helical stator **82'** has mounted upon it a plurality of second stator magnets **11'** having a direction of magnetisation aligned with a radial line of the rotor **12** and having a direction of magnetisation opposite in direction to the first stator magnets **11** mounted on each of the first helical stators **82**. As a consequence of the second helical stators **82'** being located midway between the first helical stators **82**, a point at about a midpoint between each rotor magnet pair **32, 32', 32''** is apposite to one of the second helical stators **82'** as each rotor **12** rotates about the axis **65** of the rail **80'** and slides along the rail **80'**.

The thirteenth preferred embodiment also includes five rotors **12**, (for clarity, only three are shown), having an axis of rotation **16** generally aligned with the longitudinal axis **65** of the rail **80'**. Each rotor **12** is connected to the rail **80'** by a bearing assembly **84'** so that the rotor **12** is free to rotate about the axis **65** of the rail **80'** and slide along the rail **80'**. Preferably, each rotor **12** includes three pairs **32, 32', 32''** of U-shaped magnets **20** wherein each U-shaped magnet **20** generates a second magnetic field, a portion of which adjacent to a rear **26** of the pair of U-shaped magnets **20** interacts with the first magnetic field of each first stator magnet to cause each rotor **12** to rotate about the axis **65** of the rail **80'**.

The bearing assembly **84'** (shown in detail in **Fig.11B** and **Fig.12**) connects each rotor **12** to the helical groove **86** around the periphery of the rail **80**. The bearing assembly **84'** is similar to the bearing assembly **84'** described in the twelfth preferred embodiment except for the openings in the first bearings **88'** and in the second bearing **90'** which allow the bearing assembly **84'** past the rail mounting posts **76** as the bearing assembly **84'** moves along the rail **80'**.

The thirteenth preferred embodiment may be constructed as either a linear motor or a rotary motor. In the case of the linear motor, the axes of the rail **80'** and of each helical stator **82** are substantially straight. The rail **80'** is supported on the base **18** by rail mounting posts **76** placed at intervals along the rail **80'**. The posts **76** are situated at locations along the rail **80'** at which the rotation of the rotor **12** orients the openings in the first and second bearings **88'**, **90'** to correspond to the mounting posts **76**. Each helical stator **82a, 82b, 82c** is supported on the base by stator mounting posts **75**. The rotors **12** are connected together by a cross-link **94'** which connects the first bearings **88'** of each bearing assembly **84'** to the first bearing **88'** of the bearing assembly **84'** of an adjacent rotor **12**. In this manner, the rotational motion of each rotor assembly **14'** is added together to provide the linear motive power of the linear motor.

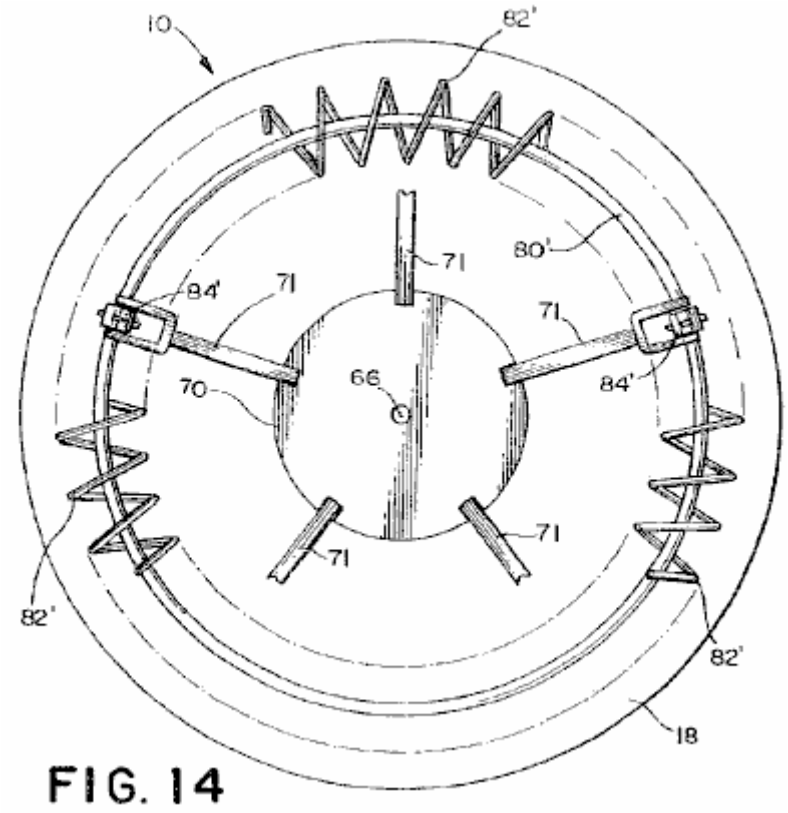

FIG. 14

The thirteenth preferred embodiment may also be constructed as a rotary motor **10** as shown in **Fig.14**. In this case, the axes of the rail **80'** and the helical stators **82** are configured to be circular. The circularly configured motor **10** includes an armature **70** centrally located within the perimeter of the rail **80'**. The armature **70** rotates

about an armature axis of rotation **58** connected for rotation within a motor base **18** to which the rail **80'** is also attached by mounting posts **76** (not shown). The pitch of the first and the second helical stators **82**, **82'**, measured at a radius of the rail **80**, preferably equals the predetermined pitch of the helical groove **86**. The armature **70** is fixedly attached to the first bearing **88** (see **Fig.11B**) of each bearing assembly **84'** by an armature strut **71** thereby adding together the rotational motive power of each rotor assembly **14**. In order that the armature strut **71** does not interfere with the first and second helical stators **82**, **82'**, the first and second helical stators **82**, **82'** are made to have an opening toward the armature axis of rotation **58**.

Preferably, each first helical stator **82a, 82b, 82c** has mounted upon it a plurality of first stator magnets **11** with each stator magnet **11** having a direction of magnetisation aligned with a radial line of the rotor **12**. Preferably, the first helical stators **82** are uniformly spaced along the longitudinal axis **65** of the rail **80'** with each first helical stator **82** corresponding to one of the plurality of magnet pairs **32, 32', 32"**. Preferably, each rotor **12** is positioned on the rail **80'** so that one of the rotor magnet pairs **32, 32', 32"** is apposite to one of the corresponding first helical stators **82** as the rotor **12** rotates about the axis **65** of the rail **80** and slides along the rail **80'**. However, as those skilled in the art will appreciate, the rotor magnet pairs **32, 32', 32"** need not be directly apposite to each helical stator **82** as the rotors **12** rotate in order to generate a rotational force.

Alternatively, as will be appreciated by those skilled in the art, the motor **10** can be constructed without the second helical stator **82'**. In the simplest case the motor **10** could comprise only a single first helical stator **82** and a single rotor **12** comprising a single U-shaped magnet **20** generating the second magnetic field. The single rotor **12** is preferably positioned in the groove **86** on the rail **80'** so that the U-shaped rotor magnet **20** is continually apposite to the single first helical stator **82**. Consequently, a portion of the second magnetic field directly adjacent to a rear **26** of the U-shaped magnet **20** interacts with the first magnetic field generated by each first stator magnet **11"** mounted on the helical stator **82** to cause the rotor **12** to rotate about the axis **65** of the rail **80** and to slide along the rail **80'**. Preferably, when only a single first stator **82** set of first stators **82** is used, each first stator magnet **11"** has a direction of magnetisation oriented to be in the plane of the rotor **12** and generally perpendicular to a radial line of the rotor **12**. The north pole and the south pole of the first stator magnet **11"** are preferably spaced apart so that when one pole of the first stator magnet **11** is directly apposite to the rotor magnet **20**, the pole of opposite polarity is equally spaced from the U-shaped magnet **20** of the rotor **12**. As one skilled in the art would appreciate, a plurality of U-shaped rotor magnets **20** and corresponding first helical stators could be used. Further, as those skilled in the art will appreciate, other configurations of the rotor magnet **20** and the stator magnet **11** are possible, all of which rely on the novel attributes of the magnetic field adjacent to the rear **26** of a U-shaped rotor magnet **20**. For example, the previously described stator magnet **11"** perpendicular to the radial line of the rotor **12** could be two separate bar magnets, spaced apart, with the magnetisation of each of the two magnets aligned with a radial line of the rotor and having opposite directions of magnetisation.

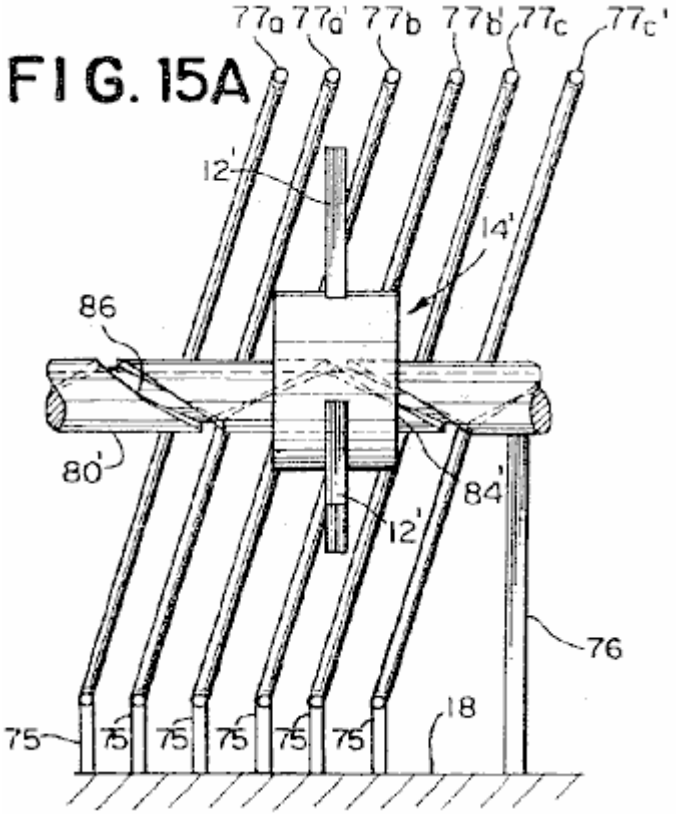

FIG. 15A

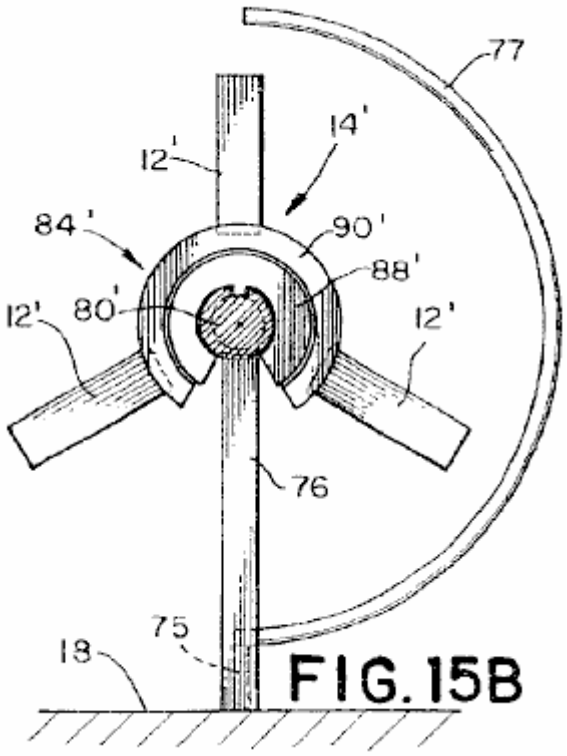

FIG. 15B

Referring now to **Fig.15A** and **Fig.15B** there is shown a fourteenth preferred embodiment of the motor **10**. The fourteenth embodiment is identical in structure to the thirteenth preferred embodiment except that the stator comprises a plurality of first ribs **77a, 77b, 77c** (**77**) and second ribs **77a', 77b', 77c'** (**77'**) in place of the first and the second helical stators **82, 82'** of the thirteenth embodiment. By substituting ribs **77, 77'** for the helical stators **82, 82'**, the attachment of the armature **70** to the rotors **12** is simplified. As those skilled in the art will appreciate, the length of the ribs **77, 77'** may vary from as little as 45 degrees to up to 265 degrees, with the motive power of the motor **10** being proportional to the length of the ribs.

Preferably, the first and the second ribs **77, 77'** have a pitch and a spacing that conforms to the pre-determined pitch of the rail **80'**. Further the orientation of the first and second stator magnets **11, 11'** and of the U-shaped rotor magnets **20** would be identical to the thirteenth embodiment. Accordingly, the operation of the fourteenth embodiment is identical to that of the thirteenth embodiment and is not repeated here for the sake of brevity.

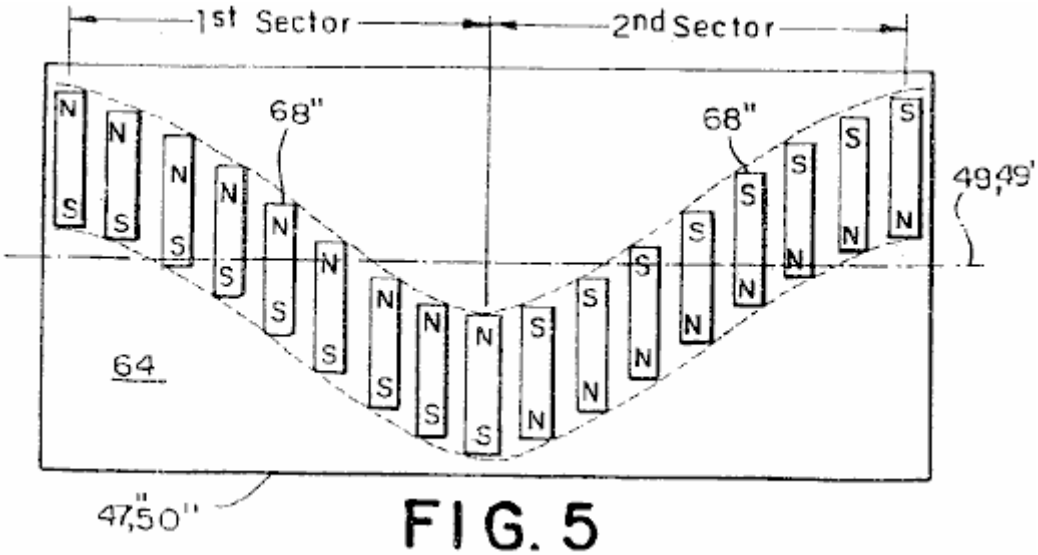

FIG. 5

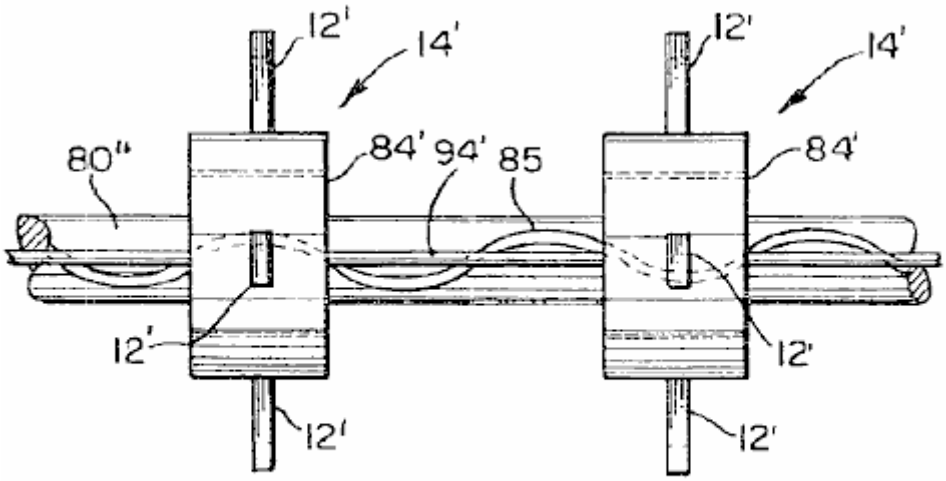

FIG. 16

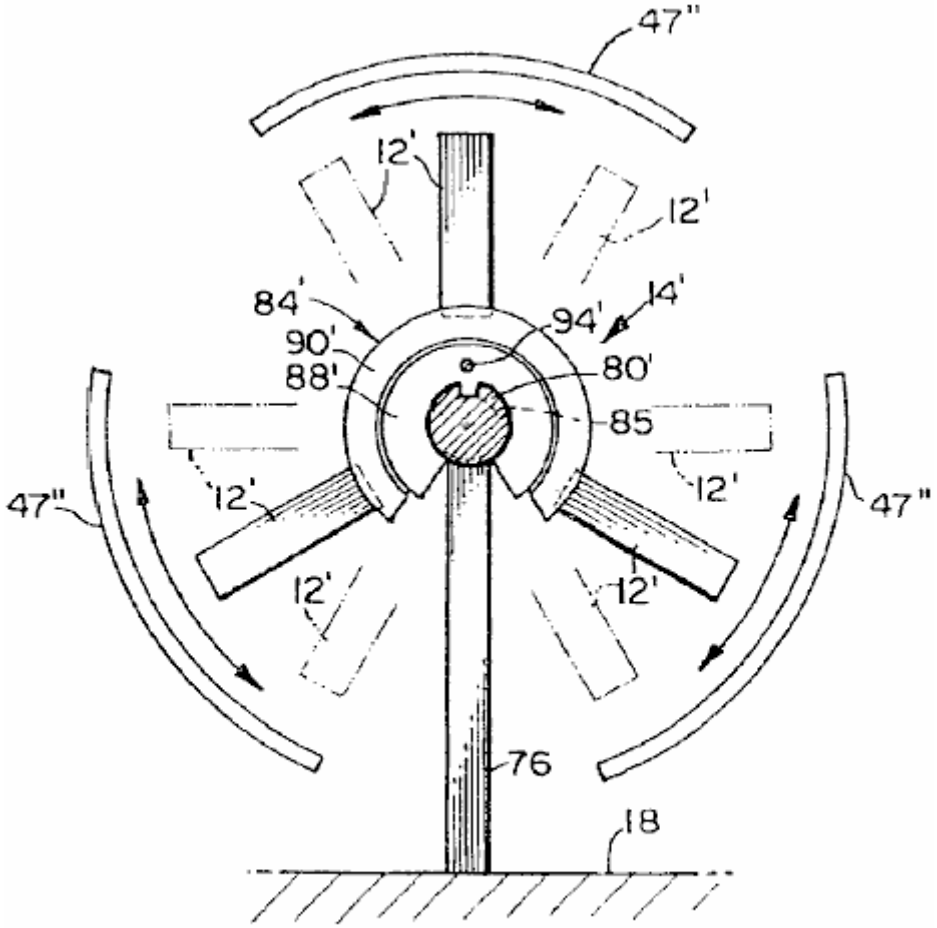

FIG. 17

Referring now to **Fig.5**, **Fig.16** and **Fig.17** there is shown a fifteenth preferred embodiment of the motor **10** comprising a rail **80"** having a longitudinal axis **65** and a generally sinusoidal groove **85** having a pre-determined period running around a periphery of the rail **80"**.

Preferably, the fifteenth preferred embodiment includes three generally identical stators **50"** arrayed in a circular fashion around the rail **80"**. Each stator **50"** has a surface **64** facing the rail **80"** and disposed generally equidistant from and parallel to the axis **65** of the rail **80"**. As shown in **Fig.5** and **Fig.17** each stator **50"** has a generally curved cross-section and a longitudinal line of demarcation **49** perpendicular to the cross-section and located about a midpoint of the surface **64**.

A plurality of stator magnets **68"** are attached to the surface **64** of the stator **50"** generating a first magnetic field. The stator magnets **68"** are displaced on the surface **64** in a sinusoidal pattern around the line of demarcation **49**. The sinusoidal pattern has a pre-determined period and a pre-determined maximum (peak) amplitude along the line of demarcation **49**. In the case where the rail **80"** and the longitudinal line of demarcation **49** of the stator **50"** are in a straight line, the period of the sinusoid is preferably equal to the period of the groove **85** on the rail **80**.

The sinusoidal pattern is also divided into a plurality of first and second alternating sectors with a boundary between the alternating sectors occurring at each maximum (peak) amplitude of the sinusoid. The direction of magnetisation of the stator magnets **68"** is opposite in the first and the second segments so that the direction of the first magnetic field in each first segment is opposite to the direction of the first magnetic field in each second segment. Preferably, the direction of magnetisation of the stator magnets **68"** is generally perpendicular to a radial line of the rotor **12**. Alternatively, the direction of magnetisation of the stator magnets **68"** could be generally aligned with a radial line of the rotor **12**. Further, as will be apparent to those skilled in the art, the first magnetic field need not be formed by a plurality of bar magnets but could be formed from a single magnet so that the first magnetic field would be sinusoidally displaced from the line of demarcation **49** and would alternate in opposite directions between the peaks of the sinusoid. Further, as will be appreciated by those skilled in the art, the displacement of the first magnetic field need not be precisely sinusoidal. For instance the displacement may be in a shape of a sawtooth or in a shape having a portion with constant plus and minus amplitude values, within the spirit and scope of the invention.

Preferably, the fifteenth preferred embodiment includes five rotors **12**, each rotor **12** having an axis **16** aligned with the axis of the rail **80''**. Each rotor **12** is connected to the rail **80''** by a bearing assembly **84'** so that the rotor **12** is free to rotate about the axis of the rail **65** and slide along the rail **80''**. Preferably, each rotor **12** includes three U-shaped magnet pairs **32, 32' 32''**, each pair comprising two U-shaped magnets **20**. Each U-shaped magnet **20** has a rear side and generates a second magnetic field. Each of the U-shaped magnet pairs **32, 32', 32''** is positioned on each rotor **12** so that the rear side **26** of each U-shaped magnet **20** is apposite to the first and the second segments of the sinusoidal pattern as the at least one rotor assembly **14** rotates about the rotor axis **16**, wherein an interaction of a portion of the second magnetic field directly adjacent to the rear **26** of each U-shaped magnet **20** with the first magnetic field of a corresponding stator **50''** causes the at least one rotor **12** to oscillate rotationally about the axis **65** of the rail **80''**. Those skilled in the art will appreciate that it is not necessary to have three pairs of U-shaped magnets **32, 32', 32''**. For instance, the number of U-shaped magnets **20** (or groups of abutted U-shaped magnets) spaced apart around the periphery of the rotor **12** may range from merely a single U-shaped magnet **20**, or may range in number up to a number of magnets limited only by the physical space around the periphery of the rotor **12**. Further the number of abutted U-shaped magnets **20** in a group of magnets **32** may also range from 1 up to a number of magnets limited only by the physical space around the periphery of the rotor **12**. Preferably, the number of stators **50''** equals the number of U-shaped magnet pairs **32, 32', 32''**. However, as will be appreciated by those skilled in the art, the number of stators **50''** is not limited to three but could be any number ranging upward from one, where the number of stators **50''** would preferably equal the number of U-shaped magnet pairs **32, 32', 32''**.

As shown in **Fig.16** the bearing assembly **84'** converts the oscillatory motion of the at least one rotor **12** about the rail to unidirectional linear motion along the rail **80'** by following the sinusoidal groove **85** in the rail **80'** with the boss **92** (shown in **Fig.11B**). A cross-link **94** connects the bearing assembly **84'** of adjacent rotors **12** together, thereby adding together the linear motion of each rotor assembly **14'** along the rail to provide the unidirectional linear motive power. The structure of the bearing assembly **84'** and the cross-link **94** is shown in **Fig.11B** and **Fig.12**, and the operation is identical to the linkage **84'** and the cross-link **94'** described for the twelfth embodiment. Accordingly, a detailed description of the linkage **84'** and the cross-link **94** is not repeated, for the sake of brevity.

In another aspect, the fifteenth preferred embodiment may also be configured in a circular arrangement similar to that of the fourteenth embodiment. In the fifteenth preferred embodiment, the helical stator **82'** shown in **Fig.14** is replaced with one or more curved stators **50''** spaced around the rotors **12**. In this case, the period of the sinusoidal pattern of the stator magnets is adjusted in accordance with the distance of the surface **64** of the respective stator **50''** from the armature axis of rotation **58** in order that the U-shaped magnets **20** on the rotors **12** remain apposite to the first and the second segments, as the rotors **12** slide along the rail **80''**. Accordingly, a description of those elements of circular arrangement of the fifteenth embodiment which are the same as for the linear embodiment are not repeated, for the sake of brevity.

Referring now to **Fig.4**, **Fig.18** and **Fig.19** there is shown a sixteenth preferred embodiment of the motor **10** for providing unidirectional motive power comprising a rail **80''** having a longitudinal axis **65** and a helical groove **86** having a pre-determined pitch, running around a periphery of the rail **80**.

Preferably, the sixteenth preferred embodiment further includes three generally identical stators **50'**, each stator **50'** having a surface **64** disposed generally equidistant from and parallel to the axis **65** of the rail **80**. Each stator **50'** has a longitudinal line of demarcation **49** located about a midpoint of the surface **64**. Preferably, a plurality of stator magnets **68'** are attached to the surface of the stator **50'** generating a first magnetic field. The plurality of stator magnets **68'** have a direction of magnetisation which rotates about a magnetic axis parallel to the line of demarcation **49**. In the case where the rail **80''** and the longitudinal line of demarcation **49** of the stator **50'** are in a straight line, the pitch of the rotation of the stator magnets **68'** is preferably equal to the pre-determined pitch of the helical groove **86** on the rail **80**.

The sixteenth embodiment further includes five rotors **12**, each rotor **12** having an axis of rotation **16** aligned with the axis **65** of the rail **80**. Each rotor **12** is connected to the rail **80** so that the rotor **12** is free to rotate about the axis **65** of the rail **80** and slide along the rail **80**. Each rotor **12** includes three pairs **32, 32', 32''** of U-shaped magnets **20** spaced around the periphery of the rotor **12**, each U-shaped magnet **20** generating a second magnetic field. The U-shaped magnets **20** are positioned on each rotor **12** so that a portion of the second magnetic field directly adjacent to the rear side **26** of the U-shaped magnet **20** interacts with the first magnetic field generated by the plurality of stator magnets **68'** to cause each rotor **12** to rotate about the rotor axis **16**. Those skilled in the art will appreciate that it is not necessary to have exactly three pairs of U-shaped magnets **32, 32', 32''**. For instance, the number of U-shaped magnets **20** (or groups of abutted U-shaped magnets) spaced apart around the periphery of the rotor **12** may range from merely a single U-shaped magnet **20**, or may range in number up to a number of U shaped magnets **20** limited only by the physical space around the periphery of the

rotor **12**. Further the number of abutted U-shaped magnets **20** in a group of magnets **32** may also range from 1 up to a number of magnets limited only by the physical space around the periphery of the rotor **12**.

The sixteenth embodiment also includes a bearing assembly 84' connecting each rotor **12** to the helical groove **86**, the bearing assembly **84'** converting the rotary motion of each rotor **12** about the rail **80'** to unidirectional linear motion along the rail **80'**. A cross-link **94** connects the bearing assembly **84'** of adjacent rotors **12** together, thereby adding together the linear motion of each rotor assembly **14'** along the rail **80'** to provide the unidirectional linear motive power. The structure of the bearing assembly **84'** and the cross-link **94** is shown in **Fig.11B** and **Fig.12**, is identical to the bearing assembly **84'** and cross-link **94** described for the twelfth embodiment. Accordingly, a description of the linkage **84** and the cross-link **94** is not repeated, for the sake of brevity.

In another aspect of the sixteenth preferred embodiment the motor **10** may be configured in a circular arrangement similar to that of the fourteenth embodiment, as shown in **Fig.14**, except that the helical stator **82'** shown in **Fig.14** is replaced with one or more stators **50'** spaced around the rotors **12**. In this case, the pitch of the rotation of the plurality of stator magnets **68'** is adjusted in accordance with the distance of the surface **64** of the respective stator **50'** from the armature axis of rotation **58** in order that the U-shaped magnets **20** on the rotors **12** remain aligned with the plurality of stator magnets **68'** as the rotors **12** rotate about the axis **65** of the rail **80'** and slide along the rail **80'**. Accordingly, a description of those elements of the circular arrangement of the sixteenth embodiment which are the same as for the straight line configuration are not repeated, for the sake of brevity.

It will be appreciated by those skilled in the art that changes could be made to the embodiments described above without departing from the broad inventive concept thereof. It is understood, therefore, that this invention is not limited to the particular embodiments disclosed, but it is intended to cover modifications within the spirit and scope of the present invention as defined by the appended claims.

CLAIMS

1. An apparatus (10, 10') characterised by:

at least one rotor (12) having a periphery and a rotor axis (16), the at least one rotor (12) comprising a first rotor magnet (20) producing a first magnetic field, said first rotor magnet being U-shaped and having a north pole (23), a south pole (25) and a rear side (26), the rear side (26) of the first rotor magnet being adjacent to the periphery;

an axle (80) to which the at least one rotor (12) is connected at the rotor axis (16) for rotation of the at least one rotor (12) about the rotor axis (16); and

a stationary stator (48, 51) comprising a generally curved cross-section, said stator (51) having a surface (64) opposing the periphery of the at least one rotor (12), and a longitudinal line of demarcation (49) perpendicular to the cross-section at about a midpoint of the surface, the line of demarcation (49) delineating a first side (52) of the surface from a second side (54) of the surface (64), wherein a plurality of pairs of stator magnets (40, 42) producing a second magnetic field are attached to the surface (64), each pair of stator magnets (40, 42) comprising a first stator magnet (40) having a north pole and a south pole and a direction of magnetisation substantially parallel to the surface (64), and a second stator magnet (42) having a north pole and a south pole and a direction of magnetisation substantially parallel to the surface (64), the first stator magnet (40) being on the first side of the surface (64) with the north pole of the first stator magnet being closest to the line of demarcation (49), the second stator magnet (42) being on the second side (52) of the surface with the south pole of the second stator magnet (42) being closest to the line of demarcation (49), wherein the plurality of pairs of stator magnets (40, 42) are spaced along the line of demarcation (49) so that a first inter-magnet distance measured along the line of demarcation (49) between the north pole of the first stator magnet (40) and the south pole of the second stator (42) magnet of an adjacent pair of stator magnets (40, 42) is about equal to a second inter-magnet distance measured along the line of demarcation between the south pole of the first stator magnet (40) and the north pole of the second stator magnet (42), and wherein the interaction of the first and the second magnetic fields cause the at least one rotor (12) to translate in a predetermined direction along the line of demarcation.

2. The apparatus (10, 10') of claim 1, characterised by the north pole of each first stator magnet (40) and the south pole of each second stator magnet (42) being inclined toward the predetermined direction.

3. The apparatus (10, 10') of claim 1, further characterised by the rotor (12) including a second rotor magnet (22), said second rotor magnet (24) being U-shaped and having a north pole, a south pole and a rear side, the south pole of the second rotor magnet (22) abutting the north pole of the first rotor magnet (26) and the north pole of the second rotor magnet being adjacent to the periphery, and a third rotor magnet (24), said third rotor

magnet (24) having a north pole, a south pole and a rear side, the north pole of the third rotor magnet (24) abutting the south pole of the first rotor magnet (26) and the south pole of the third rotor magnet (24) being adjacent to the periphery, said second magnet producing a third magnetic field and third magnet producing a fourth magnetic field.

4. The apparatus (10) of claim 1, characterised by the apparatus further including an armature (70) having an armature axis (58), the at least one rotor (12) being spaced from the armature (70) by an armature strut (71) and connected thereto by the axle (80) for rotation about the rotor axis (16), the at least one rotor (12) configured for rotation in a plane generally aligned with the armature axis (58), wherein the stator (51) is circular-cylindrical, with a stator axis (72) aligned with the armature axis (58).

5. The apparatus (10') of claim 1, further characterised by the stator (48) being linear, the stator (48) oriented so that the surface (64) of the stator (48) is generally parallel to the axle (80), each at least one rotor (12) being connected to the axle (80) by a bearing assembly (84) comprising a pair of first bearings (88) slidably attached to the axle (80), and a second bearing (90) connected to the pair of first bearings (88) for rotation about the first pair of bearings (88), said at least one rotor (12) being fixedly attached to the second bearing (90).

6. The apparatus (10') of claim 5, further characterised by a crosslink (94) which connects together the at least one rotors (12).

7. A apparatus (10, 10') characterised by:

at least one rotor (12) having a periphery, a rotor axis (16) and a thruster axis (34) perpendicular to the rotor axis (16) and intersecting the rotor axis (16), the at least one rotor (12) comprising spaced apart first and second rotor magnets (36, 38) having north and south poles aligned with the thruster axis (34), and a third rotor magnet (20, 20') located between the first and second rotor magnets (34, 38) on an axis generally perpendicular to the thruster axis (34), said first, second and third magnets producing a first magnetic field;

an axle (80) to which the at least one rotor (12) is connected at the rotor axis (16) for rotation of the at least one rotor (12) about the rotor axis (16); and

a stationary stator (48', 51') comprising a generally curved cross-section, said stator (48', 51') having a surface 64 opposing the periphery of the at least one rotor (12), and a longitudinal line of demarcation (49) perpendicular to the cross-section at about a midpoint of the surface (64), the line of demarcation (49) delineating a first side (52) of the surface from a second side (54) of the surface, wherein a plurality of sets of stator magnets (40', 42', 41) producing a second magnetic field are attached to the surface (64), each set of stator magnets (40', 42', 41) comprising a first stator magnet (40') having a north pole and a south pole and a direction of magnetisation substantially perpendicular to the surface (64), a second stator magnet (42') having a north pole and a south pole and a direction of magnetisation substantially perpendicular to the surface (64), and a third stator magnet (41), the third stator magnet (41) being attached to the stator (48', 51') along the line of demarcation (49) midway between the first stator magnet (40') and the second stator magnet (42'), the first stator magnet (40') being on the first side (52) of the surface with the south pole of the first stator magnet (40') being closest surface (64), the second stator magnet (42') being on the second side (54) of the surface (64) with the north pole of the second stator magnet (42') being closest to the surface (64), wherein the plurality of sets of stator magnets (40', 42', 41) are spaced along the line of demarcation (49) so that a first inter-magnet distance measured along the line of demarcation (49) between the north pole of the first stator magnet (40') and the south pole of the second stator magnet (42') of an adjacent pair of stator magnets (40', 42', 41) is about equal to a second inter-magnet distance measured along the line of demarcation (49) between the south pole of the first stator magnet (40') and the north pole of the second stator magnet (42'), wherein the interaction of the first and the second magnetic fields cause the at least one rotor (12) to translate in a predetermined direction along the line of demarcation.

8. The apparatus (10, 10') of claim 7, characterised by the third rotor magnet (20) being a U-shaped magnet and the third stator magnet (41) being a bar magnet.

9. The apparatus (10, 10') of claim 7, characterised by the third rotor magnet (20') being a bar magnet and the third stator magnet (41') being a U-shaped magnet.

10. The apparatus (10) of claim 7, characterised by the apparatus further including an armature (70) having an armature axis (58), the at least one rotor (12) being spaced from the armature (70) by an armature strut (71) and connected thereto by the axle (80) for rotation about the rotor axis (16), the at least one rotor (12) being configured for rotation in a plane generally aligned with the armature axis (58), wherein the stator (51') is circular, with a stator axis (72) aligned with the armature axis (58).

11. The apparatus (10') of claim 7, further characterised by the stator (48') being linear, the stator (48') oriented so that the surface (64) of the stator (48') is generally parallel to the axle (80), each at least one rotor (12) being connected to the axle (80) by a bearing assembly (84) comprising a pair of first bearings (88) slidably attached to the axle (80), and a second bearing (90) connected to the pair of first bearings (88) for rotation about the pair of first bearings (88), said at least one rotor (12) being fixedly attached to the second bearing (90).

12. The apparatus (10') of claim 11, further characterised by a crosslink (94) which connects together the at least one rotors (12).

13. An apparatus (10) for providing motion characterised by:

a stationary, generally circular, stator (50, 50', 50'') having a stator axis (58), an outer surface (64), and a circumferential line of demarcation (49) in a plane perpendicular to the stator axis (58) at about a midpoint of the outer surface (64);

at least one stator magnet (68, 68', 68'') attached to the outer surface (64) of the stator (50, 50', 50''), the at least one stator magnet (68, 68', 68'') being arranged in a generally circular arrangement about the stator axis (58);
an armature (70) attached to the stator (50, 50'', 50'') for rotation therewith, the armature (70) having an axis parallel to the stator axis (58);

at least one rotor (12) including at least one rotor magnet (20), the at least one rotor (12) being spaced from the armature (70) by an armature strut (71) and connected thereto by an axle (80) for rotation about a rotor axis (16), the at least one rotor (12) being configured for rotation in a plane generally aligned with the stator axis (58); and

a driving linkage assembly (53, 55, 62) connecting the at least one rotor to the stator, the linkage assembly (53, 55, 62) configured to cause the armature (70) to rotate about the stator axis (58) when the at least one rotor (12) rotates about the rotor axis (16).

14. The apparatus according to claim 13 wherein a direction of magnetisation of the at least one stator magnet (68) is generally perpendicular to a radial line of the at least one rotor (12).

15. The apparatus according to claim 13 wherein a direction of magnetisation of the at least one stator magnet (68) is generally aligned with a radial line of the at least one rotor (12).

16. The apparatus according to claim 13 wherein the at least one rotor magnet (20) comprises a U-shaped magnet.

17. The apparatus according to claim 13 wherein the at least one rotor magnet (20) comprises a bar magnet and the at least one stator magnet (68) is a U-shaped magnet.

18. The apparatus according to claim 13, the at least one stator magnet (68') having a direction of magnetisation which rotates about the circumferential line of demarcation (49) with a predetermined periodicity.

19. The apparatus according to claim 13, the at least one stator magnet (68'') having a direction of magnetisation in a plane of the stator (50'') and which is displaced in a sinusoidal pattern from the line of demarcation (49), the sinusoidal pattern having a pre-determined period and a pre-determined maximum amplitude and divided into a plurality of alternating first and second sectors with a boundary between the alternating first and second sectors occurring at peak amplitudes of the sinusoid, the direction of magnetisation of the at least one magnet (68'') being opposite in direction in the first and the second segments.

HOWARD JOHNSON

Patent US 4,151,431 **24th April 1979** **Inventor: Howard R. Johnson**

PERMANENT MAGNET MOTOR

This is a re-worded extract from this Patent. It describes a motor powered solely by permanent magnets and which it is claimed can power an electrical generator.

ABSTRACT

The invention is directed to the method of utilising the unpaired electron spins in ferromagnetic and other materials as a source of magnetic fields for producing power without any electron flow as occurs in normal conductors, and to permanent magnet motors for utilising this method to produce a power source. In the practice of the invention the unpaired electron spins occurring within permanent magnets are utilised to produce a motive power source solely through the superconducting characteristics of a permanent magnet, and the magnetic flux created by the magnets is controlled and concentrated to orientate the magnetic forces generated in such a manner to produce useful continuous work, such as the displacement of a rotor with respect to a stator. The timing and orientation of magnetic forces at the rotor and stator components produced by the permanent magnets is accomplished by the proper geometrical relationship of these components.

BACKGROUND OF THE INVENTION:

Conventional electric motors employ magnetic forces to produce either rotational or linear motion. Electric motors operate on the principal that when a conductor which carries a current is located in a magnetic field, a magnetic force is exerted upon it. Normally, in a conventional electric motor, the rotor, or stator, or both, are so wired that magnetic fields created by electromagnets use attraction, repulsion, or both types of magnetic forces, to impose a force upon the armature causing rotation, or linear displacement of the armature. Conventional electric motors may employ permanent magnets either in the armature or stator components, but to date they require the creation of an electromagnetic field to act upon the permanent magnets. Also, switching gear is needed to control the energising of the electromagnets and the orientation of the magnetic fields producing the motive power.

It is my belief that the full potential of magnetic forces existing in permanent magnets has not been recognised or utilised because of incomplete information and theory with respect to atomic motion occurring within a permanent magnet. It is my belief that a presently unnamed atomic particle is associated with the electron movement of a superconducting electromagnet and the loss-less flow of currents in permanent magnets. The unpaired electron flow is similar in both situations. This small particle is believed to be opposite in charge to an electron and to be located at right angles to the moving electron. This particle must be very small to penetrate all known elements in their various states as well as their known compounds (unless they have unpaired electrons which capture these particles as they endeavour to pass through).

The electrons in ferrous materials differ from those found in most elements in that they are unpaired, and being unpaired they spin around the nucleus in such a way that they respond to magnetic fields as well as creating a magnetic field themselves. If they were paired, their magnetic fields would cancel out. However, being unpaired they create a measurable magnetic field if their spins are orientated in one direction. The spins are at right angles to their magnetic fields.

In niobium superconductors, at a critical state, the magnetic lines of force cease to be at right angles. This change must be due to establishing the required conditions for unpaired electronic spins instead of electron flow in the conductor, and the fact that very powerful electromagnets can be formed with superconductors illustrates the tremendous advantage of producing the magnetic field by unpaired electron spins rather than conventional electron flow. In a superconducting metal, wherein the electrical resistance becomes greater in the metal than the proton resistance, the flow turns to electron spins and the positive particles flow parallel in the metal in the manner occurring in a permanent magnet where a powerful flow of magnetic positive particles or magnetic flux

causes the unpaired electrons to spin at right angles. Under cryogenic superconduction conditions the freezing of the crystals in place makes it possible for the spins to continue, and in a permanent magnet the grain orientation of the magnetised material allows these spins, permitting them to continue and causing the flux to flow parallel to the metal. In a superconductor, at first the electron is flowing and the positive particle is spinning; later, when critical, the reverse occurs, i.e., the electron is spinning and the positive particle is flowing at right angles. These positive particles will thread or work their way through the electron spins present in the metal.

In a sense, a permanent magnet may be considered a room-temperature superconductor. It is a superconductor because the electron flow does not cease, and this electron flow can be made to do work through the magnetic field which it creates. Previously, this source of power has not been used because it was not possible to modify the electron flow to accomplish the switching functions of the magnetic field. Such switching functions are common in a conventional electric motor where electrical current is employed to align the much greater electron current in the iron pole pieces and concentrate the magnetic field at the proper places to give the thrust necessary to move the motor armature. In a conventional electric motor, switching is accomplished by the use of brushes, commutators, alternating current, or other means.

In order to accomplish the switching function in a permanent magnet motor, it is necessary to shield the magnetic leakage so that it will not appear as too great a loss factor at the wrong places. The best method to accomplish this is to concentrate the magnetic flux in the place where it will be the most effective. Timing and switching can be achieved in a permanent magnet motor by concentrating the flux and using the proper geometry of the motor rotor and stator to make most effective use of the magnetic fields. By the proper combination of materials, geometry and magnetic concentration, it is possible to achieve a mechanical advantage of high ratio, greater than 100 to 1, capable of producing continuous motive force.

To my knowledge, previous work done with permanent magnets, and motive devices utilising permanent magnets, have not achieved the result desired in the practice of the inventive concept, and it is with the proper combination of materials, geometry and magnetic concentration that the presence of the magnetic spins within a permanent magnet may be utilised as a motive force.

SUMMARY OF THE INVENTION:

It is an object of the invention to utilise the magnetic spinning phenomenon of unpaired electrons occurring in ferromagnetic material to produce the movement of a mass in a unidirectional manner so as to permit a motor to be driven solely by the magnetic forces occurring within permanent magnets. Both linear and rotational types of motor may be produced. It is an object of the invention to provide the proper combination of materials, geometry and magnetic concentration to power a motor. Whether the motor is a linear type or a rotary type, in each instance the "stator" may consist of several permanent magnets fixed relative to each other, to create a track. This track is linear for a linear motor and circular for a rotary motor. An armature magnet is carefully positioned above this track so that an air gap exists between it and the track. The length of the armature magnet is defined by poles of opposite polarity, and the longer axis of the armature magnet is pointed in the direction of its movement.

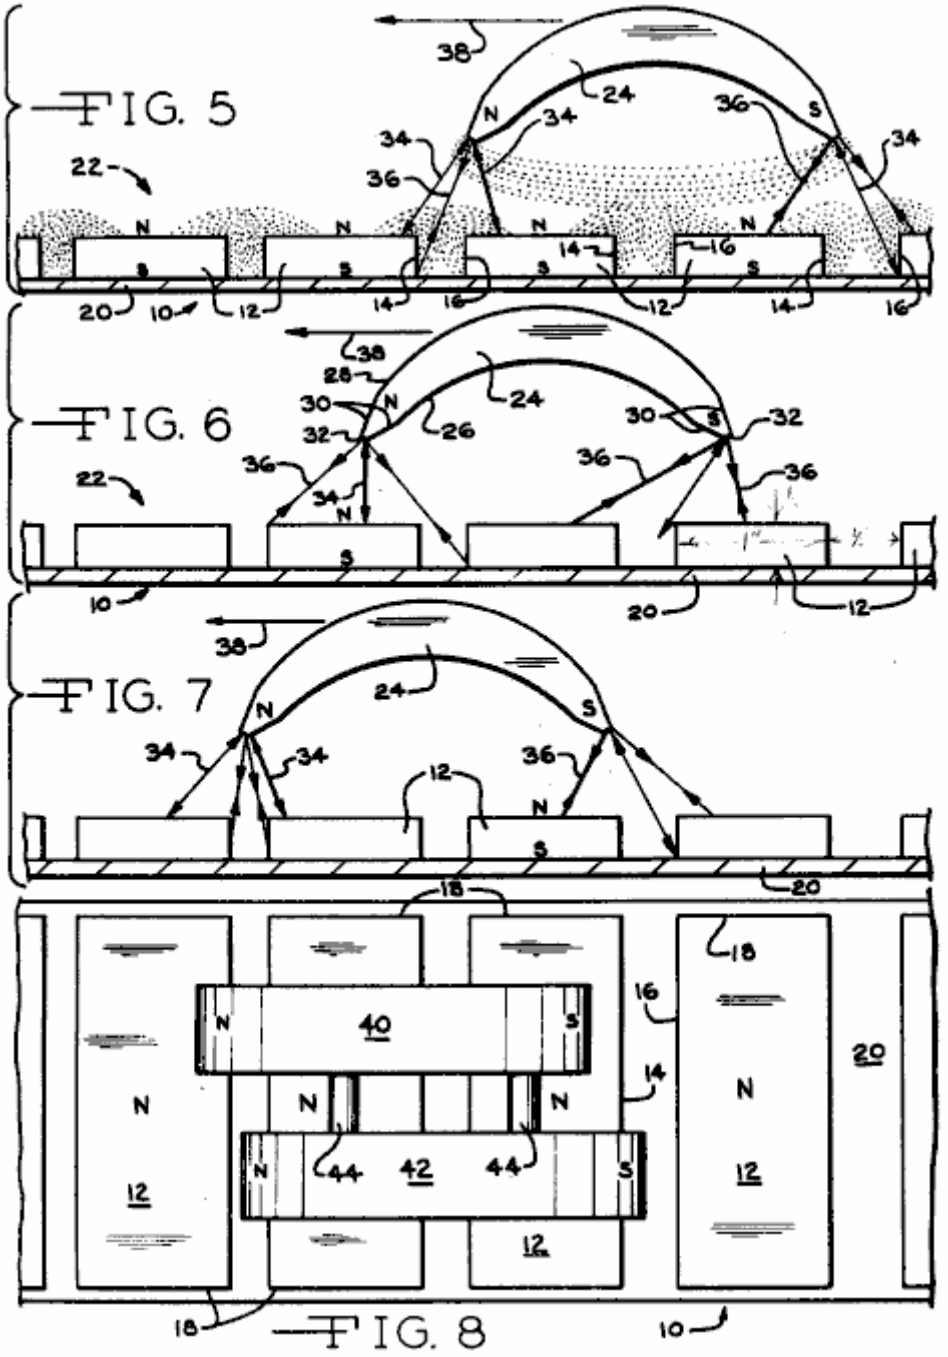
The stator magnets are mounted so that all the same poles face the armature magnet. The armature magnet has poles which are both attracted to and repelled by the adjacent pole of the stator magnets, so both attractive and repulsive forces act upon the armature magnet to make it move.

The continuing motive force which acts on the armature magnet is caused by the relationship of the length of the armature magnet to the width and spacing of the stator magnets. This ratio of magnet and magnet spacings, and with an acceptable air gap spacing between the stator and armature magnets, produces a continuous force which causes the movement of the armature magnet.

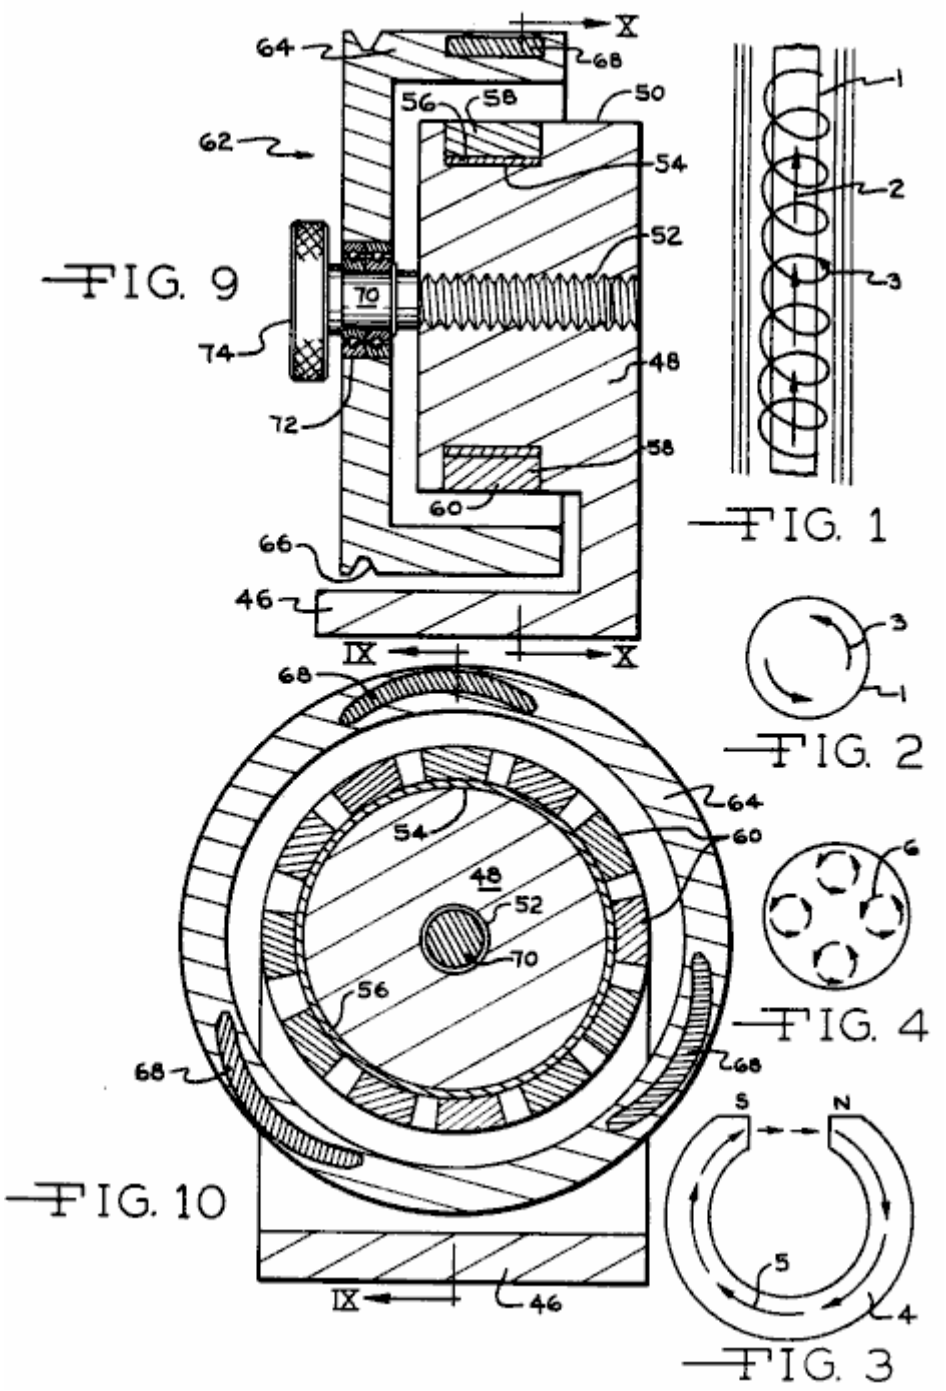
In the practice of the invention, movement of the armature magnet relative to the stator magnets results from a combination of attractive and repulsive forces between the stator and armature magnets. By concentrating the magnetic fields of the stator and armature magnets the motive force imposed upon the armature magnet is intensified, and in the disclosed embodiments, the means for achieving this magnetic field concentration are shown.

This method comprises of a plate of high magnetic field permeability placed behind one side of the stator magnets and solidly engaged with them. The magnetic field of the armature magnet may be concentrated and directionally oriented by bowing the armature magnet, and the magnetic field may further be concentrated by shaping the pole ends of the armature magnet to concentrate the magnet field at a relatively limited surface at the armature magnet pole ends.

Preferably, several armature magnets are used and these are staggered relative to each other in the direction their movement. Such an offsetting or staggering of the armature magnets distributes the impulses of force



imposed upon the armature magnets and results in a smoother application of forces to the armature magnet producing a smoother and more uniform movement of the armature component.



In the rotary embodiment of the permanent magnet motor of the invention the stator magnets are arranged in a circle, and the armature magnets rotate about the stator magnets. A mechanism is shown which can move the armature relative to the stator and this controls the magnitude of the magnetic forces, altering the speed of rotation of the motor.

BRIEF DESCRIPTION OF THE DRAWINGS

The objects and advantages of the invention mentioned earlier, will be appreciated from the following description and accompanying drawings:

Fig. 1 is a schematic view of electron flow in a superconductor indicating the unpaired electron spins,
Fig. 2 is a cross-sectional view of a superconductor under a critical state illustrating the electron spins,
Fig. 3 is a view of a permanent magnet illustrating the flux movement through it,
Fig. 4 is a cross-sectional view illustrating the diameter of the magnet of Fig.3,
Fig. 5 is an elevational representation of a linear motor embodiment of the permanent magnet motor of the invention illustrating one position of the armature magnet relative to the stator magnets, and indicating the magnetic forces imposed upon the armature magnet,
Fig. 6 is a view similar to Fig.5 illustrating displacement of the armature magnet relative to the stator magnets, and the influence of magnetic forces thereon at this location,
Fig. 7 is a further elevational view similar to Fig.5 and Fig.6 illustrating further displacement of the armature magnet to the left, and the influence of the magnetic forces thereon,
Fig. 8 is a top plan view of a linear embodiment of the inventive concept illustrating a pair of armature magnets in linked relationship disposed above the stator magnets,
Fig. 9 is a diametrical, elevational, sectional view of a rotary motor embodiment in accord with the invention as taken along section IX-IX of Fig.10, and
Fig. 10 is an elevational view of the rotary motor embodiment as taken along X-X of Fig.9.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

In order to better understand the theory of the inventive concept, reference is made to **Figs. 1 through 4**. In **Fig.1** a superconductor 1 is illustrated having a positive particle flow as represented by arrow **2**, the unpaired electrons of the ferrous conductor **1** spin at right angles to the proton flow in the conductor as represented by the spiral line and arrow **3**. In accord with the theory of the invention the spinning of the ferrous unpaired electrons results from the atomic structure of ferrous materials and this spinning atomic particle is believed to be opposite in charge and located at right angles to the moving electrons. It is assumed to be very small in size capable of penetrating other elements and their compounds unless they have unpaired electrons which capture these particles as they endeavour to pass through.

The lack of electrical resistance of conductors at a critical superconductor state has long been recognised, and superconductors have been utilised to produce very high magnetic flux density electromagnets. **Fig.2** represents a cross section of a critical superconductor and the electron spins are indicated by the arrows **3**. A permanent magnet may be considered a superconductor as the electron flow therein does not cease, and is without resistance, and unpaired electric spinning particles exist which, in the practice of the invention, are utilised to produce motor force. **Fig.3** illustrates a horseshoe shaped permanent magnet at **4** and the magnetic flux through it is indicated by arrows **5**, the magnetic flow being from the south pole to the north pole and through the magnetic material. The accumulated electron spins occurring about the diameter of the magnet **5** are represented at **6** in

Fig.4, and the spinning electron particles spin at right angles in the iron as the flux travels through the magnet material.

By utilising the electron spinning theory of ferrous material electrons, it is possible with the proper ferromagnetic materials, geometry and magnetic concentration to utilise the spinning electrons to produce a motive force in a continuous direction, thereby resulting in a motor capable of doing work.

It is appreciated that the embodiments of motors utilising the concepts of the invention may take many forms, and in the illustrated forms the basic relationships of components are illustrated in order to disclose the inventive concepts and principles. The relationships of the plurality of magnets defining the stator 10 are best appreciated from **Figs. 5 through 8**. The stator magnets **12** are preferably of a rectangular configuration, **Fig.8**, and so magnetised that the poles exist at the large surfaces of the magnets, as will be appreciated from the N (North) and S (South) designations. The stator magnets include side edges **14** and **16** and end edges **18**. The stator magnets are mounted upon a supporting plate **20**, which is preferably of a metal having a high permeability to magnetic fields and magnetic flux such as that available under the trademark Netic CoNetic sold by Perfection Mica Company of Chicago, Illinois. Thus, the plate **20** will be disposed toward the south pole of the stator magnets **12**, and preferably in direct engagement therewith, although a bonding material may be interposed between the magnets and the plate in order to accurately locate and fix the magnets on the plate, and position the stator magnets with respect to each other.

Preferably, the spacing between the stator magnets **12** slightly differs between adjacent stator magnets as such a variation in spacing varies the forces being imposed upon the armature magnet at its ends, at any given time, and thus results in a smoother movement of the armature magnet relative to the stator magnets. Thus, the stator magnets so positioned relative to each other define a track **22** having a longitudinal direction left to right as viewed in **Figs. 5 through 8**.

In **Figs. 5 through 7** only a single armature magnet **24** is disclosed, while in **Fig.8** a pair of armature magnets are shown. For purposes of understanding the concepts of the invention the description herein will be limited to the use of single armature magnet as shown in **Figs. 5 through 7**.

The armature magnet is of an elongated configuration wherein the length extends from left to right, **Fig.5**, and may be of a rectangular transverse cross-sectional shape. For magnetic field concentrating and orientation purposes the magnet **24** is formed in an arcuate bowed configuration as defined by concave surfaces **26** and convex surfaces **28**, and the poles are defined at the ends of the magnet as will be appreciated from **Fig.5**. For further magnetic field concentrating purposes the ends of the armature magnet are shaped by bevelled surfaces **30** to minimise the cross sectional area at the magnet ends **32**, and the magnetic flux existing between the poles of the armature magnet are as indicated by the light dotted lines. In like manner the magnetic fields of **6** the stator magnets **12** are indicated by the light dotted lines.

The armature magnet **24** is maintained in a spaced relationship above the stator track **22**. This spacing may be accomplished by mounting the armature magnet upon a slide, guide or track located above the stator magnets, or the armature magnet could be mounted upon a wheeled vehicle carriage or slide supported upon a non-magnetic surface or guideway disposed between the stator magnets and the armature magnet. To clarify the illustration, the means for supporting the armature magnet **24** is not illustrated and such means form no part of invention, and it is to be understood that the means supporting the armature magnet prevents the armature magnet from moving away from the stator magnets, or moving closer thereto, but permits free movement of the armature magnet to the left or right in a direction parallel to the track **22** defined by the stator magnets.

It will be noted that the length of the armature magnet **24** is slightly greater than the width of two of the stator magnets **12** and the spacing between them. The magnetic forces acting upon the armature magnet when in the position of **Fig.5** will be repulsion forces **34** due to the proximity of like polarity forces and attraction forces at **36** because of the opposite polarity of the south pole of the armature magnet, and the north pole field of the sector magnets. The relative strength of this force is represented by the thickness of the force line.

The resultant of the force vectors imposed upon the armature magnet as shown in **Fig.5** produce a primary force vector **38** toward the left, **Fig.5**, displacing the armature magnet **24** toward the left. In **Fig.6** the magnetic forces acting upon the armature magnet are represented by the same reference numerals as in **Fig.5**. While the forces **34** constitute repulsion forces tending to move the north pole of the armature magnet away from the stator magnets, the attraction forces imposed upon the south pole of the armature magnet and some of the repulsion forces, tend to move the armature magnet further to the left, and as the resultant force **38** continues to be toward the left the armature magnet continues to be forced to the left. **Fig.7** represents further displacement of the armature magnet **24** to the left with respect to the position of **Fig.6**, and the magnetic forces acting thereon are represented by the same reference numerals as in **Fig.5** and **Fig.6**, and the stator magnet will continue to move to the left, and such movement continues the length of the track **22** defined by the stator magnets **12**.

Upon the armature magnet being reversed such that the north pole is positioned at the right as viewed in **Fig.5**, and the south pole is positioned at the left, the direction of movement of the armature magnet relative to the stator magnets is toward the right, and the theory of movement is identical to that described above.

In **Fig.8** a plurality of armature magnets **40** and **42** are illustrated which are connected by links **44**. The armature magnets are of a shape and configuration identical to that of the embodiment of **Fig.5**, but the magnets are staggered with respect to each other in the direction of magnet movement, i.e., the direction of the track **22** defined by the stator magnets **12**. By so staggering a plurality of armature magnets a smoother movement of the interconnected armature magnets is produced as compared when using a single armature magnet as there is variation in the forces acting upon each armature magnet as it moves above the track **22** due to the change in magnetic forces imposed thereon. The use of several armature magnets tends to "smooth out" the application of forces imposed upon linked armature magnets, resulting in a smoother movement of the armature magnet assembly. Of course, any number of armature magnets may be interconnected, limited only by the width of the stator magnet track **22**.

In **Fig.9** and **Fig.10** a rotary embodiment embracing the inventive concepts is illustrated. In this embodiment the principle of operation is identical to that described above, but the orientation of the stator and armature magnets is such that rotation of the armature magnets is produced about an axis, rather than a linear movement being achieved.

In **Fig.9** and **Fig.10** a base is represented at **46** serving as a support for a stator member **48**. The stator member **48** is made of a non-magnetic material, such as synthetic plastic, aluminium, or the like. The stator includes a cylindrical surface **50** having an axis, and a threaded bore **52** is concentrically defined in the stator. The stator includes an annular groove **54** receiving an annular sleeve **56** of high magnetic field permeability material such as Netic Co-Netic and a plurality of stator magnets **58** are affixed upon the sleeve **56** in spaced circumferential relationship as will be apparent in **Fig.10**. Preferably, the stator magnets **58** are formed with converging radial sides as to be of a wedge configuration having a curved inner surface engaging sleeve **56**, and a convex pole surface **60**.

The armature **62**, in the illustrated embodiment, is of a dished configuration having a radial web portion, and an axially extending portion **64**. The armature **62** is formed of a non-magnetic material, and an annular belt receiving groove **66** is defined therein for receiving a belt for transmitting power from the armature to a generator, or other power consuming device. Three armature magnets **68** are mounted on the armature portion **64**, and such magnets are of a configuration similar to the armature magnet configuration of **Figs. 5 through 7**.

The magnets **68** are staggered with respect to each other in a circumferential direction wherein the magnets are not placed exactly 120 degrees apart but instead, a slight angular staggering of the armature magnets is desirable to "smooth out" the magnetic forces being imposed upon the armature as a result of the magnetic forces being simultaneously imposed upon each of the armature magnets. The staggering of the armature magnets **68** in a circumferential direction produces the same effect as the staggering of the armature magnets **40** and **42** as shown in **Fig.8**.

The armature **62** is mounted upon a threaded shaft **70** by anti-friction bearings **72**, and the shaft **70** is threaded into the stator threaded bore **52**, and may be rotated by the knob **74**. In this manner rotation of the knob **74**, and shaft **70**, axially displaces the armature **62** with respect to the stator magnets **58**, and such axial displacement will very the magnitude of the magnetic forces imposed upon the armature magnets **68** by the stator magnets thereby controlling the speed of rotation of the armature. As will be noted from **Figs. 4 to 7, 9 and 10**, an air gap exists between the armature magnets and the stator magnets and the dimension of this spacing, effects the magnitude of the forces imposed upon the armature magnet or magnets. If the distance between the armature magnets and the stator magnets is reduced the forces imposed upon the armature magnets by the stator magnets are increased, and the resultant force **8** vector tending to displace the armature magnets in their path of movement increases. However, the decreasing of the spacing between the armature and stator magnets creates a "pulsation" in the movement of the armature magnets which is objectionable, but can be, to some extent, minimised by using a plurality of armature magnets. Increasing the distance between the armature and stator magnets reduces the pulsation tendency of the armature magnet, but also reduces the magnitude of the magnetic forces imposed upon the armature magnets. Thus, the most effective spacing between the armature and stator magnets is that spacing which produces the maximum force vector in the direction of armature magnet movement, with a minimum creation of objectionable pulsation.

In the disclosed embodiments the high permeability plate **20** and sleeve **56** are disclosed for concentrating the magnetic field of the stator magnets, and the armature magnets are bowed and have shaped ends for magnetic field concentration purposes. While such magnetic field concentration means result in higher forces imposed upon

the armature magnets for given magnet intensities, it is not intended that the inventive concepts be limited to the use of such magnetic field concentrating means.

As will be appreciated from the above description of the invention, the movement of the armature magnet or magnets results from the described relationship of components. The length of the armature magnets as related to the width of the stator magnets and spacing between them, the dimension of the air gap and the configuration of the magnetic field, combined, produce the desired result and motion. The inventive concepts may be practised even though these relationships may be varied within limits not yet defined and the invention is intended to encompass all dimensional relationships which achieve the desired goal of armature movement. By way of example, with respect to **Figs. to 7**, the following dimensions were used in an operating prototype:

The length of armature magnet **24** is 3.125", the stator magnets **12** are 1" wide, .25" thick and 4" long and grain oriented. The air gap between the poles of the armature magnet and the stator magnets is approximately 1.5" and the spacing between the stator magnets is approximately .5" inch.

In effect, the stator magnets define a magnetic field track of a single polarity transversely interrupted at spaced locations by the magnetic fields produced by the lines of force existing between the poles of the stator magnets and the unidirectional force exerted on the armature magnet is a result of the repulsion and attraction forces existing as the armature magnet traverses this magnetic field track.

It is to be understood that the inventive concept embraces an arrangement wherein the armature magnet component is stationary and the stator assembly is supported for movement and constitutes the moving component, and other variations of the inventive concept will be apparent to those skilled in the art without departing from the scope thereof. As used herein the term "track" is intended to include both linear and circular arrangements of the static magnets, and the "direction" or "length" of the track is that direction parallel or concentric to the intended direction of armature magnet movement.

CLAIMS

1. A permanent magnet motor comprising, in combination, a stator track defining a track direction and having first and second sides and composed of a plurality of track permanent magnets each having first and second poles of opposite polarity, said magnets being disposed in side-by-side relationship having a spacing between adjacent magnets and like poles defining said track sides, an elongated armature permanent magnet located on one of said track sides for relative movement thereto and in spaced relationship to said track side wherein an air gap exists between said armature magnet and said track magnets, said armature magnet having first and second poles of opposite polarity located at the opposite ends of said armature magnet deeming the length thereof, the length of said armature magnet being disposed in a direction in general alignment with the direction of said track, the spacing of said armature magnet poles from said track associated side and the length of said armature magnet as related to the width and spacing of said track magnets in the direction of said track being such as to impose a continuous force on said armature magnet in said general direction of said track.

2. In a permanent magnet motor as in claim 1 wherein the spacing between said poles of said armature and the adjacent stator track side are substantially equal.

3. In a permanent magnet motor as in claim 1 wherein the spacing between adjacent track magnets varies.

4. In a permanent magnet motor as in claim 1 wherein a plurality of armature magnets are disposed on a common side of said stator track, said armature magnets being mechanically interconnected.

5. In a permanent magnet motor as in claim 4 wherein said armature magnets are staggered with respect to each other in the direction of said track.

6. In a permanent magnet motor as in claim 1 wherein magnetic field concentrating means are associated with said track magnets.

7. In a permanent magnet motor as in claim 6 wherein said field concentrating means comprises a sheet of magnetic material of high field permeability engaging side and pole of said track opposite to that side and pole disposed toward said armature magnet.

8. In a permanent magnet as in claim 1 wherein said armature magnet is of an arcuate configuration in its longitudinal direction bowed toward said track, said armature magnet having ends shaped to concentrate the magnetic field at said ends.

9. In a permanent magnet motor as in claim 1 wherein said stator track is of a generally linear configuration, and means supporting said armature magnet relative to said track for generally linear movement of said armature magnet.

10. In a permanent magnet motor as in claim 1 wherein said stator track magnets define a circle having an axis, an armature rotatably mounted with respect to said track and concentric and coaxial thereto, said armature magnet being mounted upon said armature.

11. In a permanent magnet motor as in claim 10, means axially adjusting said armature relative to said track whereby the axial relationship of said armature magnet and said stator magnets may be varied to adjust the rate of rotation of said armature.

12. In a permanent magnet motor as in claim 10 wherein a plurality of armature magnets are mounted on said armature.

13. In a permanent magnet motor as in claim 12 wherein said armature magnets are circumferentially non-uniformly spaced on said armature.

14. A permanent magnet motor comprising, in combination, a stator comprising a plurality of circumferentially spaced stator permanent magnets having poles of opposite polarity, said magnets being arranged to substantially define a circle having an axis, the poles of said magnets facing in a radial direction with respect to said axis and poles of the same polarity facing away from said axis and the poles of opposite polarity facing toward said axis, an armature mounted for rotation about said axis and disposed adjacent said stator, at least one armature permanent magnet having poles of opposite polarity mounted on said armature and in radial spaced relationship to said circle of stator magnets, said armature magnet poles extending in the circumferential direction of armature rotation, the spacing of said armature magnet poles from said stator magnets and the circumferential length of said armature magnet and the spacing of said stator magnets being such as to impose a continuing circumferential force on said armature magnet to rotate said armature.

15. In a permanent magnet motor as in claim 14 wherein a plurality of armature magnets are mounted upon said armature.

16. In a permanent magnet motor as in claim 14 wherein said armature magnets are asymmetrically circumferentially spaced on said armature.

17. In a permanent magnet motor as in claim 14 wherein the poles of said armature magnet are shaped to concentrate the magnetic field thereof.

18. In a permanent magnet motor as in claim 14, magnetic field concentrating means associated with said stator magnets concentrating the magnetic fields thereof at the spacings between adjacent stator magnets.

19. In a permanent magnet motor as in claim 18 wherein said magnet field concentrating means comprises an annular ring of high magnetic field permeability material concentric with said axis and in substantial engagement with poles of like polarity of said stator magnets.

20. In a permanent magnet motor as in claim 14 wherein said armature magnet is of an arcuate bowed configuration in the direction of said poles thereof defining a concave side and a convex side, said concave side being disposed toward said axis, and said poles of said armature magnet being shaped to concentrate the magnetic field between said poles thereof.

21. In a permanent magnet motor as in claim 14, means for axially displacing said stator and armature relative to each other to adjust the axial alignment of said stator and armature magnets.

22. The method of producing a unidirectional motive force by permanent magnets using a plurality of spaced stator permanent magnets having opposite polarity poles defining a track having a predetermined direction, and an armature magnet having a length defined by poles of opposite polarity movably mounted for movement relative to the track in the direction thereof, and of a predetermined length determined by the width and dimensions of said stator magnets comprising forming a magnetic field track by said stator magnets having a magnetic field of common polarity interrupted at spaced locations in a direction transverse to the direction of said magnetic field track by magnetic fields created by magnetic lines of force existing between the poles of the stator magnets and positioning the armature magnet in spaced relation to said magnetic field track longitudinally related to the direction of the magnetic field track such a distance that the repulsion and attraction forces imposed on the armature magnet by said magnetic field track imposes a continuing unidirectional force on the armature magnet in the direction of the magnetic field track.

23. The method of producing a unidirectional motive force as in claim 22 including concentrating the magnetic fields created by magnetic lines of force between the poles of the stator magnets.

24. The method of producing a unidirectional motive force as in claim 22 including concentrating the magnetic field existing between the poles of the armature magnet.

25. The method of producing a unidirectional motive force as in claim 22 including concentrating the magnetic fields created by magnetic lines of force between the poles of the stator magnets and concentrating the 12 magnetic field existing between the poles of the armature magnet.

26. The method of producing a motive force by permanent magnets wherein the unpaired electron spinning particles existing within a permanent magnet are utilised for producing a motive force comprising forming a stator magnetic field track by means of at least one permanent magnet, producing an armature magnetic field by means of a permanent magnet and shaping and locating said magnetic fields in such a manner as to produce relative continuous unidirectional motion between said stator and armature field producing magnets.

27. The method of producing a motive force by permanent magnets as in claim 26 wherein said stator magnetic field is substantially of a single polarity.

28. The method of producing a motive force by permanent magnets as in claim 26 including concentrating the magnetic field of said stator field track and armature magnetic field.

US Patent 5,625,241 **29th April 1997** **Inventor: Harold E. Ewing et al.**

CAROUSEL ELECTRIC GENERATOR

This is a reworded excerpt form this patent which shows a compact, self-powered, combined permanent magnet motor and electrical generator. There is a little extra information at the end of this document.

ABSTRACT

A permanent magnet generator or motor having stationary coils positioned in a circle, a rotor on which are mounted permanent magnets grouped in sectors and positioned to move adjacent to the coils, and a carousel carrying corresponding groups of permanent magnets through the centres of the coils, the carousel movies with the rotor by virtue of its being magnetically coupled to it.

BACKGROUND OF THE INVENTION

There are numerous applications for small electric generators in ratings of a few kilowatts or less. Examples include electric power sources for emergency lighting in commercial and residential buildings, power sources for remote locations such as mountain cabins, and portable power sources for motor homes, pleasure boats, etc.

In all of these applications, system reliability is a primary concern. Because the power system is likely to sit idle for long periods of time without the benefit of periodic maintenance, and because the owner-operator is often inexperienced in the maintenance and operation of such equipment, the desired level of reliability can only be achieved through system simplicity and the elimination of such components as batteries or other secondary power sources which are commonly employed for generator field excitation.

Another important feature for such generating equipment is miniaturisation particularly in the case of portable equipment. It is important to be able to produce the required level of power in a relatively small generator.

Both of these requirements are addressed in the present invention through a novel adaptation of the permanent magnet generator or magneto in a design that lends itself to high frequency operation as a means for maximising power output per unit volume.

DESCRIPTION OF THE PRIOR ART

Permanent magnet generators or magnetos have been employed widely for many years. Early applications of such generators include the supply of electric current for spark plugs in automobiles and aeroplanes. Early telephones used magnetos to obtain electrical energy for ringing. The Model T Ford automobile also used magnetos to power its electric lights.

The present invention differs from prior art magnetos in terms of its novel physical structure in which a multiplicity of permanent magnets and electrical windings are arranged in a fashion which permits high-speed/high-frequency operation as a means for meeting the miniaturisation requirement. In addition, the design is enhanced through the

use of a rotating carousel which carries a multiplicity of field source magnets through the centres of the stationary electric windings in which the generated voltage is thereby induced.

SUMMARY OF THE INVENTION

In accordance with the invention claimed, an improved permanent magnet electric generator is provided with a capability for delivering a relatively high level of output power from a small and compact structure. The incorporation of a rotating carousel for the transport of the primary field magnets through the electrical windings in which induction occurs enhances field strength in the locations critical to generation.

It is, therefore, one object of this invention to provide an improved permanent magnet generator or magneto for the generation of electrical power. Another object of this invention is to provide in such a generator a relatively high level of electrical power from a small and compact structure. A further object of this invention is to achieve such a high level of electrical power by virtue of the high rotational speed and high frequency operation of which the generator of the invention is capable.

A further object of this invention is to provide such a high frequency capability through the use of a novel field structure in which the primary permanent magnets are carried through the centres of the induction windings of the generator by a rotating carousel.

A still further object of this invention is to provide a means for driving the rotating carousel without the aid of mechanical coupling but rather by virtue of magnetic coupling between other mechanically driven magnets and those mounted on the carousel.

A still further object of this invention is to provide an enhanced capability for high speed/high frequency operation through the use of an air bearing as a support for the rotating carousel.

Yet another object of this invention is to provide in such an improved generator a sufficiently high magnetic field density in the locations critical to voltage generation without resort to the use of laminations or other media to channel the magnetic field.

Further objects an advantages of the invention will become apparent as the following description proceeds and the features of novelty which characterise the invention will be pointed out with particularity in the claims annexed to and forming a part of this specification.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention may be more readily described by reference to the accompanying drawings, in which:

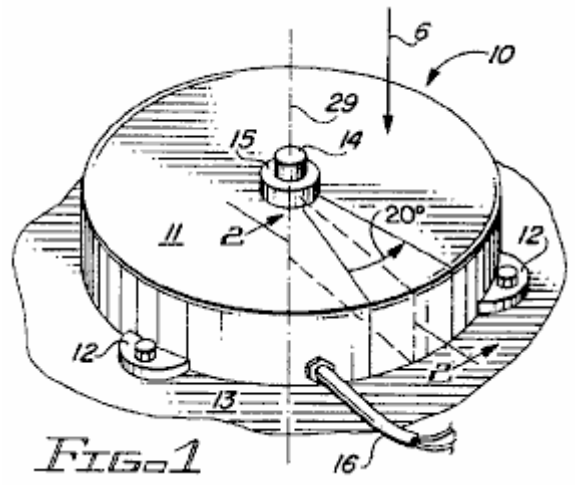

FIG-1

Fig.1 is a simplified perspective view of the carousel electric generator of the invention;

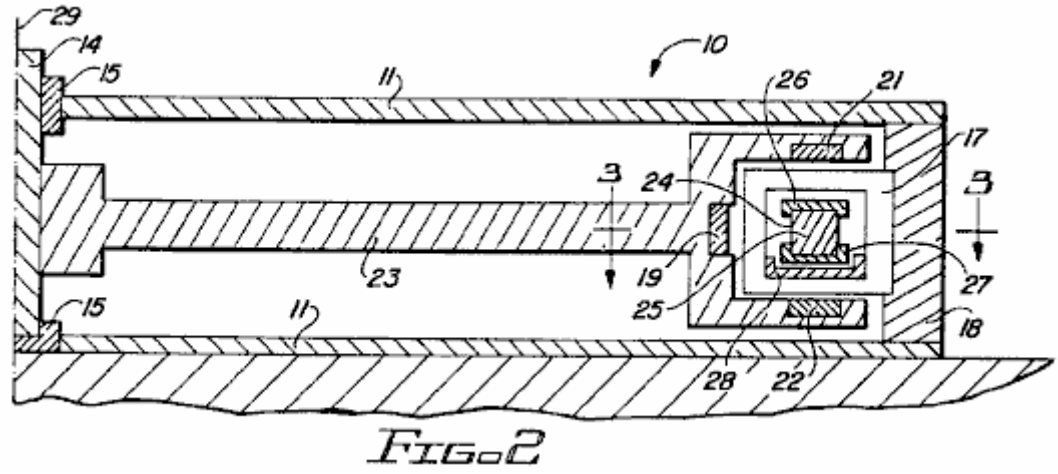

FIG. 2

Fig.2 is a cross-sectional view of **Fig.1** taken along line **2--2**;

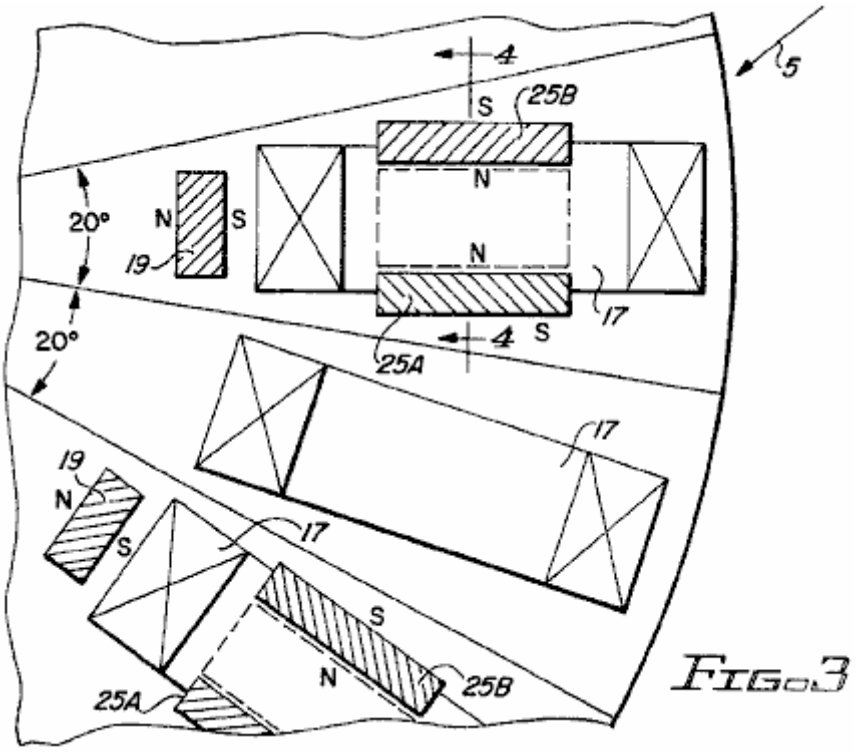

FIG. 3

Fig.3 is a cross-sectional view of the generator of **Fig.1** and **Fig.2** taken along line **3--3** of **Fig.2**;

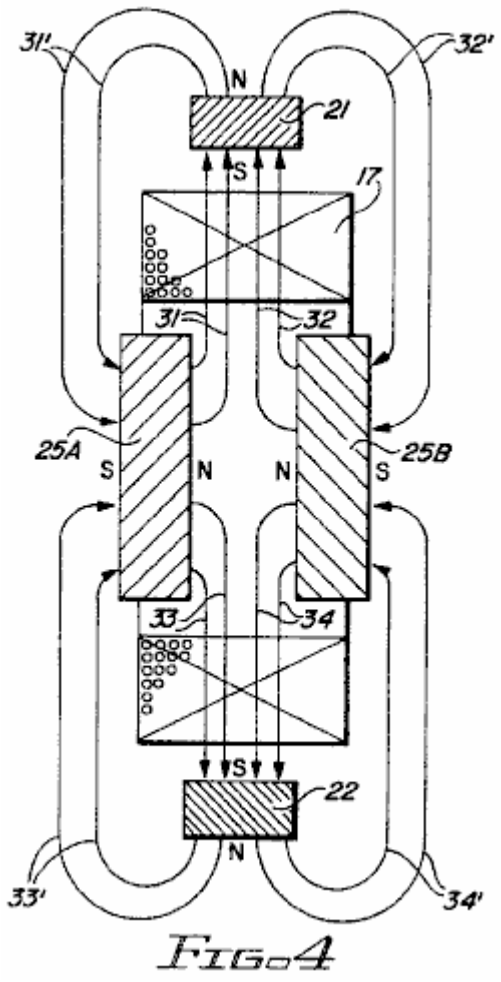

FIG-4

Fig.4 is a cross-sectional view of **Fig.3** taken along line **4--4**;

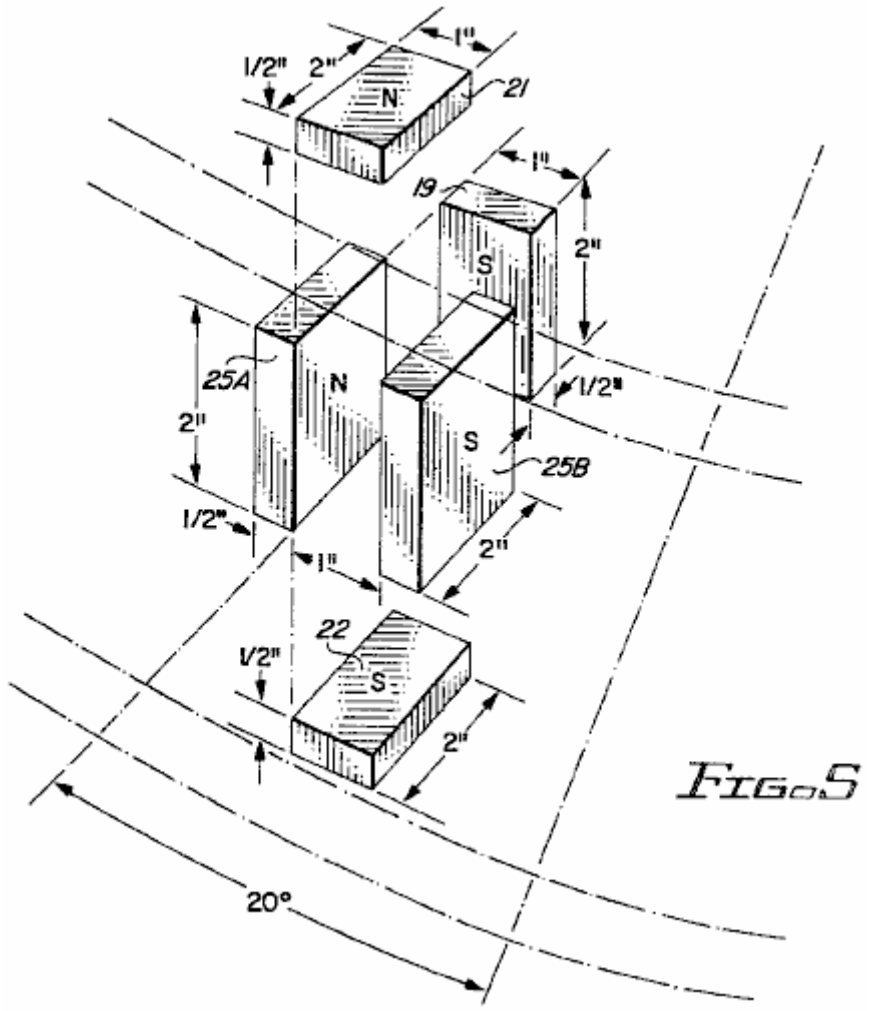

FIG. 5

Fig.5 is a partial perspective view showing the orientation of a group of permanent magnets within a twenty degree sector of the generator of the invention as viewed in the direction of arrow **5** of **Fig.3**;

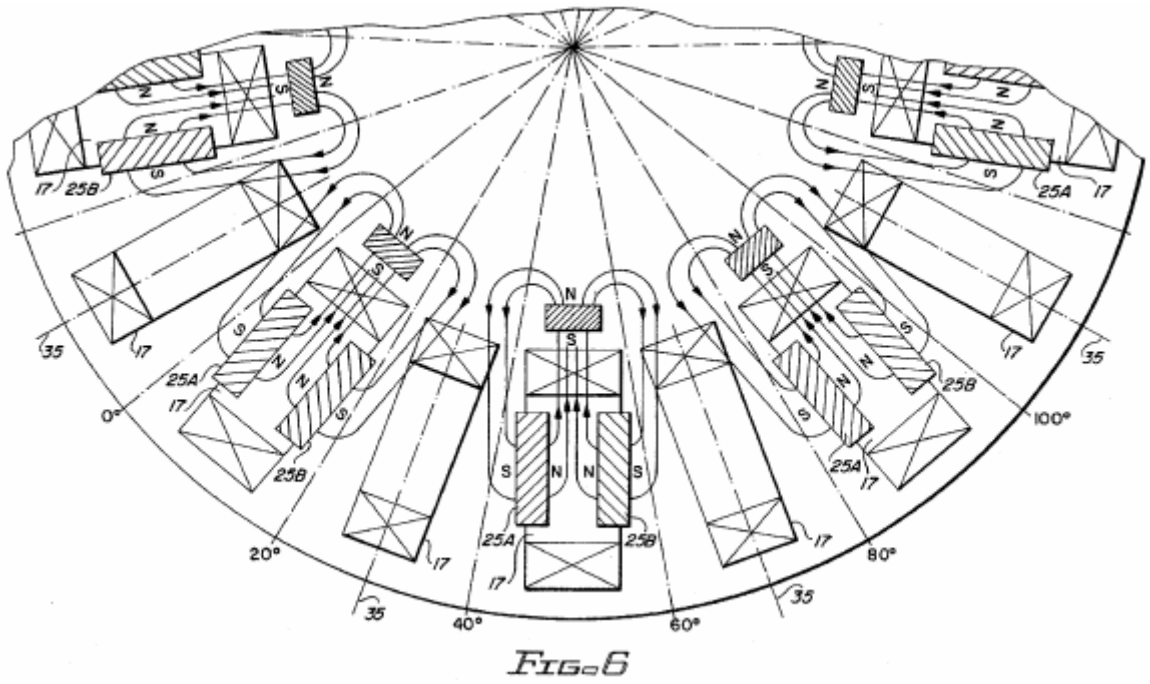

FIG. 6

Fig.6 is an illustration of the physical arrangement of electrical windings and permanent magnets within the generator of the invention as viewed in the direction of arrow **6** in **Fig.1**;

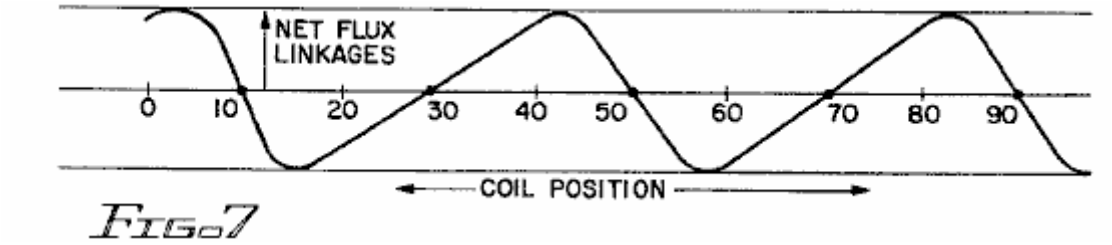

FIG. 7

Fig.7 is a wave form showing flux linkages for a given winding as a function of rotational position of the winding relative to the permanent magnets;

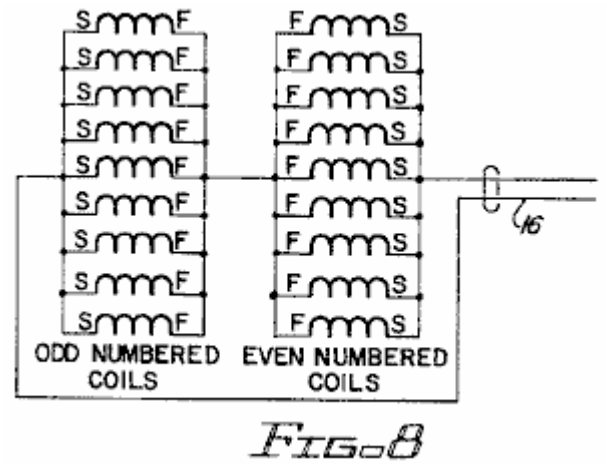

FIG. 8

Fig.8 is a schematic diagram showing the proper connection of the generator windings for a high current low voltage configuration of the generator;

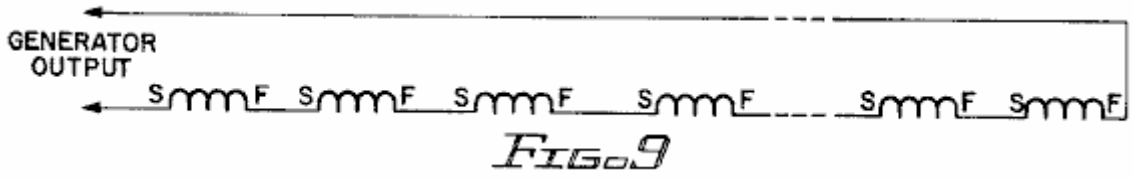

FIG. 9

Fig.9 is a schematic diagram showing a series connection of generator coils for a low current, high voltage configuration;

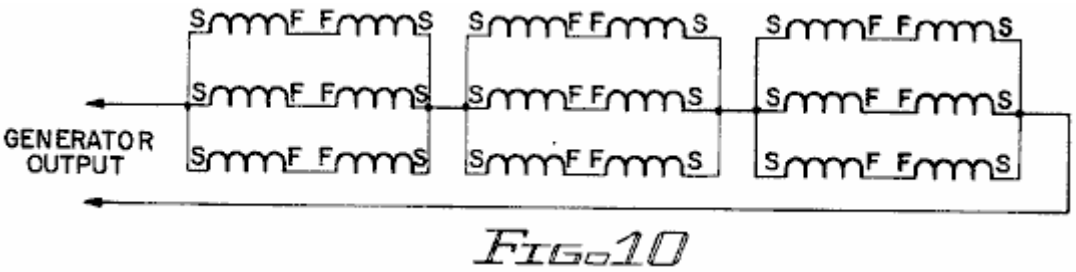

FIG. 10

Fig.10 is a schematic diagram showing a series/parallel connection of generator windings for intermediate current and voltage operation;

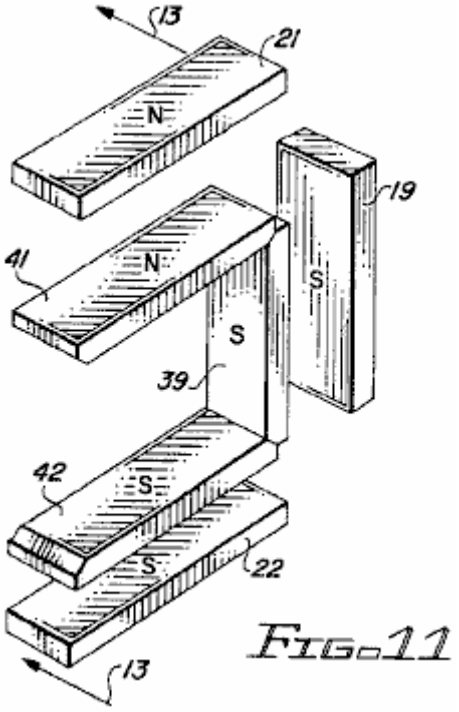

FIG. 11

Fig.11 is a perspective presentation of a modified carousel magnet configuration employed in a second embodiment of the invention;

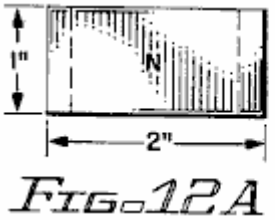

FIG. 12A

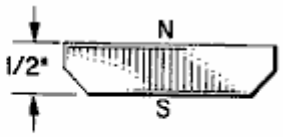

FIG. 12B

Fig.12A and **Fig.12B** show upper and lower views of the carousel magnets of **Fig.11**;

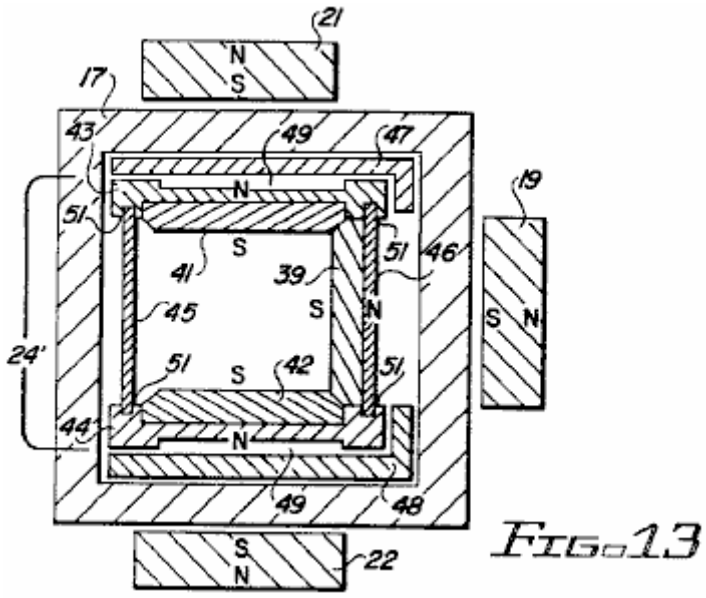

FIG. 13

Fig.13 is a cross-sectional view of the modified magnet configuration of **Fig.11** taken along line **13--13** with other features of the modified carousel structure also shown;

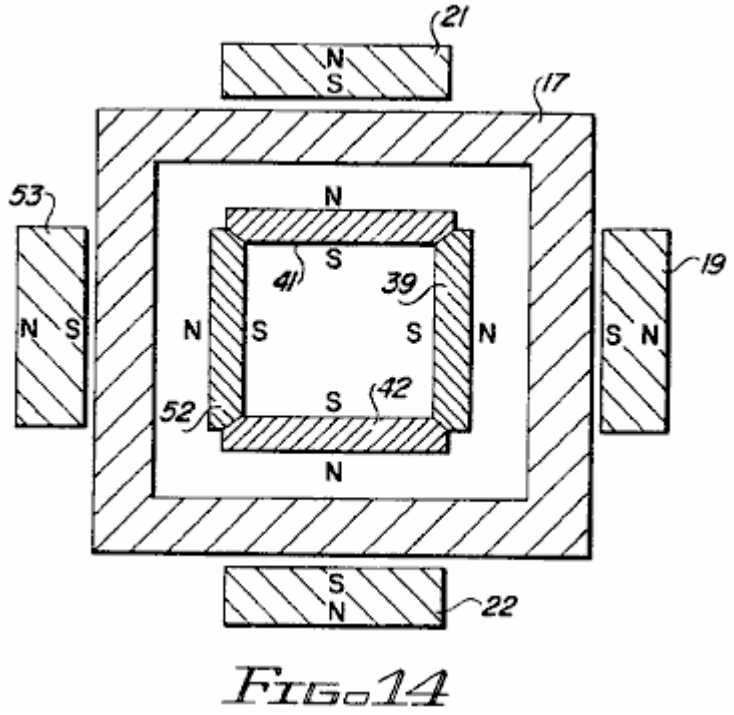

FIG. 14

Fig.14 is a modification of the carousel structure shown in **Figs. 1-13** wherein a fourth carousel magnet is positioned at each station; and

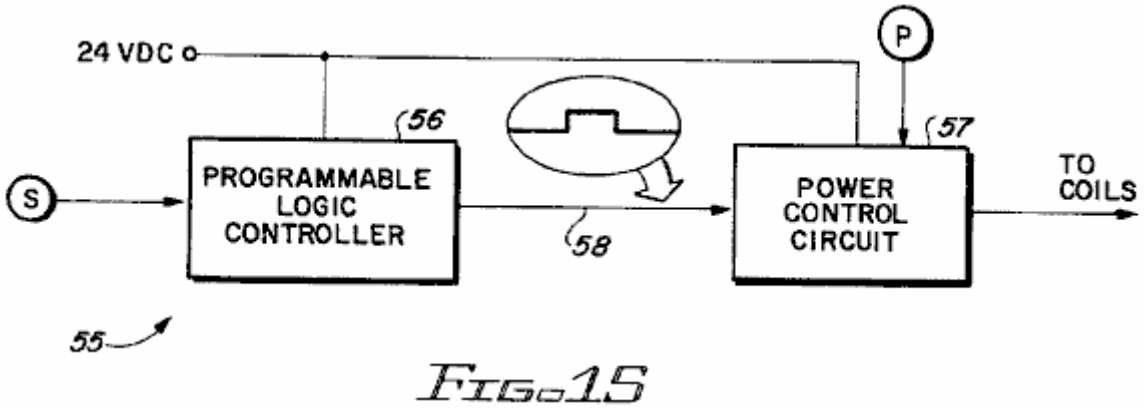

FIG. 15

Fig.15 illustrates the use of the claimed device as a pulsed direct current power source.

DESCRIPTION OF THE PREFERRED EMBODIMENT

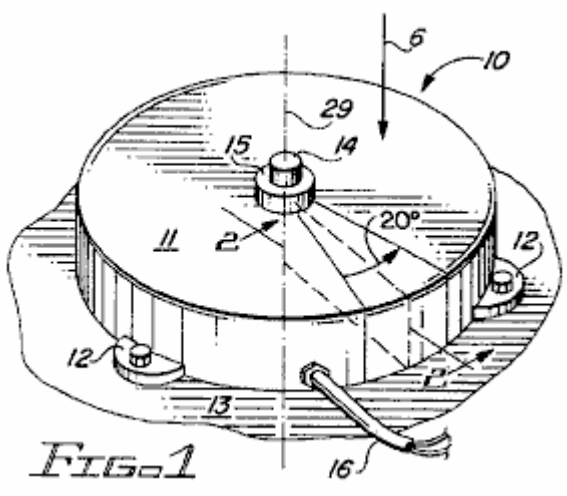

FIG. 1

Referring more particularly to the drawings by characters of reference, **Fig.1** shows the external proportions of a carousel electric generator **10** of the invention. As shown in **Fig.1**, generator **10** is enclosed by a housing **11** with mounting feet **12** suitable for securing the generator to a flat surface **13**. The surface **13** is preferably horizontal, as shown in **Fig.1**.

Housing **11** has the proportions of a short cylinder. A drive shaft **14** extends axially from housing **11** through a bearing **15**. The electrical output of the generator is brought out through a cable **16**.

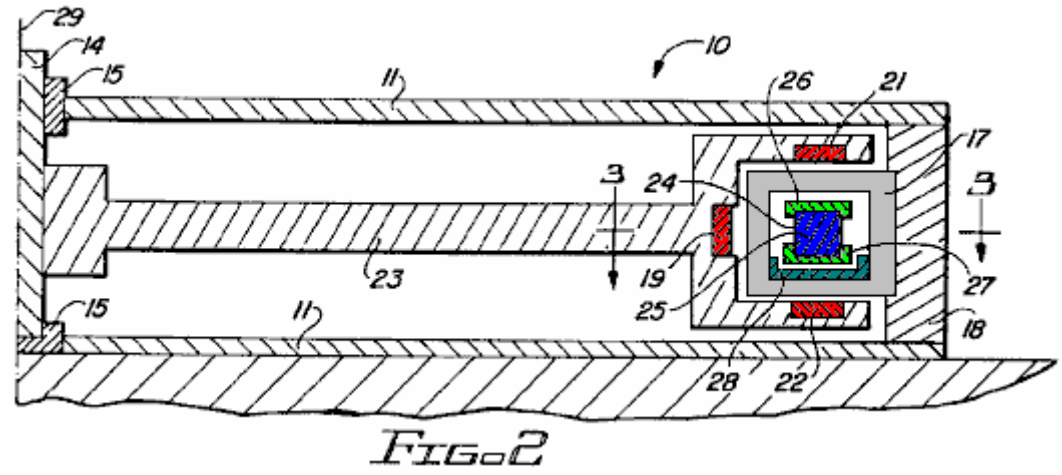

FIG. 2

The cross-sectional view of **Fig.2** shows the active elements incorporated in one twenty degree sector of the stator and in one twenty degree sector of the rotor.

In the first implementation of the invention, there are eighteen identical stator sectors, each incorporating a winding or coil **17** wound about a rectangular coil frame or bobbin. Coil **17** is held by a stator frame **18** which may also serve as an outer wall of frame **11**.

The rotor is also divided into eighteen sectors, nine of which incorporate three permanent magnets each, including an inboard rotor magnet **19**, an upper rotor magnet **21** and a lower rotor magnet **22**. All three of these magnets have their south poles facing coil **17**, and all three are mounted directly on rotor frame **23** which is secured directly to drive shaft **14**.

The other nine sectors of the rotor are empty, i.e. they are not populated with magnets. The unpopulated sectors are alternated with the populated sectors so that adjacent populated sectors are separated by an unpopulated sector as shown in **Fig.3** and **Fig.6**.

With reference again to **Fig.2**, generator **10** also incorporates a carousel **24**. The carousel comprises nine pairs of carousel magnets **25** clamped between upper and lower retainer rings **26** and **27**, respectively. The lower retainer ring **27** rests inside an air bearing channel **28** which is secured to stator **18** inside the bobbin of coil **17**. Air passages (not shown) admit air into the space between the lower surface of ring **27** and the upper or inside

surface of channel **28**. This arrangement comprises an air bearing which permits carousel **24** to rotate freely within the coils **17** about rotational axis **29** of rotor frame **23**.

Carousel **24** is also divided into **18** twenty-degree sectors, including nine populated sectors interspersed with nine unpopulated sectors in an alternating sequence. Each of the nine populated sectors incorporates a pair of carousel magnets as described in the preceding paragraph.

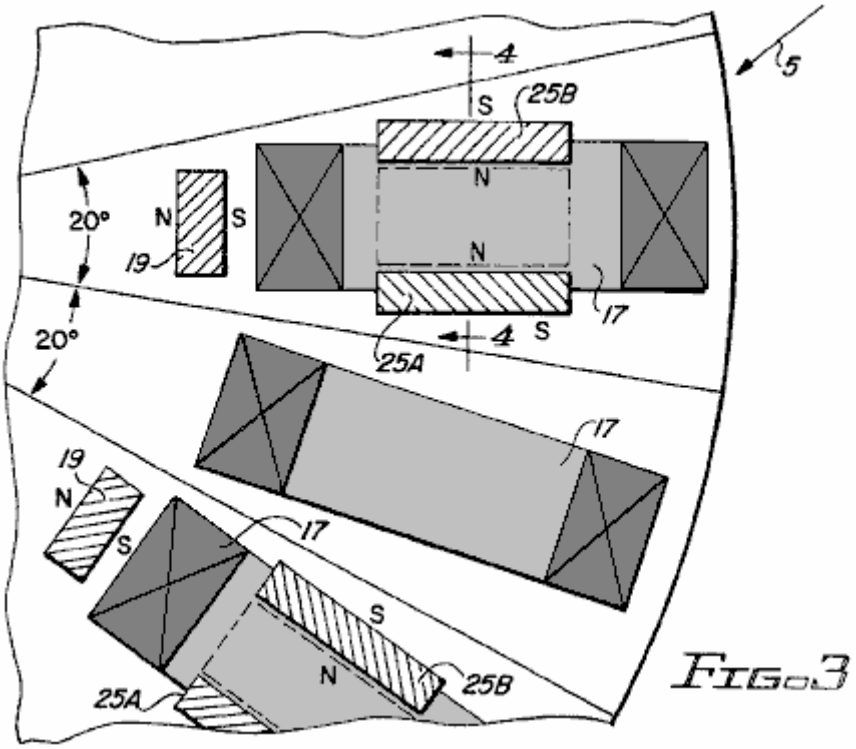

FIG. 3

The geometrical relationship between the rotor magnets, the carousel magnets and the coils, is further clarified by **Fig.3**, **Fig.4** and **Fig.5**. In each of the three figures, the centre of each populated rotor sector is shown aligned with the centre of a coil **17**. Each populated carousel sector, which is magnetically locked into position with a populated rotor sector, is thus also aligned with a coil **17**.

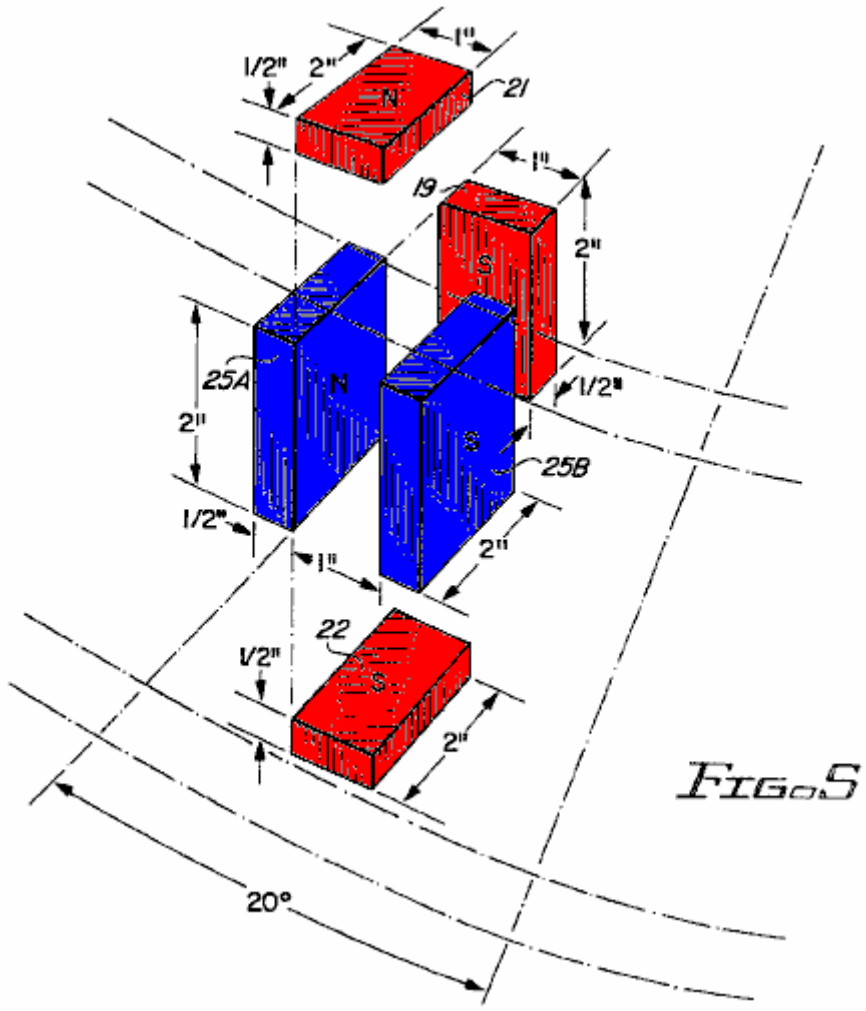

Fig.5

In an early implementation of the invention, the dimensions and spacings of the rotor magnets **19**, **21** and **22** and carousel magnets, **25A** and **25B** of carousel magnet pairs **25** were as shown in **Fig.5**. Each of the rotor magnets **19**, **21** and **22** measured one inch by two inches by one-half inch with north and south poles at opposite one-inch by two-inch faces. Each of the carousel magnets **25A** and **25B** measured two inches by two inches by one-half inch with north and south poles at opposite two-inch by two-inch faces. The magnets were obtained from Magnet Sales and Manufacturing, Culver City, Calif. The carousel magnets were part No.35NE2812832; the rotor magnets were custom parts of equivalent strength (MMF) but half the cross section of the carousel magnets.

Coil supports and other stationary members located within magnetic field patterns are fabricated from Delrin or Teflon plastic or equivalent materials. The use of aluminium or other metals introduce eddy current losses and in some cases excessive friction.

As shown in **Fig.5**, carousel magnets **25A** and **25B** stand on edge, parallel with each other, their north poles facing each other, and spaced one inch apart. When viewed from directly above the carousel magnets, the space between the two magnets **25A** and **25B** appears as a one-inch by two-inch rectangle. When the carousel magnet pair **25** is perfectly locked into position magnetically, upper rotor magnet **21** is directly above this one-inch by two-inch rectangle, lower rotor magnet **22** is directly below it, and their one-inch by two-inch faces are directly aligned with it, the south poles of the two magnets **21** and **22** facing each other.

In like manner, when viewed from the axis of rotation of generator **10**, the space between carousel magnets **25A** and **25B** again appears as a one-inch by two-inch rectangle, and this rectangle is aligned with the one-inch by two-inch face of magnet **19**, the south pole of magnet **19** facing the carousel magnet pair **25**.

Rotor magnets **19**, **21** and **22** are positioned as near as possible to carousel magnets **25A** and **25B** while still allowing passage for coil **17** over and around the carousel magnets and through the space between the carousel magnets and the rotor magnets.

In an electric generator, the voltage induced in the generator windings is proportional to the product of the number of turns in the winding and the rate of change of flux linkages that is produced as the winding is rotated through

the magnetic field. An examination of magnetic field patterns is therefore essential to an understanding of generator operation.

In generator **10**, magnetic flux emanating from the north poles of carousel magnets **25A** and **25B** pass through the rotor magnets and then return to the south poles of the carousel magnets. The total flux field is thus driven by the combined MMF (magnetomotive force) of the carousel and field magnets while the flux patterns are determined by the orientation of the rotor and carousel magnets.

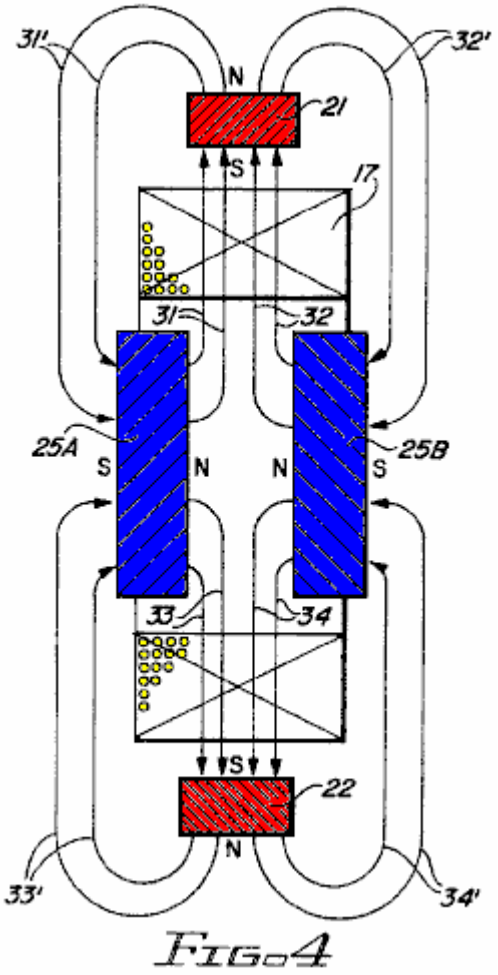

FIG. 4

The flux pattern between carousel magnets **25A** and **25B** and the upper and lower rotor magnets **21** and **22** is illustrated in **Fig.4**. Magnetic flux lines **31** from the north pole of carousel magnet **25A** extend to the south pole of upper rotor magnet **21**, pass through magnet **21** and return as lines **31'** to the south pole of magnet **25A**. Lines **33**, also from the north pole of magnet **25A** extend to the south pole of lower rotor magnet **22**, pass through magnet **22** and return to the south pole of magnet **25A** as lines **33'**. Similarly, lines **32** and **34** from the north pole of magnet **25B** pass through magnets **21** and **22**, respectively, and return as lines **32'** and **34'** to the south pole of magnet **25B**. Flux linkages produced in coil **17** by lines emanating from carousel magnet **25A** are of opposite sense from those emanating from carousel magnet **25B**. Because induced voltage is a function of the rate of change in net flux linkages, it is important to recognise this difference in sense.

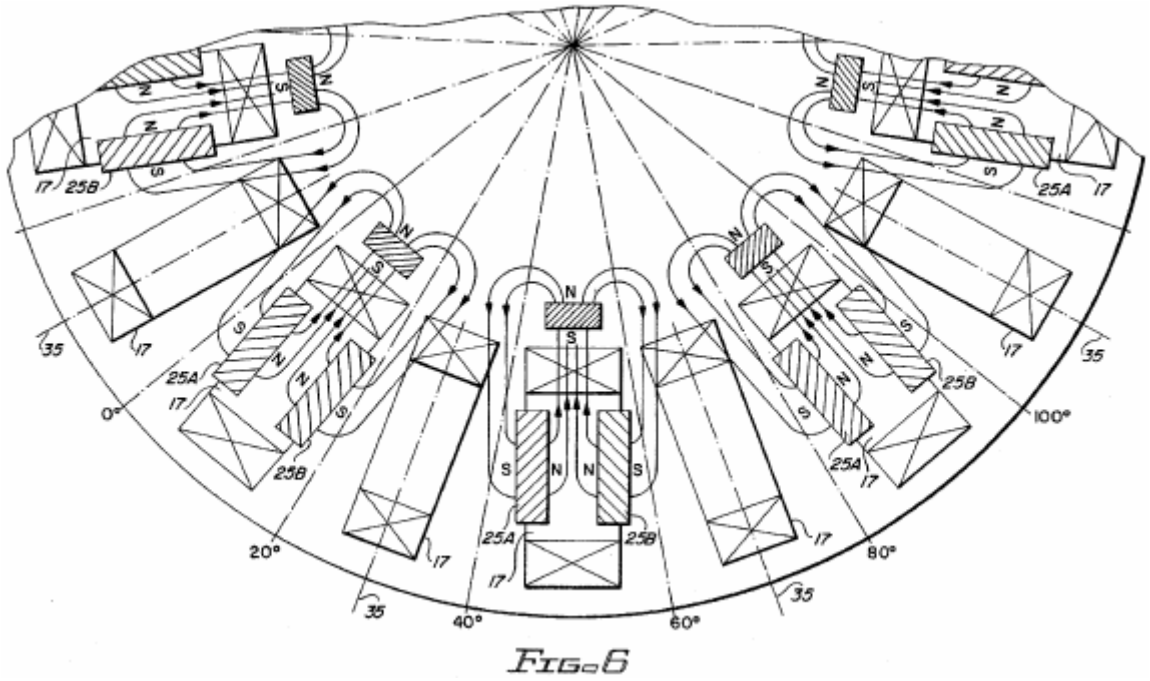

FIG. 6

Fig.6 shows a similar flux pattern for flux between carousel magnets **25A** and **25B** and inboard rotor magnet **19**. Again the lines emanating from carousel magnet **25A** and passing through rotor magnet **19** produce flux linkages in coil **17** that are opposite in sense from those produced by lines from magnet **25B**.

The arrangement of the carousel magnets with the north poles facing each other tends to confine and channel the flux into the desired path. This arrangement replaces the function of magnetic yokes or laminations of more conventional generators.

The flux linkages produced by magnets **25A** and **25B** are opposite in sense regardless of the rotational position of coil **17** including the case where coil **17** is aligned with the carousel and rotor magnets as well as for the same coils when they are aligned with an unpopulated rotor sector.

Taking into account the flux patterns of **Fig.4** and **Fig.6** and recognising the opposing sense conditions just described, net flux linkages for a given coil **17** are deduced as shown in **Fig.7**.

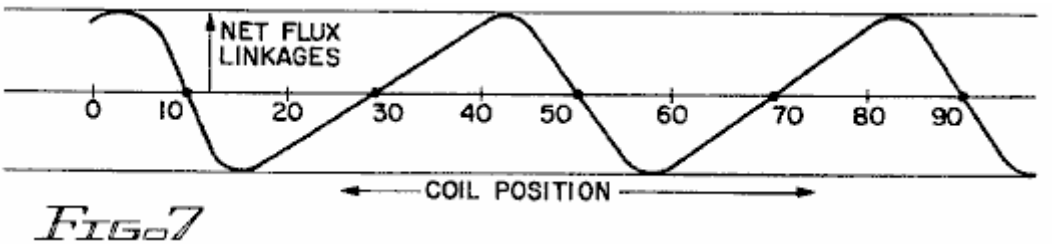

FIG. 7

In **Fig.7**, net flux linkages (coil-turns x lines) are plotted as a function of coil position in degrees. Coil position is here defined as the position of the centreline **35** of coil **17** relative to the angular scale shown in degrees in **Fig.6**. (Note that the coil is stationary and the scale is fixed to the rotor. As the rotor turns in a clockwise direction, the relative position of coil **17** progresses from zero to ten to twenty degrees etc.).

At a relative coil position of ten degrees, the coil is centred between magnets **25A** and **25B**. Assuming symmetrical flux patterns for the two magnets, the flux linkages from one magnet exactly cancel the flux linkages from the other so that net flux linkages are zero. As the relative coil position moves to the right, linkages from magnet **25A** decrease and those from magnet **25B** increase so that net flux linkages build up from zero and passes through a maximum negative value at some point between ten and twenty degrees. After reaching the negative maximum, flux linkages decrease, passing through zero at 30 degrees (where coil **17** is at the centre of an unpopulated rotor sector) and then rising to a positive maximum at some point just beyond 60 degrees. This cyclic variation repeats as the coil is subjected successively to fields from populated and unpopulated rotor sectors.

As the rotor is driven rotationally, net flux linkages for all eighteen coils are altered at a rate that is determined by the flux pattern just described in combination with the rotational velocity of the rotor. Instantaneous voltage

induced in coil **17** is a function of the slope of the curve shown in **Fig.7** and rotor velocity, and voltage polarity changes as the slope of the curve alternates between positive and negative.

It is important to note here that a coil positioned at ten degrees is exposed to a negative slope while the adjacent coil is exposed to a positive slope. The polarities of the voltages induced in the two adjacent coils are therefore opposite. For series or parallel connections of odd and even-numbered coils, this polarity discrepancy can be corrected by installing the odd and even numbered coils oppositely (odds rotated end for end relative to evens) or by reversing start and finish connections of odd relative to even numbered coils. Either of these measures will render all coil voltages additive as needed for series or parallel connections. Unless the field patterns for populated and unpopulated sectors are very nearly symmetrical, however, the voltages induced in odd and even numbered coils will have different waveforms. This difference will not be corrected by the coil reversals or reverse connections discussed in the previous paragraph. Unless the voltage waveforms are very nearly the same, circulating currents will flow between even and odd-numbered coils. These circulating currents will reduce generator efficiency.

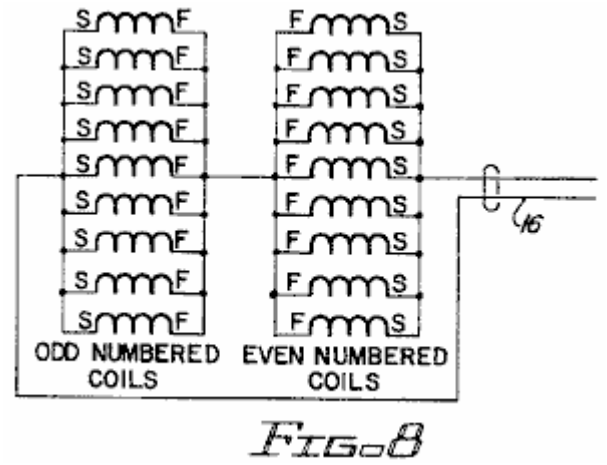

FIG. 8

To prevent such circulating currents and the attendant loss in operating efficiency for non symmetrical field patterns and unmatched voltage waveforms, the series-parallel connections of **Fig.8** may be employed in a high-current, low-voltage configuration of the generator. If the eighteen coils are numbered in sequence from one to eighteen according to position about the stator, all even-numbered coils are connected in parallel, all odd-numbered coils are connected in parallel, and the two parallel coil groups are connected in series as shown with reversed polarity for one group so that voltages will be in phase relative to output cable **16**.

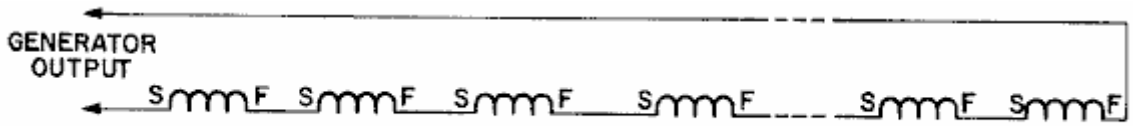

FIG. 9

For a low-current, high voltage configuration, the series connection of all coils may be employed as shown in **Fig.9**. In this case, it is only necessary to correct the polarity difference between even and odd numbered coils. As mentioned earlier, this can be accomplished by means of opposite start and finish connections for odd and even coils or by installing alternate coils reversed, end for end.

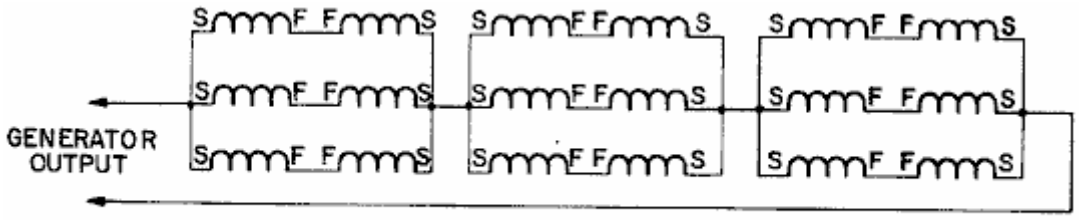

FIG. 10

For intermediate current and voltage configurations, various series-parallel connections may be employed. **Fig.10**, for example, shows three groups of six coils each connected in series. Circulating currents will be avoided so long as even-numbered coils are not connected in parallel with odd-numbered coils. Parallel connection of

series-connected odd/even pairs as shown is permissible because the waveforms of the series pairs should be very neatly matched.

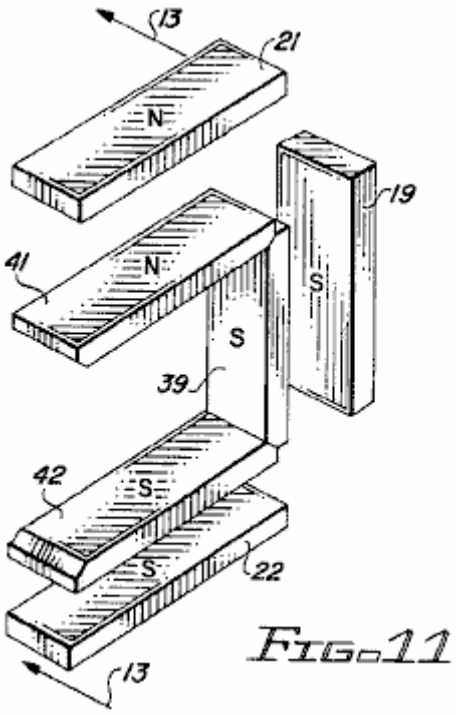

FIG. 11

In another embodiment of the invention, the two large (two-inch by two-inch) carousel magnets are replaced by three smaller magnets as shown in **Fig.11**, **Fig.12** and **Fig.13**. The three carousel magnets comprise an inboard carousel magnet **39**, an upper carousel magnet **41** and a lower carousel magnet **42** arranged in a U-shaped configuration that matches the U-shaped configuration of the rotor magnets **19**, **21** and **22**. As in the case of the first embodiment, the rotor and carousel magnets are present only in alternate sectors of the generator.

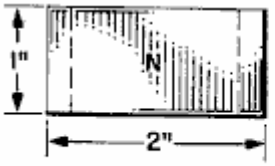

FIG. 12A

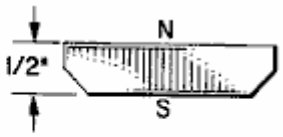

FIG. 12B

The ends of the carousel magnets are bevelled to permit a more compact arrangement of the three magnets. As shown in **Fig.12**, each magnet measures one inch by two inches by one half inch thick. The south pole occupies the bevelled one-inch by two-inch face and the north pole is at the opposite face.

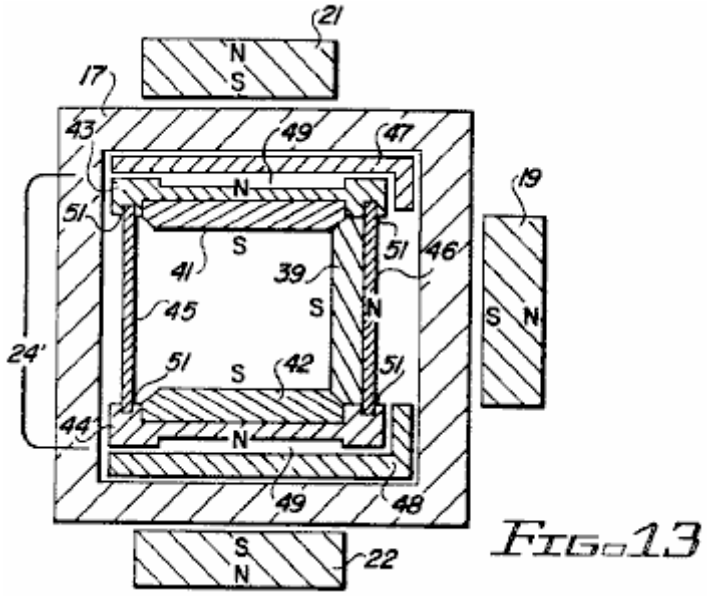

FIG. 13

The modified carousel structure **24'** as shown in **Fig.13** comprises an upper carousel bearing plate **43**, a lower carousel bearing plate **44**, an outer cylindrical wall **45** and an inner cylindrical wall **46**. The upper and lower bearing plates **43** and **44** mate with the upper and lower bearing members **47** and **48**, respectively, which are stationary and secured inside the forms of the coils **17**. Bearing plates **43** and **44** are shaped to provide air channels **49** which serve as air bearings for rotational support of the carousel **24'**. The bearing plates are also slotted to receive the upper and lower edges **51** of cylindrical walls **45** and **46**.

The modified carousel structure **24'** offers a number of advantages over the first embodiment. The matched magnet configuration of the carousel and the rotor provides tighter and more secure coupling between the carousel and the rotor. The smaller carousel magnets also provide a significant reduction in carousel weight. This was found beneficial relative to the smooth and efficient rotational support of the carousel.

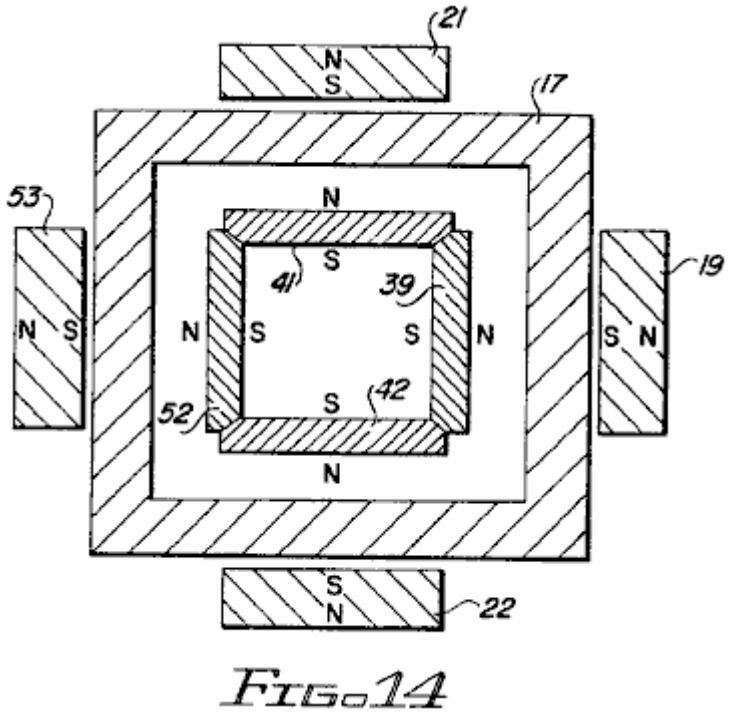

FIG.14

The modification of the carousel structure as described in the foregoing paragraphs can be taken one step further with the addition of a fourth carousel magnet **52** at each station as shown in **Fig.14**. The four carousel magnets **39**, **41**, **42** and **52** now form a square frame with each of the magnet faces (north poles) facing a corresponding inside face of the coil **17**. Carousel magnets for this modification may again be as shown in **Fig.12**. An additional rotor magnet **53** may also be added as shown, in alignment with carousel magnet **52**. These additional modifications further enhance the field pattern and the degree of coupling between the rotor and the carousel.

The carousel electric generator of the invention is particularly well suited to high speed, high frequency operation where the high speed compensates for lower flux densities than might be achieved with a magnetic medium for routing the field through the generator coils. For many applications, such as emergency lighting, the high frequency is also advantageous. Fluorescent lighting, for example, is more efficient in terms of lumens per watt and the ballasts are smaller at high frequencies.

While the present invention has been directed toward the provision of a compact generator for specialised generator applications, it is also possible to operate the device as a motor by applying an appropriate alternating voltage source to cable **16** and coupling drive shaft **14** to a load.

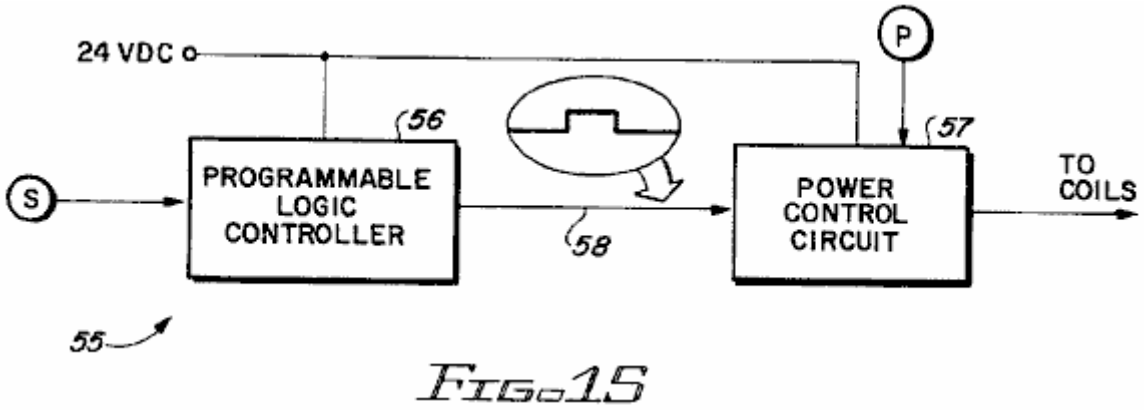

FIG. 15

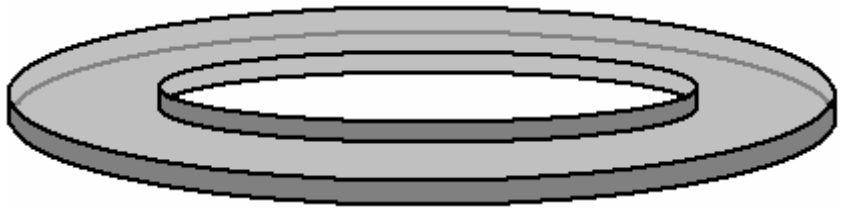
It is also possible to operate the device of the invention as a motor using a pulsed direct-current power source. A control system **55** for providing such operation is illustrated in **Fig.15**. Incorporated in the control system **55** are a rotor position sensor **S**, a programmable logic controller **56**, a power control circuit **57** and a potentiometer **P**.

Based on signals received from sensor **S**, controller **56** determines the appropriate timing for coil excitation to assure maximum torque and smooth operation. This entails the determination of the optimum positions of the rotor and the carousel at the initiation and at the termination of coil excitation. For smooth operation and maximum torque, the force developed by the interacting fields of the magnets and the excited coils should be unidirectional to the maximum possible extent.

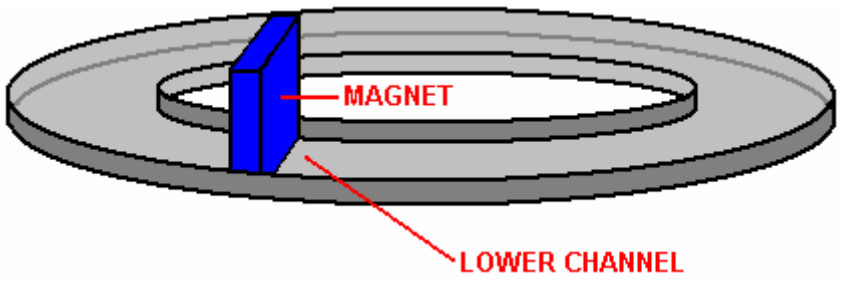
Typically, the coil is excited for only 17.5 degrees or less during each 40 degrees of rotor rotation.

The output signal **58** of controller **56** is a binary signal (high or low) that is interpreted as an ON and OFF command for coil excitation.



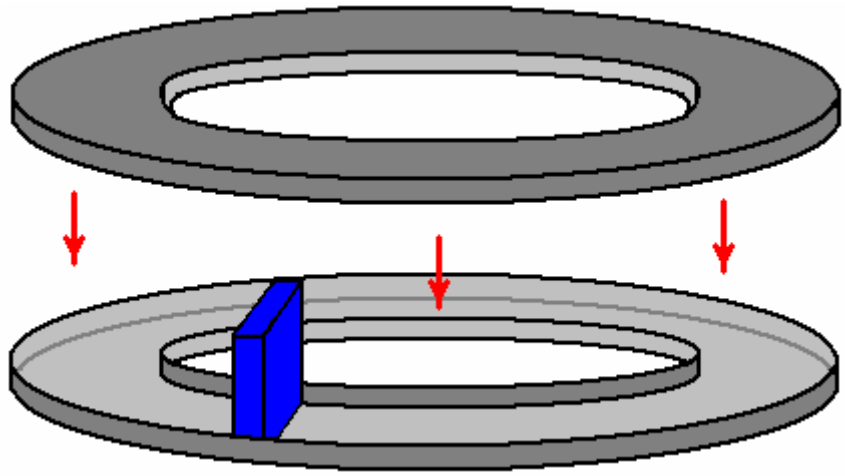
The power control circuit incorporates a solid state switch in the form of a power transistor or a MOSFET. It responds to the control signal **58** by turning the solid state switch ON and OFF to initiate and terminate coil excitation. Instantaneous voltage amplitude supplied to the coils during excitation is controlled by means of potentiometer **P**. Motor speed and torque are thus responsive to potentiometer adjustments.

The device is also adaptable for operation as a motor using a commutator and brushes for control of coil excitation. In this case, the commutator and brushes replace the programmable logic controller and the power control circuit as the means for providing pulsed DC excitation. This approach is less flexible but perhaps more efficient than the programmable control system described earlier.

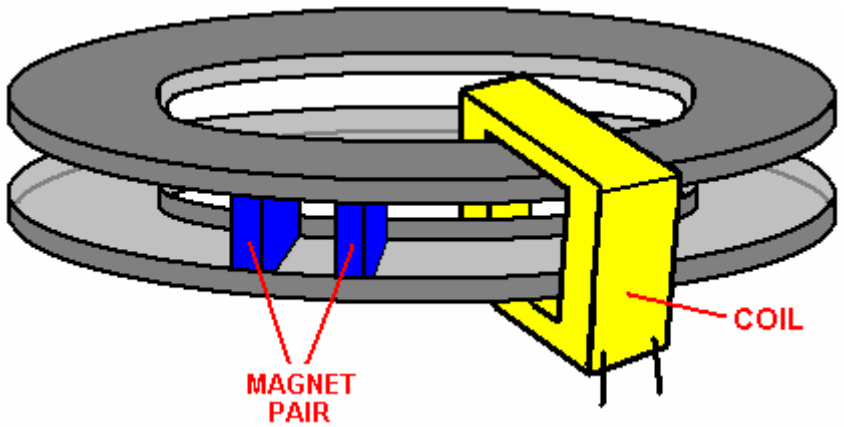


It will now be recognised that a novel and useful generator has been provided in accordance with the stated objects of the invention, and while but a few embodiments of the invention have been illustrated and described it will be apparent to those skilled in the art that various changes and modifications may be made without departing from the spirit of the invention or from the scope of the appended claims.

Notes:



I found it a little difficult to visualise the carousel part, so the following may be helpful for some people. The "carousel" is formed from two circular plastic channels like this:



These channels are placed, one below and one above, nine pairs of carousel magnets (coloured blue in some of the patent diagrams shown above. Each carousel magnet sits in the lower channel:

And these magnets are secured as a unit by an identical plastic channel inverted and placed on top of the magnet set:

And this ring assembly of magnets spins inside the wire coils used to generate the electrical output. The ring spins inside the coils because the nine pairs of magnets in the ring, lock in place opposite the matching nine pairs of magnets in the rotor and the magnetic force and rotor rotation causes the ring to spin inside the coils.

PAVEL IMRIS

US Patent 3,781,601 25th December 1973 Inventor: Pavel Imris

OPTICAL GENERATOR OF AN ELECTROSTATIC FIELD HAVING LONGITUDINAL OSCILLATION AT LIGHT FREQUENCIES FOR USE IN AN ELECTRICAL CIRCUIT

Please note that this is a re-worded excerpt from this patent. It describes a gas-filled tube which allows many standard 40-watt fluorescent tubes to be powered using less than 1-watt of power each.

ABSTRACT

An Optical generator of an electrostatic field at light frequencies for use in an electrical circuit, the generator having a pair of spaced-apart electrodes in a gas-filled tube of quartz glass or similar material with at least one capacitor cap or plate adjacent to one electrode and a dielectric filled container enclosing the tube, the generator substantially increasing the electrical efficiency of the electrical circuit.

BACKGROUND OF THE INVENTION

This invention relates to improved electrical circuits, and more particularly to circuits utilising an optical generator of an electrostatic field at light frequencies.

The measure of the efficiency of an electrical circuit may broadly be defined as the ratio of the output energy in the desired form (such as light in a lighting circuit) to the input electrical energy. Up to now, the efficiency of many circuits has not been very high. For example, in a lighting circuit using 40 watt fluorescent lamps, only about 8.8 watts of the input energy per lamp is actually converted to visible light, thus representing an efficiency of only about 22%. The remaining 31.2 watts is dissipated primarily in the form of heat.

It has been suggested that with lighting circuits having fluorescent lamps, increasing the frequency of the applied current will raise the overall circuit efficiency. While at an operating frequency of 60 Hz, the efficiency is 22%, if the frequency is raised to 1 Mhz, the circuit efficiency would only rise to some 25.5%. Also, if the input frequency were raised to 10 Ghz, the overall circuit efficiency would only be 35%.

SUMMARY OF THE PRESENT INVENTION

The present invention utilises an optical electrostatic generator which is effective for producing high frequencies in the visible light range of about 10^{14} to 10^{23} Hz. The operation and theory of the optical electrostatic generator has been described and discussed in my co-pending application serial No. 5,248, filed on 23rd January 1970. As stated in my co-pending application, the present optical electrostatic generator does not perform in accordance with the accepted norms and standards of ordinary electromagnetic frequencies.

The optical electrostatic generator as utilised in the present invention can generate a wide range of frequencies between several Hertz and those in the light frequency. Accordingly, it is an object of the present invention to provide improved electrical energy circuits utilising my optical electrostatic generator, whereby the output energy in the desired form will be substantially more efficient than possible to date, using standard circuit techniques and equipment. It is a further object of the present invention to provide such a circuit for use in fluorescent lighting or other lighting circuits. It is also an object of the present invention to provide a circuit with may be used in conjunction with electrostatic precipitators for dust and particle collection and removal, as well as many other purposes.

DESCRIPTION OF THE DRAWINGS

Fig.1 is a schematic layout showing an optical electrostatic generator of the present invention, utilised in a lighting circuit for fluorescent lamps:

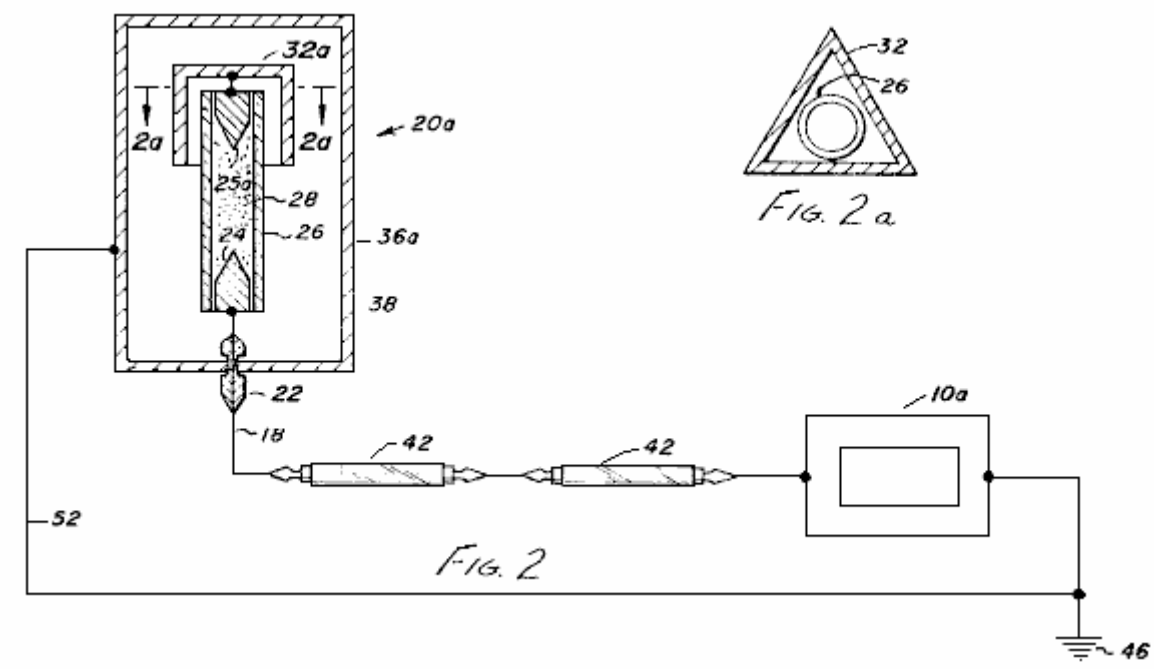

Fig. 2a

Fig. 2

Fig.2A is a sectional view through a portion of the generator and

Fig.3 is a schematic sectional view showing an optical electrostatic generator in accordance with the present invention, particularly for use in alternating current circuits, although it may also be used in direct current circuits:

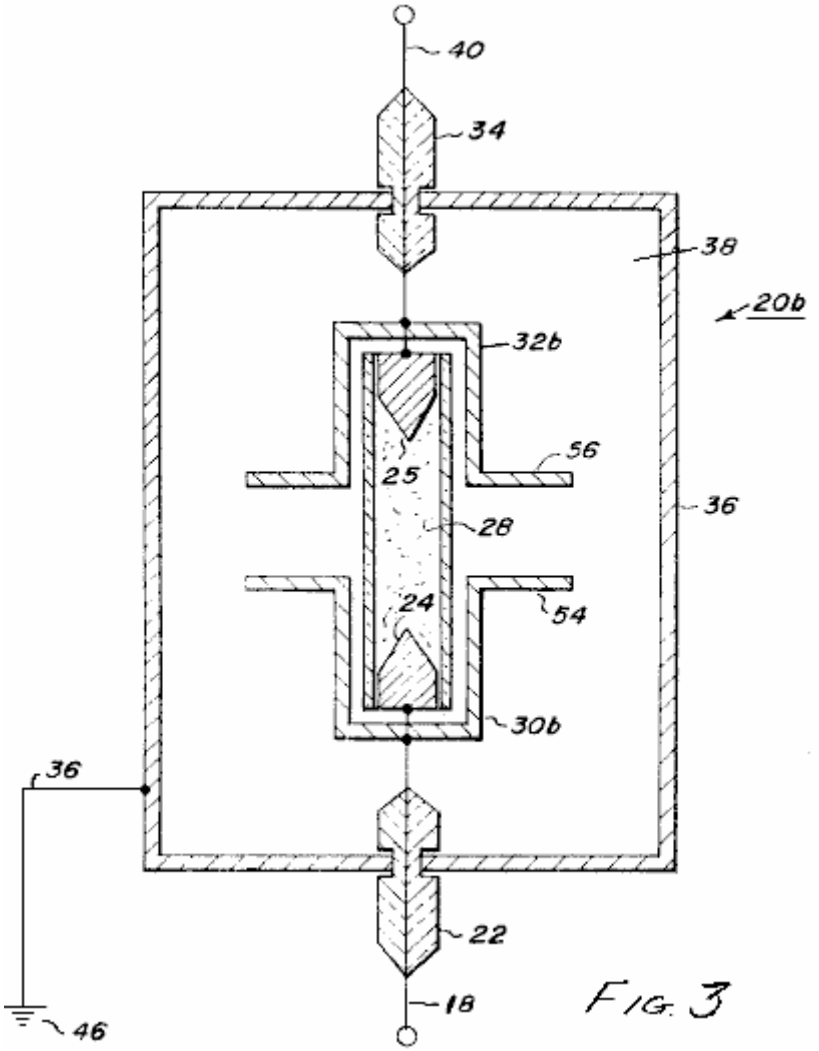

FIG. 3

DESCRIPTION OF THE ILLUSTRATED EMBODIMENTS

Referring to the drawings and to **Fig.1** in particular, a low voltage circuit utilising an optical electrostatic generator is shown. As shown in **Fig.1**, a source of alternating current electrical energy **10**, is connected to a lighting circuit. Connected to one tap of the power source **10** is a rectifier **12** for utilisation when direct current is required. The illustrated circuit is provided with a switch **14** which may be opened or closed depending on whether AC or DC power is used. Switch **14** is opened and a switch **16** is closed when AC is used. With switch **14** closed and switch **16** open, the circuit operates as a DC circuit.

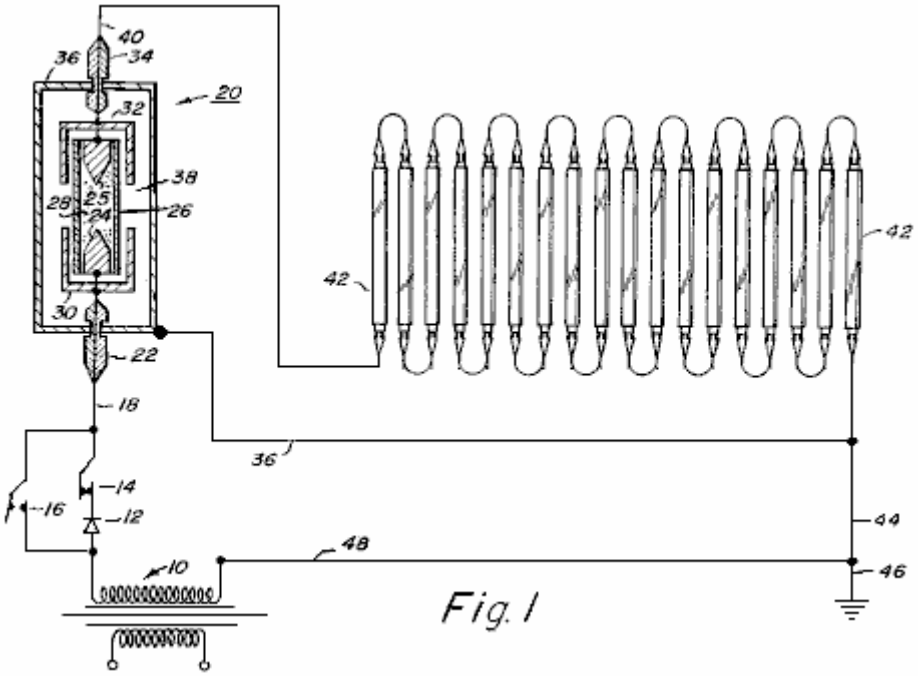

Fig. 1

Extending from switches **14** and **16** is conductor **18** which is connected to an optical electrostatic generator **20**. Conductor **18** is passed through an insulator **22** and connected to an electrode **24**. Spaced from electrode **24** is a second electrode **25**. Enclosing electrodes **24** and **25**, which preferably are made of tungsten or similar material, is a quartz glass tube **26** which is filled with an ionisable gas **28** such as xenon or any other suitable ionisable gas such as argon, krypton, neon, nitrogen or hydrogen, as well as the vapour of metals such as mercury or sodium.

Surrounding each end of tube **26** and adjacent to electrodes **24** and **25**, are capacitor plates **30** and **32** in the form of caps. A conductor is connected to electrode **25** and passed through a second insulator **34**. Surrounding the tube, electrodes and capacitor caps is a metal envelope in the form of a thin sheet of copper or other metal such as aluminium. Envelope **36** is spaced from the conductors leading into and out of the generator by means of insulators **22** and **34**. Envelope **36** is filled with a dielectric material such as transformer oil, highly purified distilled water, nitro-benzene or any other suitable liquid dielectric. In addition, the dielectric may be a solid such as ceramic material with relatively small molecules.

A conductor **40** is connected to electrode **25**, passed through insulator **24** and then connected to a series of fluorescent lamps **42** which are connected in series. It is the lamps **42** which will be the measure of the efficiency of the circuit containing the optical electrostatic generator **20**. A conductor **44** completes the circuit from the fluorescent lamps to the tap of the source of electrical energy **10**. In addition, the circuit is connected to a ground **46** by another conductor **48**. Envelope **36** is also grounded by lead **50** and in the illustrated diagram, lead **50** is connected to the conductor **44**.

The capacitor caps or plates **30** and **32**, form a relative capacitor with the discharge tube. When a high voltage is applied to the electrode of the discharge tube, the ions of gas are excited and brought to a higher potential than their environment, i.e. the envelope and the dielectric surrounding it. At this point, the ionised gas in effect becomes one plate of a relative capacitor in co-operation with the capacitor caps or plates **30** and **32**.

When this relative capacitor is discharged, the electric current does not decrease as would normally be expected. Instead, it remains substantially constant due to the relationship between the relative capacitor and an absolute capacitor which is formed between the ionised gas and the spaced metal envelope **36**. An oscillation effect occurs in the relative capacitor, but the electrical condition in the absolute capacitor remains substantially constant.

As also described in the co-pending application serial No. 5,248, there is an oscillation effect between the ionised gas in the discharge lamp and the metallic envelope **36** will be present if the capacitor caps are eliminated, but the efficiency of the electrostatic generator will be substantially decreased.

The face of the electrode can be any desired shape. However, a conical point of 60^0 has been found to be satisfactory and it is believed to have an influence on the efficiency of the generator.

In addition, the type of gas selected for use in tube **26**, as well as the pressure of the gas in the tube, also affect the efficiency of the generator, and in turn, the efficiency of the electrical circuit.

To demonstrate the increased efficiency of an electrical circuit utilising the optical electrostatic generator of the present invention as well as the relationship between gas pressure and electrical efficiency, a circuit similar to that shown in **Fig.1** may be used with 100 standard 40 watt, cool-white fluorescent lamps connected in series. The optical electrostatic generator includes a quartz glass tube filled with xenon, with a series of different tubes being used because of the different gas pressures being tested.

Table 1 shows the data to be obtained relating to the optical electrostatic generator. **Table 2** shows the lamp performance and efficiency for each of the tests shown in **Table 1**. The following is a description of the data in each of the columns of **Tables 1 and 2**.

Column	Description
B	**Gas used in discharge tube**
C	**Gas pressure in tube** (in torrs)
D	**Field strength across the tube** (measured in volts per cm. of length between the electrodes)
E	**Current density** (measured in microamps per sq. mm. of tube cross-sectional area)
F	**Current** (measured in amps)
G	**Power across the tube** (calculated in watts per cm. of length between the electrodes)
H	**Voltage per lamp** (measured in volts)
K	**Current** (measured in amps)
L	**Resistance** (calculated in ohms)
M	**Input power per lamp** (calculated in watts)
N	**Light output** (measured in lumens)

The design of a tube construction for use in the optical electrostatic generator of the type used in **Fig.1**, may be accomplished by considering the radius of the tube, the length between the electrodes in the tube and the power across the tube.

If **R** is the minimum inside radius of the tube in centimetres, **L** the minimum length in centimetres between the electrodes, and **W** the power in watts across the lamp, the following formula can be obtained from **Table 1:**

R = (Current [A] / Current Density [A/sq.mm]) / pi

L = 8R

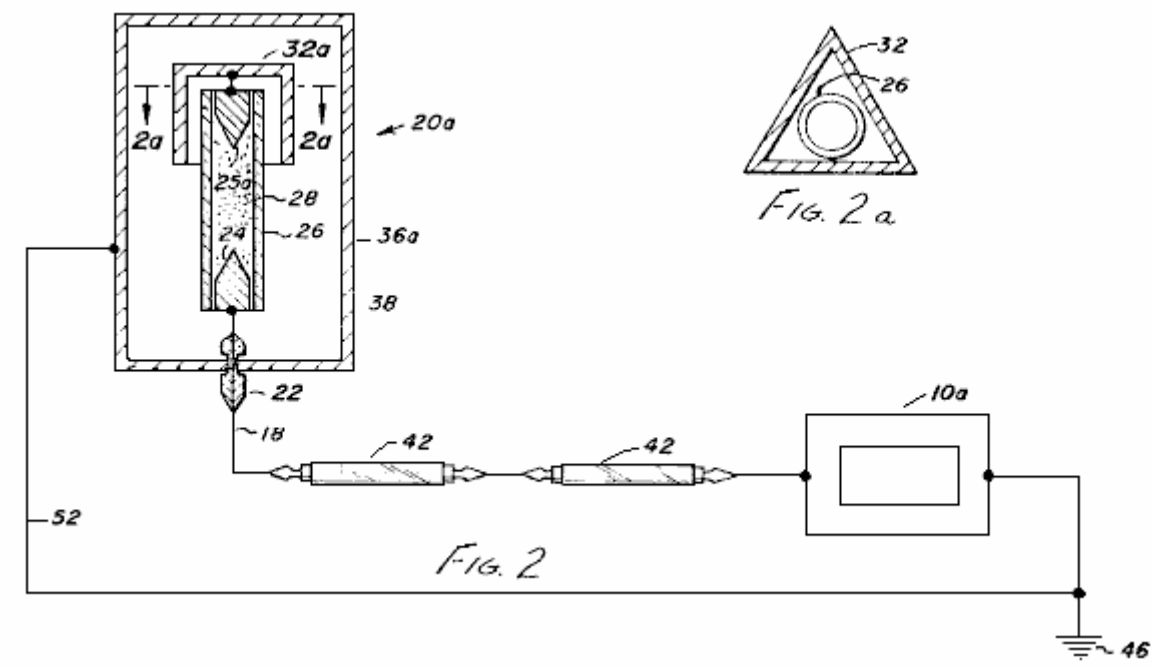
W = L[V/cm] x A

For example, for Test No. 18 in Table 1:
The current is 0.1818 A,
The current density 0.000353 A/sq.mm and
The Voltage Distribution is 122.8 V/cm; therefore

R = $(0.1818 / 0.000353)^2$ /3.14 = 12.80 mm.

L = 8 x R = 8 * 12.8 = 102.4 mm (10.2 cm.)

W = 10.2 x 122.8 x 0.1818 = 227.7 VA or 227.7 watts



The percent efficiency of operation of the fluorescent lamps in Test No. 18 can be calculated from the following equation:

% Efficiency = (Output Energy/Input energy) x 100

Across a single fluorescent lamp, the voltage is 60 volts and the current is 0.1818 amps therefore the input energy to the lamp **42** is 10.90 Watts. The output of the fluorescent lamp is 3,200 lumens which represents 8.8 Watts power of light energy. Thus, the one fluorescent lamp is operating at 80.7% efficiency under these conditions.

However, when the optical generator is the same as described for Test No. 18 and there are 100 fluorescent lamps in series in the circuit, the total power input is 227.7 watts for the optical generator and 1,090 watts for 100 fluorescent lamps, or a total of 1,318 watts. The total power input normally required to operate the 100 fluorescent lamps in a normal circuit would be 100 x 40 = 4,000 watts. So by using the optical generator in the circuit, about 2,680 watts of energy is saved.

Table 1 is an example of the functioning of this invention for a particular fluorescent lamp (40 watt cool white). However, similar data can be obtained for other lighting applications, by those skilled in the art.

In **Fig.2**, a circuit is shown which uses an optical electrostatic generator **20a**, similar to generator **20** of **Fig.1**. In generator **20**, only one capacitor cap **32a** is used and it is preferably of triangular cross-sectional design. In addition, the second electrode **25a** is connected directly back into the return conductor **52**, similar to the arrangement shown in my co-pending application serial No. 5,248, filed 23rd January 1970.

This arrangement is preferably for very high voltage circuits and the generator is particularly suited for DC usage.

In **Fig.2**, common elements have received the same numbers which were used in **Fig.1**.

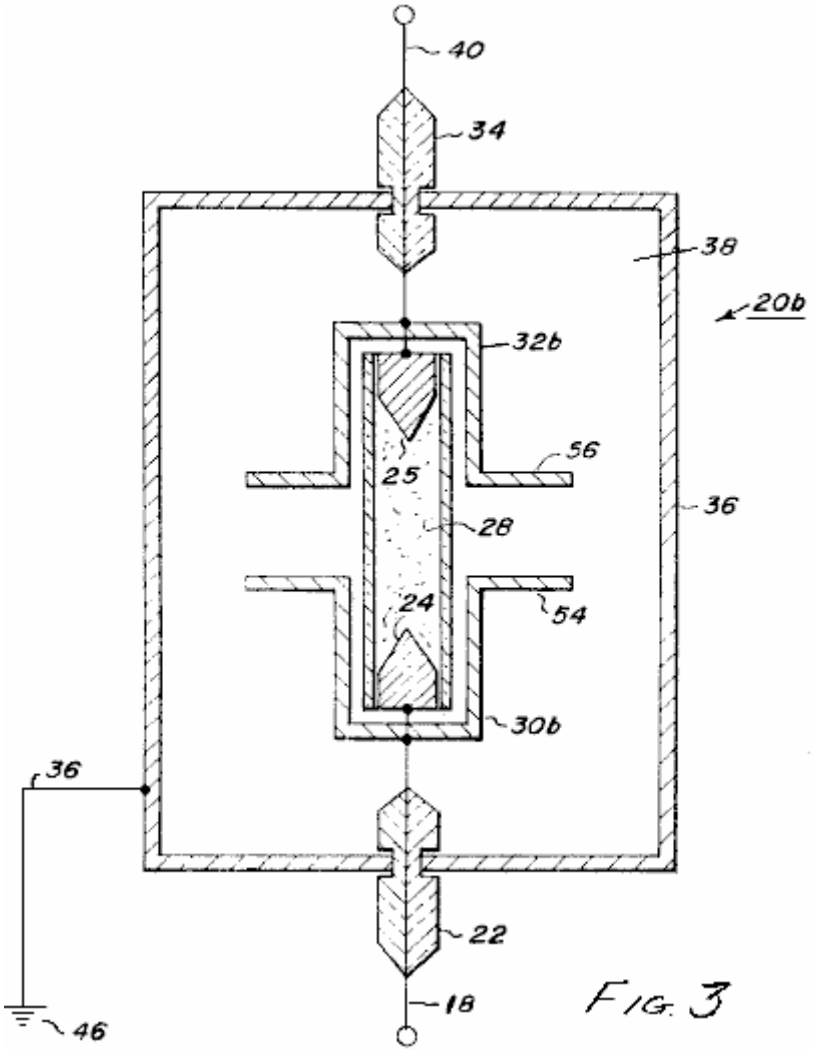


FIG. 3

In **Fig.3**, still another embodiment of an optical electrostatic generator **20b** is shown. This generator is particularly suited for use with AC circuits. In this embodiment, the capacitor plates **30b** and **32b** have flanges **54** and **56** which extend outwards towards the envelope **36**. While the utilisation of the optical electrostatic generator has been described in use in a fluorescent lighting circuit, it is to be understood that many other types of circuits may be used. For example, the high-voltage embodiment may be used in a variety of circuits such as flash lamps, high-speed controls, laser beams and high-energy pulses. The generator is also particularly usable in a circuit including electrostatic particle precipitation in air pollution control devices, chemical synthesis in electrical discharge systems such as ozone generators and charging means for high-voltage generators of the Van de Graff type, as well as particle accelerators. To those skilled in the art, many other uses and circuits will be apparent.

GB Patent GB 763,062 **5th December 1956**

Inventors: Harold Colman and Ronald Seddon-Gillespie

APPARATUS FOR PRODUCING AN ELECTRIC CURRENT

This patent shows the details of a lightweight device which can produce electricity using a self-powered electromagnet and chemical salts. The working life of the device before needing a recharge is estimated at some seventy years. The operation is controlled by a transmitter which bombards the chemical sample with 300 MHz radio waves. This produces radioactive emissions from the chemical mixture for a period of one hour maximum, so the transmitter needs to be run for fifteen to thirty seconds once every hour. The chemical mixture is shielded by a lead screen to prevent harmful radiation reaching the user. The output from the tiny device described is estimated to be some 10 amps at 100 to 110 volts DC.

DESCRIPTION

This invention relates to a new apparatus for producing electric current the apparatus being in the form of a completely novel secondary battery. The object of this invention is to provide apparatus of the above kind which is considerably lighter in weight than, and has an infinitely greater life than a known battery or similar characteristics and which can be re-activated as and when required in a minimum of time.

According to the present invention we provide apparatus comprising a generator unit which includes a magnet, a means for suspending a chemical mixture in the magnetic field, the mixture being composed of elements whose nuclei becomes unstable as a result of bombardment by short waves so that the elements become radio-active and release electrical energy, the mixture being mounted between, and in contact with, a pair of different metals such as copper and zinc, a capacitor mounted between those metals, a terminal electrically connected to each of the metals, means for conveying the waves to the mixture and a lead shield surrounding the mixture to prevent harmful radiation from the mixture.

The mixture is preferably composed of the elements Cadmium, Phosphorus and Cobalt having Atomic Weights of 112, 31 and 59 respectively. The mixture, which may be of powdered form, is mounted in a tube of non-conducting, high heat resistivity material and is compressed between granulated zinc at one end of the tube and granulated copper at the other end, the ends of the tube being closed by brass caps and the tube being carried in a suitable cradle so that it is located between the poles of the magnet. The magnet is preferably an electro-magnet and is energised by the current produced by the unit.

The means for conveying the waves to the mixture may be a pair of antennae which are exactly similar to the antennae of the transmitter unit for producing the waves, each antenna projecting from and being secured to the brass cap at each end of the tube.

The transmitter unit which is used for activating the generator unit may be of any conventional type operating on ultra-shortwave and is preferably crystal controlled at the desired frequency.

DESCRIPTION OF THE DRAWINGS

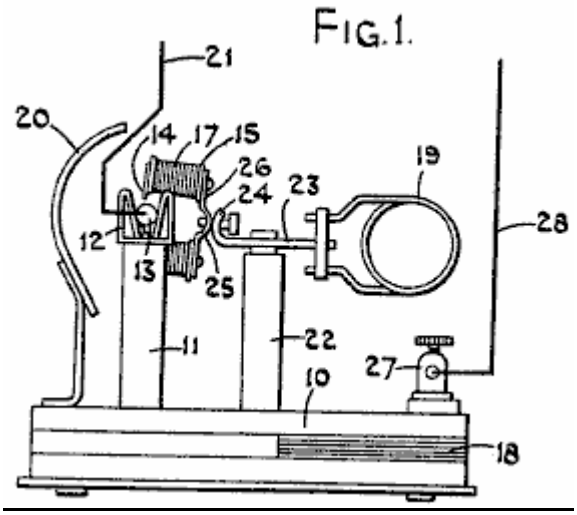

Fig.1 is a side elevation of one form of the apparatus.

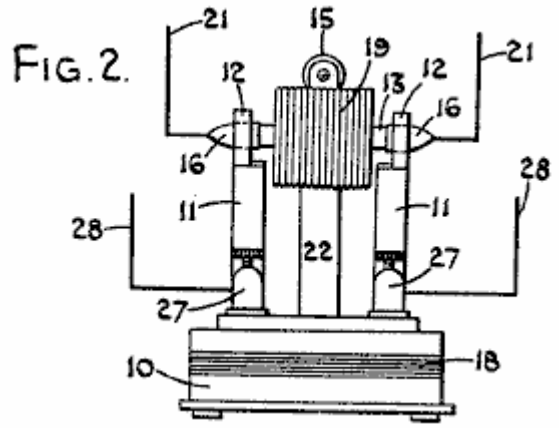

Fig.2 is a view is an end elevation

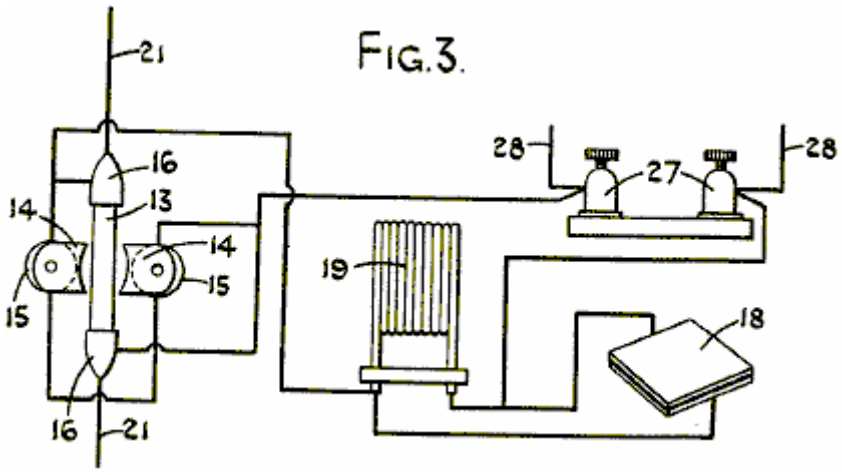

Fig.3 is a schematic circuit diagram.

In the form of our invention illustrated, the generator unit comprises a base **10** upon which the various components are mounted. This base **10**, having projecting upwards from it a pair of arms **11**, which form a cradle housing **12** for a quartz tube **13**, the cradle **12** preferably being made of spring material so that the tube **13** is firmly, yet removably held in position. The arms **11** are positioned relative to the poles **14** of an electromagnet **15** so that the tube **13** is located immediately between the poles of the magnet so as to be in the strongest magnetic field created by the electromagnet. The magnet serves to control the alpha and beta rays emitted by the cartridge when it is in operation.

The ends of the quartz tube **13** are each provided with a brass cap **16**, and these caps **16** are adapted to engage within the spring cradles **12** and the coils **17** associated with the magnet being so arranged that if the base **10** of the unit is in a horizontal plane, the poles **14** of the magnet are in a substantially vertical plane.

Also connected across the cradles is a lead capacitor **18** which may conveniently be housed in the base **10** of the unit and connected in parallel with this capacitor **18** is a suitable high frequency inductance coil **19**. The unit is provided with a lead shield **20** so as to prevent harmful radiation from the quartz tube as will be described later.

The quartz tube **13** has mounted in it, at one end, a quantity of granulated copper which is in electrical contact with the brass cap **16** at that end of the tube. Also mounted within the tube and in contact with the granulated copper is a chemical mixture which is in powdered form and which is capable of releasing electrical energy and which becomes radioactive when subjected to bombardment by ultra-short radio waves.

Mounted in the other end of the tube, and in contact with the other end of the powdered chemical mixture is a quantity of granulated zinc which is itself in contact with the brass cap on this end of the tube, the arrangement being that the chemical mixture is compressed between the granulated copper and the granulated zinc.

Projecting outwards from each brass cap **16**, and electrically connected to them, is an antenna **21**. Each antenna **21** corresponding exactly in dimension, shape and electrical characteristics to the antenna associated with a transmitter unit which is to produce the ultra shortwaves mentioned earlier.

The electromagnet **15** is conveniently carried by a centrally positioned pillar **22** which is secured to the base **10**. At the upper end of pillar **22** there is a cross-bar **23**, which has the high frequency coil **19** attached to one end of it. The other end of the cross-bar **23** is bent around into the curved shape as shown at **24** and is adapted to bear against a curved portion **25** of the base **26** of the electromagnet **15**. A suitable locking device is provided for holding the curved portions **24** and **25** in the desired angular position, so that the position of the poles **14** of the electromagnet can be adjusted about the axis of the quartz tube **13**.

The transmitter unit is of any suitable conventional type for producing ultra shortwaves and may be crystal controlled to ensure that it operates at the desired frequency with the necessity of tuning. If the transmitter is only required to operate over a short range, it may conveniently be battery powered but if it is to operate over a greater range, then it may be operated from a suitable electrical supply such as the mains. If the transmitter is to be tuned, then the tuning may be operated by a dial provided with a micrometer vernier scale so that the necessary tuning accuracy may be achieved.

The mixture which is contained within the quartz tube is composed of the elements Cadmium, Phosphorus and Cobalt, having atomic weights 112, 31 and 59 respectively. Conveniently, these elements may be present in the following compounds, and where the tube is to contain thirty milligrams of the mixture, the compounds and their proportions by weight are:

1 Part of Co (No_3) 2 $6H_2O$
2 Parts of $CdCl_2$
3 Parts of 3Ca (Po_3) 2 + 10C.

The cartridge which consists of the tube **13** with the chemical mixture in it is preferably composed of a number of small cells built up in series. In other words, considering the cartridge from one end to the other, at one end and in contact with the brass cap, there would be a layer of powdered copper, then a layer of the chemical mixture, then a layer of powdered zinc, a layer of powdered copper, etc. with a layer of powdered zinc in contact with the brass cap at the other end of the cartridge. With a cartridge some forty five millimetres long and five millimetres diameter, some fourteen cells may be included.

The cradles **12** in which the brass caps **16** engage, may themselves form terminals from which the output of the unit may be taken. Alternatively, a pair of terminals **27** may be connected across the cradles **12**, these terminals **27** being themselves provided with suitable antennae **28**, which correspond exactly in dimensions, shape and electrical characteristics to the antennae associated with the transmitter, these antennae **28**, replacing the antennae **21**.

In operation with the quartz tube containing the above mixture located between the granulated copper and the granulated zinc and with the tube itself in position between the poles of the magnet, the transmitter is switched on and the ultra shortwaves coming from it are received by the antennae mounted at each end of the tube and in contact with the copper and zinc respectively, the waves being thus passed through the copper and zinc and through the mixture so that the mixture is bombarded by the short waves and the Cadmium, Phosphorus and Cobalt associated with the mixture become radioactive and release electrical energy which is transmitted to the granulated copper and granulated zinc, causing a current to flow between them in a similar manner to the current

flow produced by a thermo couple. It has been established that with a mixture having the above composition, the optimum release of energy is obtained when the transmitter is operating at a frequency of 300 MHz.

The provision of a quartz tube is necessary for the mixture evolves a considerable amount of heat while it is reacting to the bombardment of the short waves. It is found that the tube will only last for one hour and that the tube will become discharged after an hours operation, that is to say, the radioactiveness of the tube will only last for one hour and it is therefore necessary, if the unit is to be run continuously, for the transmitter to be operated for a period of some fifteen to thirty seconds duration once every hour.

With a quartz tube having an overall length of some forty five millimetres and an inside diameter of five millimetres and containing thirty milligrams of the chemical mixture, the estimated energy which will be given off from the tube for a discharge of one hour, is 10 amps at between 100 and 110 volts. To enable the tube to give off this discharge, it is only necessary to operate the transmitter at the desired frequency for a period of some fifteen to thirty seconds duration.

The current which is given off by the tube during its discharge is in the form of direct current. During the discharge from the tube, harmful radiations are emitted in the form of gamma rays, alpha rays and beta rays and it is therefore necessary to mount the unit within a lead shield to prevent the harmful radiations from affecting personnel and objects in the vicinity of the unit. The alpha and beta rays which are emitted from the cartridge when it is in operation are controlled by the magnet.

When the unit is connected up to some apparatus which is to be powered by it, it is necessary to provide suitable fuses to guard against the cartridge being short-circuited which could cause the cartridge to explode.

The estimated weight of such a unit including the necessary shielding, per kilowatt hour output, is approximately 25% of any known standard type of accumulator which is in use today and it is estimated that the life of the chemical mixture is probably in the region of seventy to eighty years when under constant use.

It will thus be seen that we have provided a novel form of apparatus for producing an electric current, which is considerably lighter than the standard type of accumulator at present known, and which has an infinitely greater life than the standard type of accumulator, and which can be recharged or reactivated as and when desired and from a remote position depending on the power output of the transmitter. Such form of battery has many applications.

JONG-SOK AN

United States Patent 6,208,061 27th March 2001 Inventor: Jong-Sok An

NO-LOAD GENERATOR

Electrical power is frequently generated by spinning the shaft of a generator which has some arrangement of coils and magnets contained within it. The problem is that when current is drawn from the take-off coils of a typical generator, it becomes much more difficult to spin the generator shaft. The cunning design shown in this patent overcomes this problem with a simple design in which the effort required to turn the shaft is not altered by the current drawn from the generator.

ABSTRACT

A generator of the present invention is formed of ring permanent magnet trains 2 and 2' attached and fixed on to two orbits 1 and 1' about a rotational axis 3, magnetic induction primary cores 4 and 4' attached and fixed above outer peripheral surfaces of the ring permanent magnet trains 2 and 2' at a predetermined distance from the outer peripheral surfaces, magnetic induction secondary cores 5 and 5' attached and fixed on to the magnetic induction primary cores 4 and 4' and each having two coupling, holes 6 and 6' formed therein, tertiary cores 8 and 8' inserted for coupling respectively into two coupling holes 6 and 6' of each of the associated magnetic induction secondary cores 5 and 5' opposite to each other, and responsive coils 7 and 7'. The ring permanent magnetic trains 2 and 2' are formed of 8 sets of magnets with alternating N and S poles, and magnets associated with each other in the axial direction have opposite polarities respectively and form a pair.

DESCRIPTION

TECHNICAL FIELD

The present invention relates to generators, and particularly to a load-free generator which can maximise the generator efficiency by erasing or eliminating the secondary repulsive load exerted on the rotor during electric power generation.

BACKGROUND ART

The generator is a machine which converts mechanical energy obtained from sources of various types of energy such as physical, chemical or nuclear power energy, for example, into electric energy. Generators based on linear motion have recently been developed while most generators are structured as rotational type generators. Generation of electromotive force by electromagnetic induction is a common principle to generators regardless of their size or whether the generator is AC or DC generator.

The generator requires a strong magnet such as permanent magnet and electromagnet for generating magnetic field as well as a conductor for generating the electromotive force, and the generator is structured to enable one of them to rotate relative to the other. Depending on which of the magnet and the conductor rotates, generators can be classified into rotating-field type generators in which the magnetic field rotates and rotating-armature type generators in which the conductor rotates.

Although the permanent magnet can be used for generating the magnetic field, the electromagnet is generally employed which is formed of a magnetic field coil wound around a core to allow direct current to flow through them. Even if a strong magnet is used to enhance the rotational speed, usually the electromotive force produced from one conductor is not so great. Thus, in a generally employed system, a large number of conductors are provided in the generator and the electromotive forces generated from respective conductare serially added up so as to achieve a high electric power.

As discussed above, a usual generator produces electricity by mechanically rotating a magnet (or permanent magnet) or a conductor (electromagnet, electrically responsive coil and the like) while reverse current generated at this time by magnetic induction (electromagnetic induction) and flowing through the coil causes magnetic force which pulls the rotor so that the rotor itself is subjected to unnecessary load which reaches at least twice the electric power production.

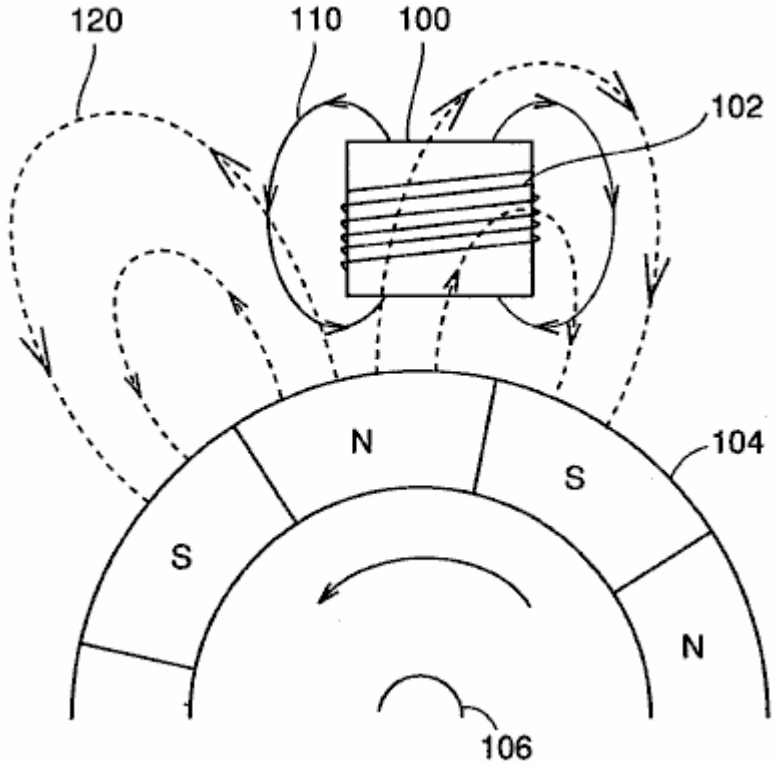

Fig.6 illustrates that the load as discussed above is exerted on a rotor in a rotating-field type generator mentioned above.

Referring to **Fig.6**, a permanent magnet train **104** is arranged about an axis of rotation **106** such that N poles and S poles are alternately located on the outer peripheral surface of the train. At a certain distance outward from the outer periphery of permanent magnet train **104**, a magnetic induction core **100** is arranged and a coil **102** is wound around magnetic induction core **100**.

As permanent magnet train **104** rotates, the magnetic field produced in the coil by permanent magnet train **104** changes to cause induced current to flow through coil **102**. This induced current allows coil **102** to generate a magnetic field **110** which causes a repulsive force exerted on permanent magnet train **104** in the direction which interferes the rotation of the magnet train.

For example, in the example shown in **Fig.6**, the S pole of magnetic field **110** faces permanent magnet train **104**. The S pole of permanent magnet train **104** approaches coil **102** because of rotation of permanent magnet train **104**, resulting in the repulsive force as described above.

If reverse current flows in a responsive coil of an armature wound around a magnetic induction core of a generator so that the resulting load hinders the rotor from rotating, reverse magnetic field of the armature responsive coil becomes stronger in proportion to the electricity output and accordingly a load corresponding to at least twice the instantaneous consumption could occur.

If electric power of 100W is used, for example, reverse magnetic field of at least 200W is generated so that an enormous amount of load affects the rotor to interfere the rotation of the rotor.

All of the conventional generators are subjected to not only a mechanical primary load, i.e. the load when the electric power is not consumed but a secondary load due to reverse current which is proportional to electric power consumption and consequently subjected to a load of at least twice the instantaneous consumption.

Such an amount of the load is a main factor of reduction of the electric power production efficiency, and solution of the problem above has been needed.

DISCLOSURE OF THE INVENTION

One object of the present invention is to provide a generator capable of generating electric power with high efficiency by cancelling out the secondary load except the mechanical load of the generator, i.e. cancelling out the load which is generated due to reverse current of a responsive coil of an armature wound around a magnetic induction core, so as to entirely prevent the secondary load from being exerted.

In short, the present invention is applied to a load-free generator including a rotational axis, a first ring magnet train, a second ring magnet train, a first plurality of first magnetic induction primary cores, a first plurality of second magnetic induction primary cores, a first responsive coil, and a second responsive coil.

The first ring magnet train has N poles and S poles successively arranged on an outer periphery of a first rotational orbit about the rotational axis. The second ring magnet train has magnets successively arranged on an outer periphery of a second rotational orbit about the rotational axis at a predetermined distance from the first rotational orbit such that the polarities of the magnets on the second rotational orbit are opposite to the polarities at opposite locations on the first rotational orbit respectively. The first plurality of first magnetic induction primary cores are fixed along a first peripheral surface of the first ring magnet train at a predetermined distance from the first peripheral surface. The first plurality of second magnetic induction primary cores are fixed along a second peripheral surface of the second ring magnet train at a predetermined distance from the second peripheral surface. A first plurality of first coupling magnetic induction cores and a first plurality of second coupling magnetic induction cores are provided in pairs to form a closed magnetic circuit between the first and second magnetic induction primary cores opposite to each other in the direction of the rotational axis. The first responsive coil is wound around the first coupling magnetic induction core. The second responsive coil is wound around the second coupling magnetic induction core, the direction of winding of the second responsive coil being reversed relative to the first responsive coil.

Preferably, in the load-free generator of the invention, the first ring magnet train includes a permanent magnet train arranged along the outer periphery of the first rotational orbit, and the second ring magnet train includes a permanent magnet train arranged along the outer periphery of the second rotational orbit.

Still preferably, the load-free generator of the present invention further includes a first plurality of first magnetic induction secondary cores provided on respective outer peripheries of the first magnetic induction primary cores and each having first and second coupling holes, and a first plurality of second magnetic induction secondary cores provided on respective outer peripheries of the second magnetic induction primary cores and each having third and fourth coupling holes. The first coupling magnetic induction cores are inserted into the first and third coupling holes to couple the first and second magnetic induction secondary cores, and the second coupling magnetic induction cores are inserted into the second and fourth coupling holes to couple the first and second magnetic induction secondary cores.

Alternatively, the load-free generator of the present invention preferably has a first plurality of first responsive coils arranged in the rotational direction about the rotational aids that are connected zigzag to each other and a first plurality of second responsive coils arranged in the rotational direction about the rotational axis that are connected zigzag to each other.

Alternatively, in the load-free generator of the present invention, preferably the first plurality is equal to 8, and the 8 first responsive coils arranged in the rotational direction about the rotational axis are connected zigzag to each other, and the 8 second responsive coils arranged in the rotational direction about the rotational axis are connected zigzag to each other.

Accordingly, a main advantage of the present invention is that two responsive coils wound respectively in opposite directions around a paired iron cores are connected to cancel reverse magnetic forces generated by reverse currents (induced currents) flowing through the two responsive coils, so that the secondary load which interferes the rotation of the rotor is totally prevented and thus a load-free generator can be provided which is subjected to just a load which is equal to or less than mechanical load when electric power production is not done, i.e. the rotational load even when the generator is operated to the maximum.

Another advantage of the present invention is that the reverse magnetic force, as found in the conventional generators, due to reverse current occurring when the rotor rotates is not generated, and accordingly load of energy except the primary gravity of the rotor and dynamic energy of the rotor is eliminated to increase the amount of electricity output relative to the conventional electric power generation system and thus enhance the electric power production and economic efficiency.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig.1 is a cross sectional view of a rotating-field type generator according to an embodiment of the present invention illustrating an arrangement a permanent magnet, magnetic induction cores and coils.

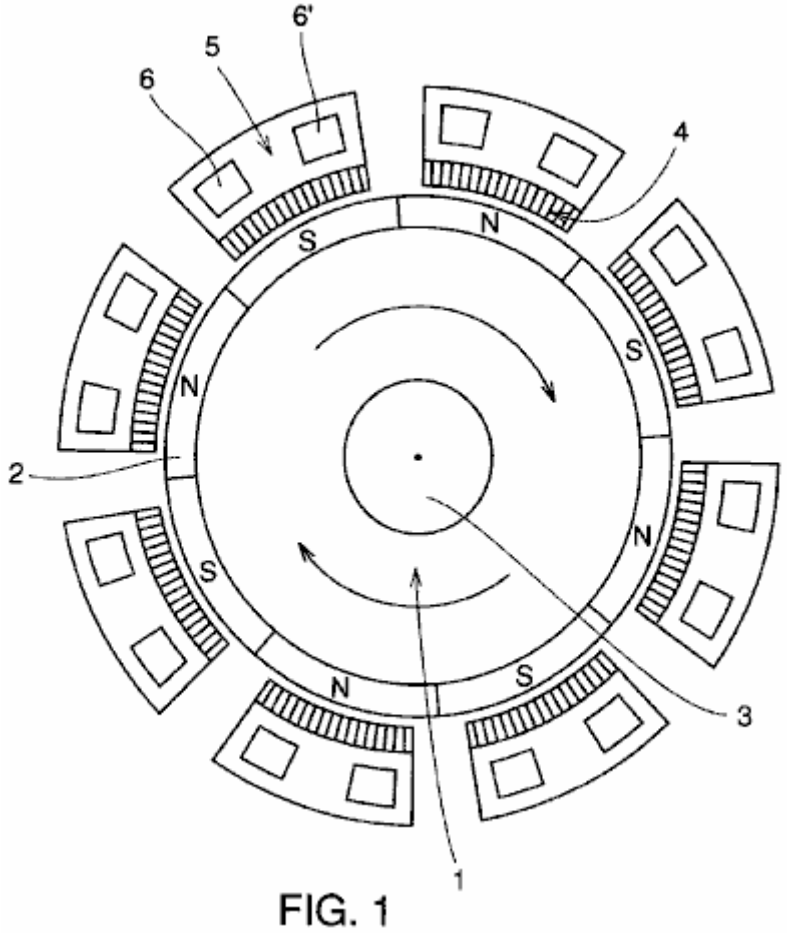

FIG. 1

Fig.2 is a partial schematic view illustrating a magnetic array of the permanent magnet rotor and an arrangement of one of magnetically responsive coils placed around that rotor in an embodiment of the present invention.

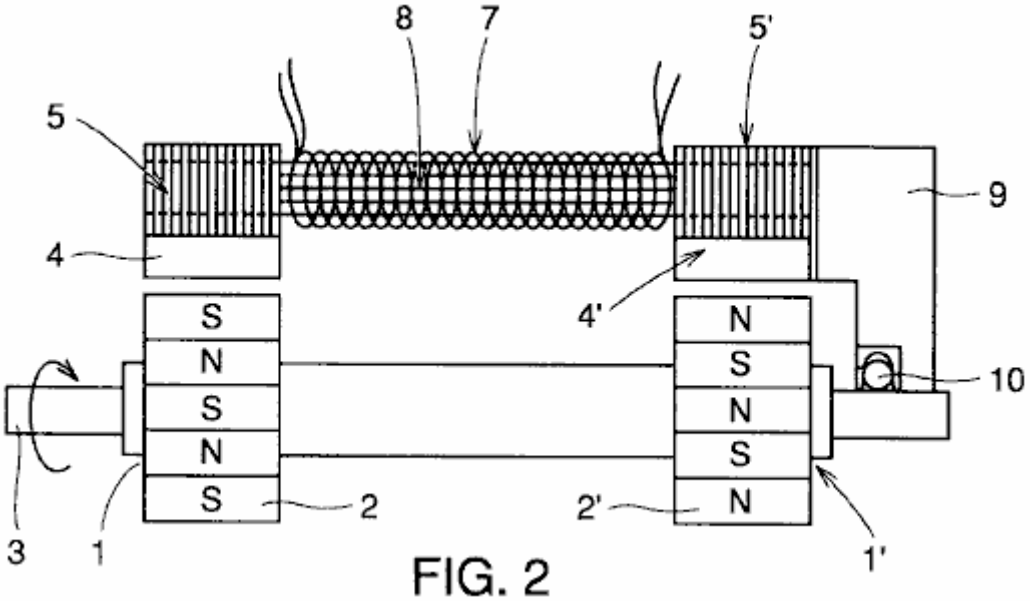

FIG. 2

Fig.3 illustrates a structure of the magnetically responsive coils and cores in the embodiment of the present invention.

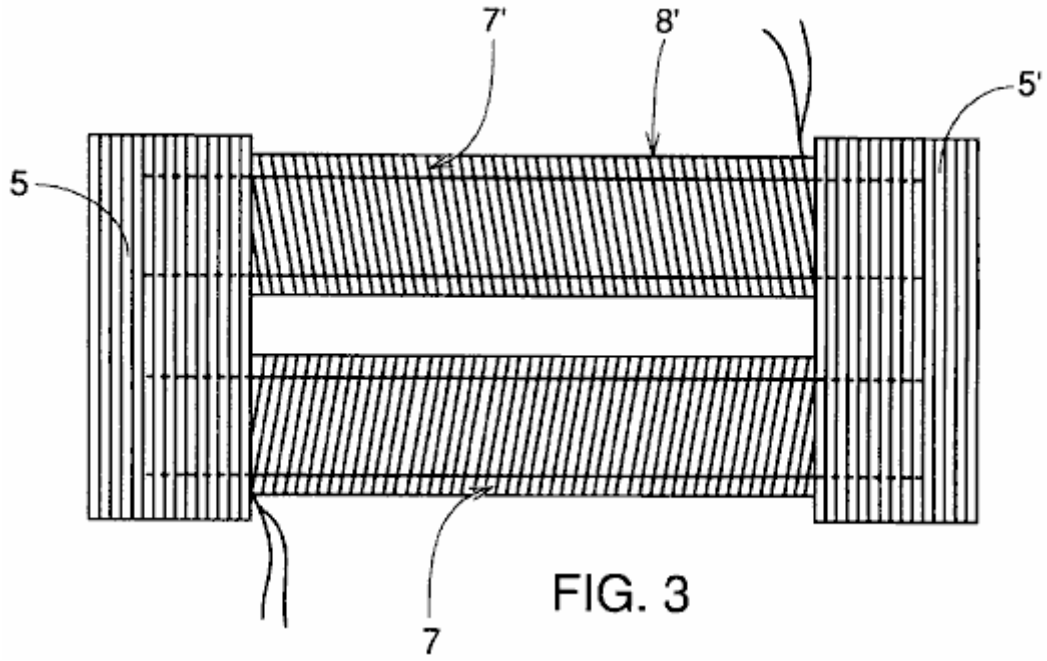

FIG. 3

Fig.4 is an enlarged plan view of magnetically sensitive cores and coil portions of the load-free generator of the present invention illustrating magnetic flow therethrough.

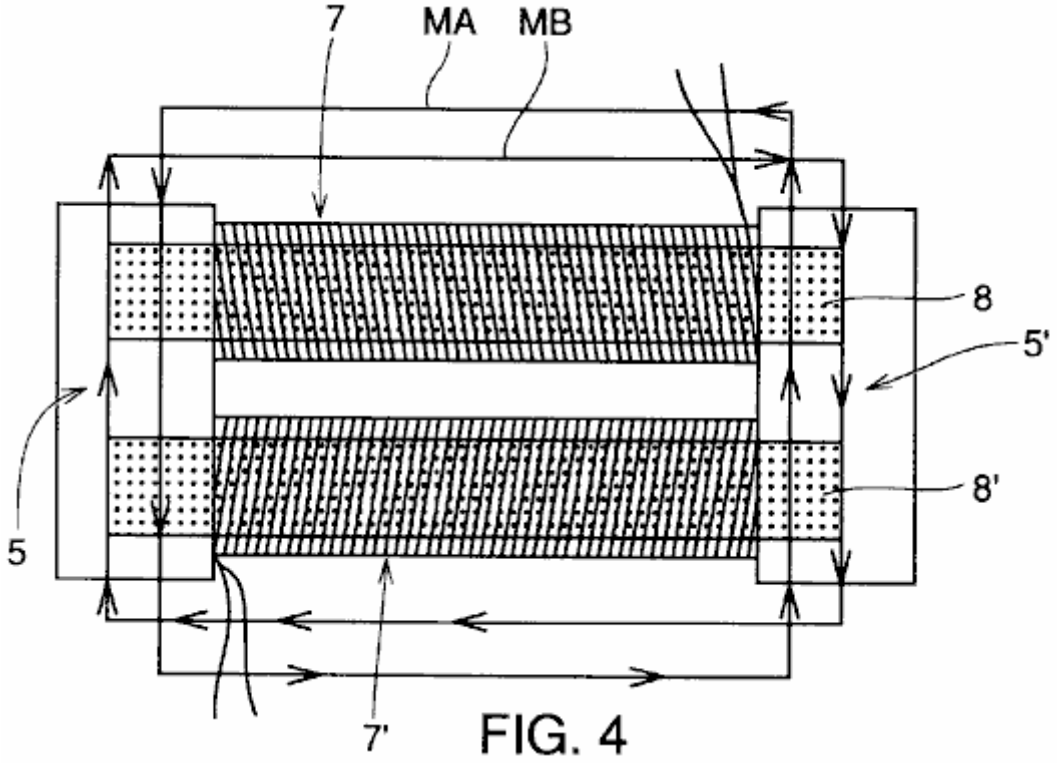

FIG. 4

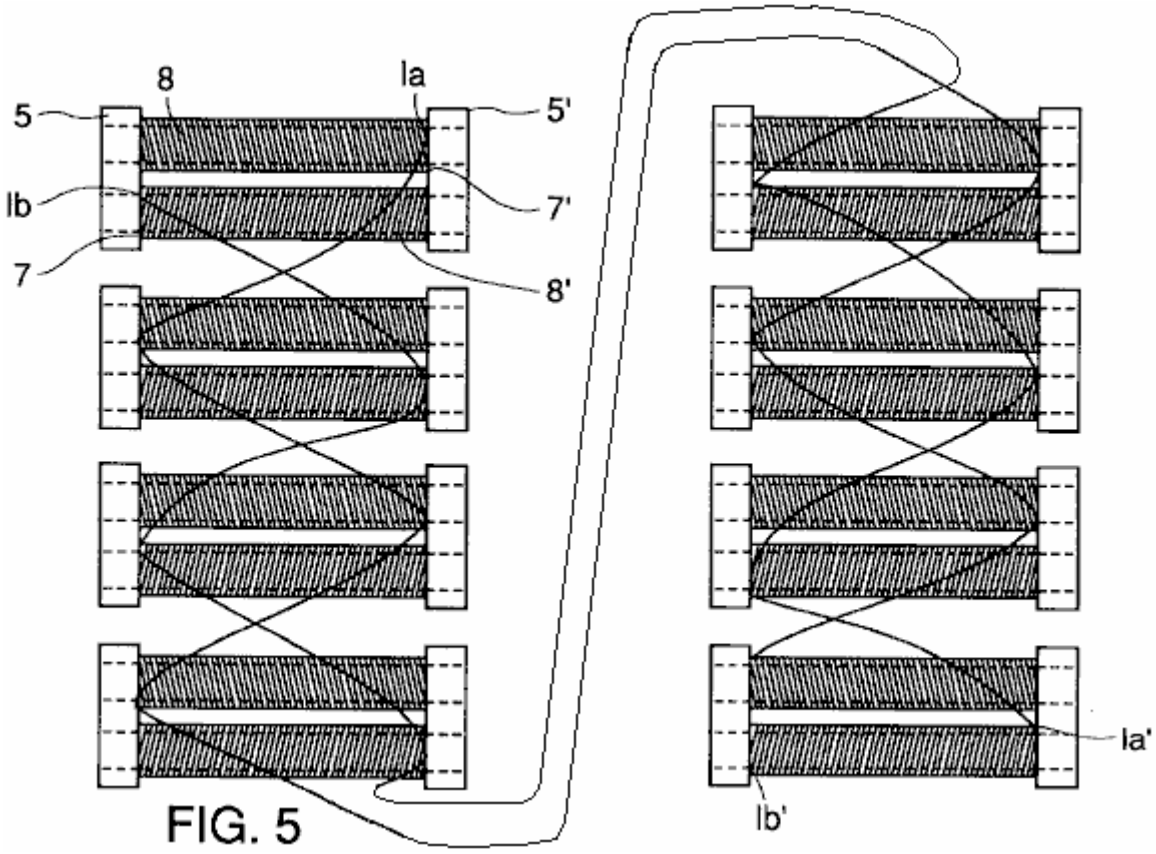
Fig.5 is an exploded view about a central axis showing the interconnection of magnetic field coils which are respectively wound around tertiary cores surrounding the permanent magnet rotor in FIG. 1 according to the present invention.



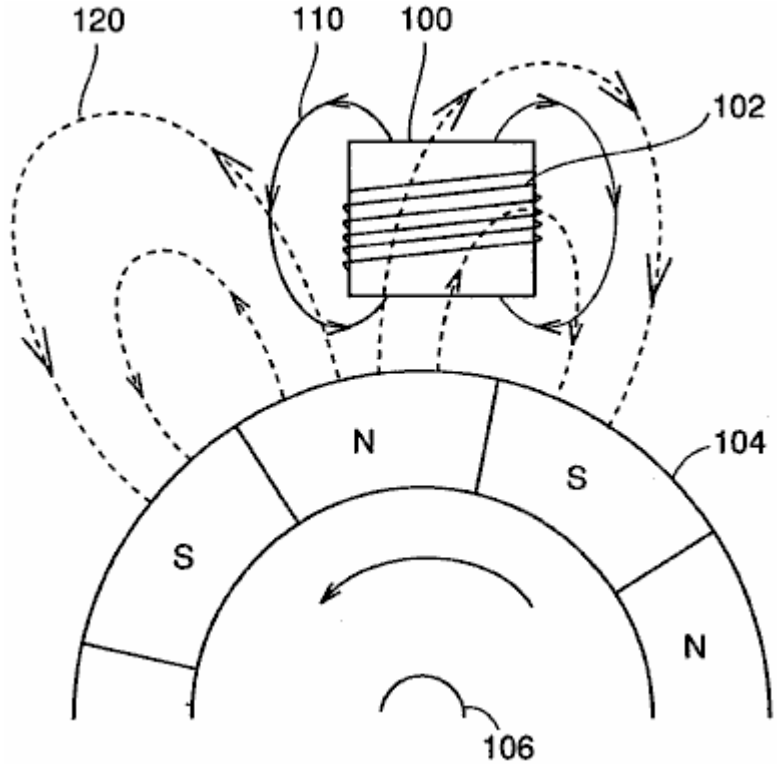


FIG. 5

Fig.6 illustrates generation of the secondary load in a conventional generator.

BEST MODES FOR CARRYING OUT THE INVENTION

The structure and operation of a load-free generator according to the present invention are now described in conjunction with the drawings.

Fig.1 illustrates a cross sectional structure of the load-free generator of the invention perpendicular to a rotational axis **3**.

Fig.2 partially illustrates a cross sectional structure of the load-free generator of the invention in parallel to rotational axis **3**. Specifically, in **Fig.2**, only one of eight sets of magnetic induction primary cores **4** and **4'** arranged around rotational axis **3** as described below is representatively shown.

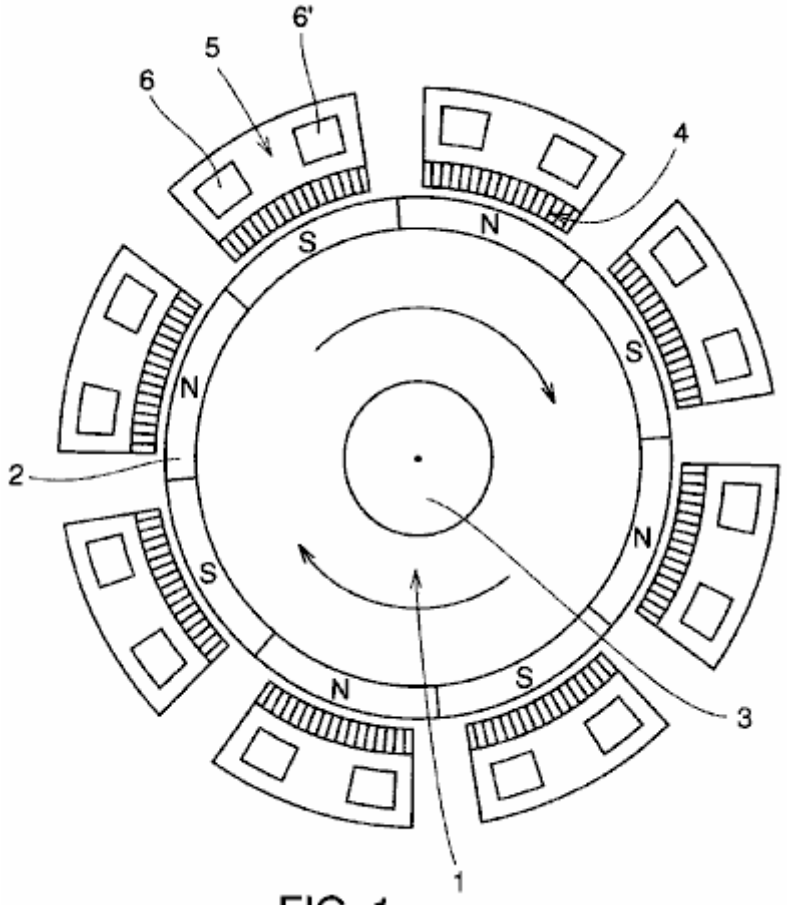

FIG. 1

Referring to **Fig.1** and **Fig.2**, the structure of the load-free generator of the invention is now described. Permanent magnet trains **2** and **2'** in ring forms are attached and fixed to respective left and right orbits **1** and **1'** provided relative to rotational axis **3** with a certain interval between them. Permanent magnet trains **2** and **2'** are fixed onto left and right orbits **1** and **1'** respectively such that the polarities on the outer peripheral surface of each magnet train relative to the rotational axis are alternately N poles and S poles. The permanent magnet trains are rotatable about the axis. Further, the facing polarities of respective permanent magnet train **2** and permanent magnet train **2'** relative to the direction of rotational axis **3** are arranged to be opposite.

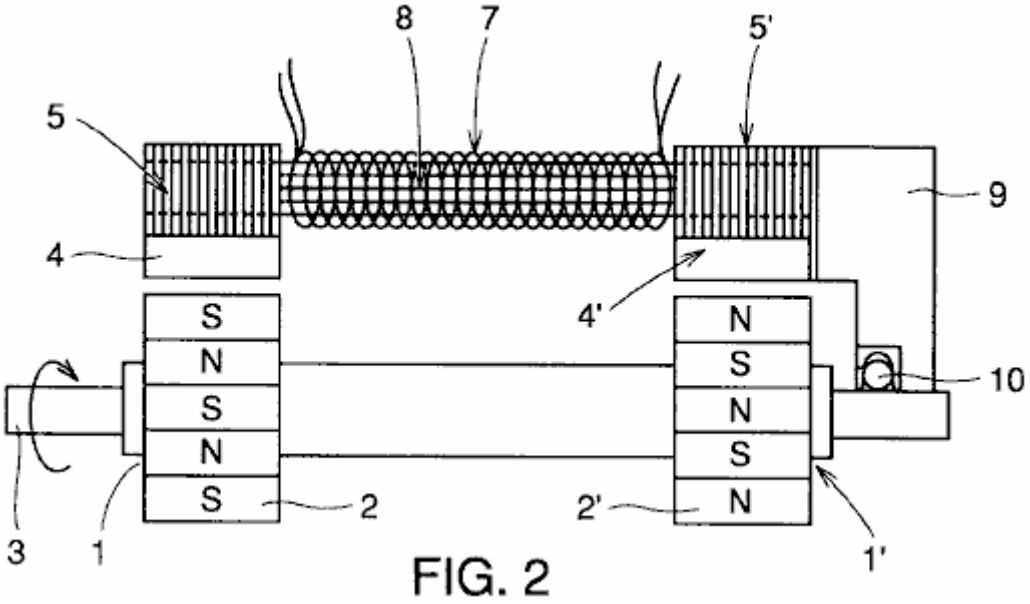

FIG. 2

As shown in **Fig.2**, rotational axis **3** and a case **9** are joined by a bearing **10** at a certain distance from the permanent magnet trains **2** and **2'**.

At a predetermined distance from permanent magnet trains **2** and **2'**, magnetic induction primary cores **4** and **4'** with respective coils wound around them are fixed to case **9**.

In addition, magnetic induction secondary cores **5** and **5'** each having two coupling holes **6** and **6'** formed therein are structured by stacking and coupling a plurality of thin cores attached and fixed to magnetic induction primary cores **4** and **4'** respectively and the secondary cores are attached and fixed to case **9**.

Magnetic induction tertiary cores **8** and **8'** are inserted respectively into coupling holes **6** and **6'** of magnetic induction secondary cores **5** and **5'** so as to couple magnetic induction secondary cores **5** and **5'** of each other.

Responsive coils **7** and **7'** are wound in opposite directions to each other around respective magnetic induction cores **8** and **8'**.

Fig.3 illustrates a structure formed of magnetic induction secondary cores **5** and **5'**, magnetic induction cores **8** and **8'** and responsive coils **7** and **7'** viewed in the direction perpendicular to rotational axis **3**.

As explained above, the directions of windings of responsive coils **7** and **7'** are respectively opposite to each other around magnetic induction cores **8** and **8'** which couple magnetic induction secondary cores **5** and **5'**.

In the structure described in conjunction with **Fig.1**, **Fig.2** and **Fig.3**, when rotational axis **3** of the generator rotates, permanent magnetic trains **2** and **2'** accordingly rotate to generate magnetically sensitive currents (electromagnetically induced current) in responsive coils **7** and **7'** and the current thus produced can be drawn out for use.

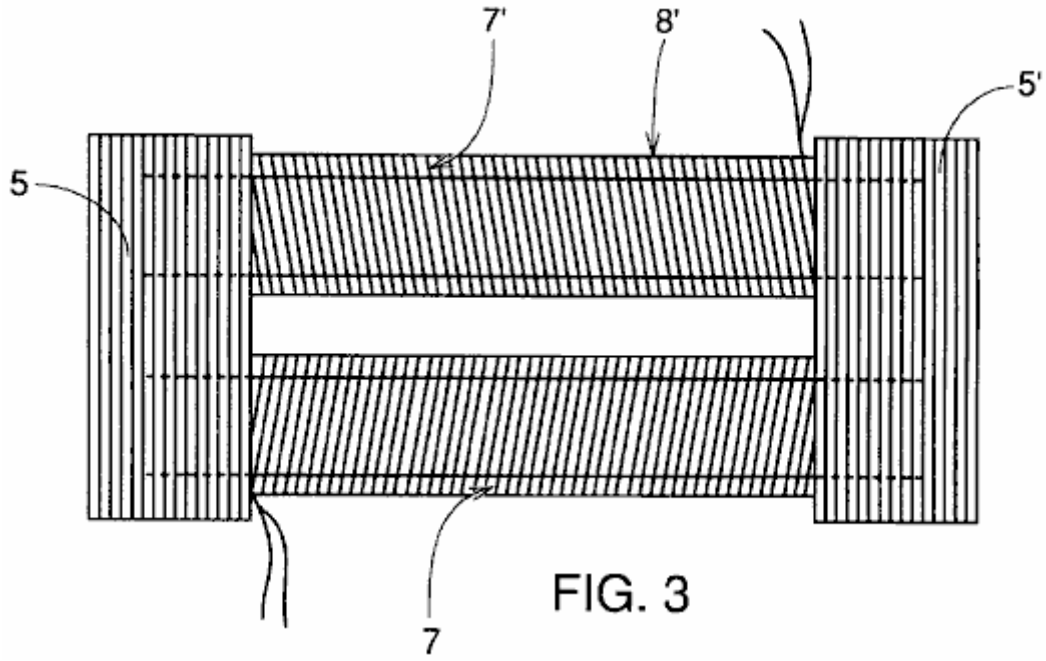

FIG. 3

As shown in **Fig.3**, the coils are wound about magnetic induction cores **8** and **8'** respectively in the opposite directions in the generator of the present invention, and the directions of the magnetic fields generated by the flow of the induced currents are arranged such that the N pole and S pole alternately occurs around rotational axis **3**.

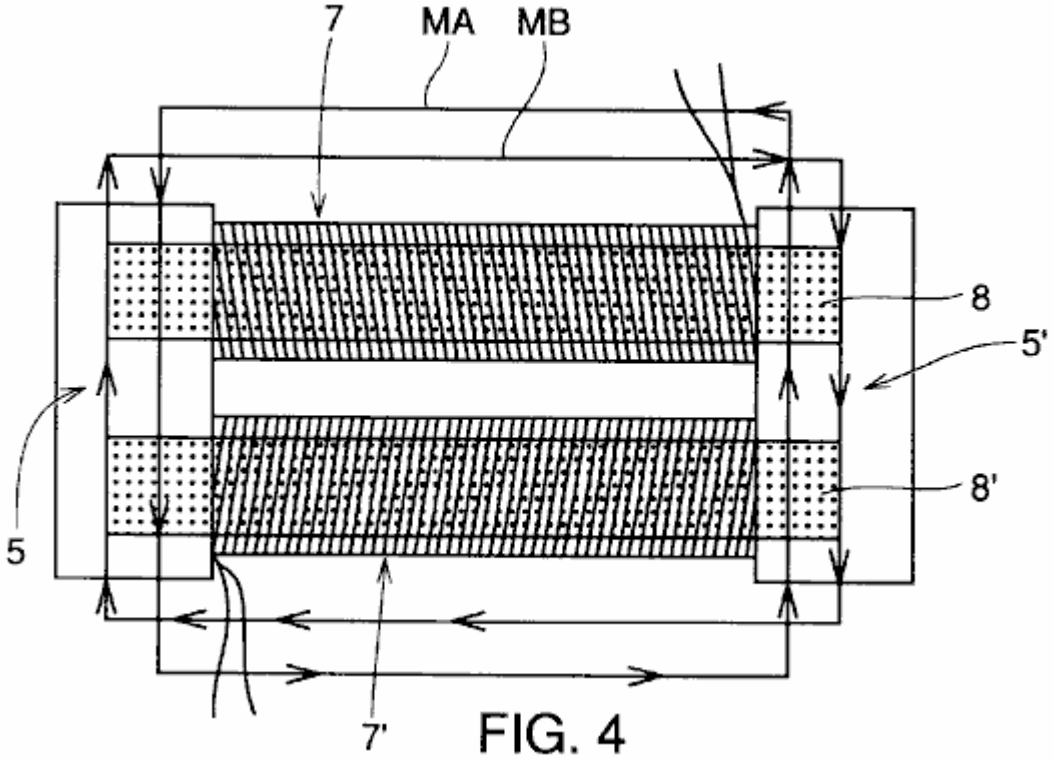

FIG. 4

Fig.4 illustrates magnetic fields induced in a set of magnetic induction secondary cores **5** and **5'**, magnetic induction cores **8** and **8'** and responsive coils **7** and **7'**.

At iron strips on both ends of respective magnetic induction secondary cores **5** and **5'**, a reverse current magnetic field is generated by responsive coil **7** upon the rotation of N and S poles of permanent magnet trains **2** and **2'** is in the direction of **MA** shown in **Fig.4**, for example, while a reverse current magnetic field generated by responsive coil **7** is in the direction of **MB** in **Fig.4**. Consequently, the reverse magnetic fields generated by the flow of currents cancel each other. The cores are formed of a plurality of iron strips in order to eliminate heat generated by eddy currents.

The magnetic field of the rotor thus has no dependence on the flow of currents, the load caused by the induced magnetisation phenomenon disappears, and energy of movement necessary for rotation against the mechanical primary load of the rotor itself is applied to the rotor.

At this time, a magnetic circuit including magnetic induction secondary cores **5** and **5'** and magnetic induction tertiary cores **8** and **8'** should be shaped into ".quadrature." form. If the circuit does not structured as ".quadrature." form, a part of the reverse magnetic field functions as electrical force which hinders the rotational force of the rotor.

Further, permanent magnet trains **2** and **2'** of the rotor are arranged to have opposite poles to each other on the left and right sides as shown in **Fig.2** so as to constitute the flow of magnetic flux. Each rotor has alternately arranged magnets, for example, eight poles are provided to enhance the generator efficiency.

More detailed description of the operational principle is given now. When the rotor in **Fig.1** rotates once, S and N poles of permanent magnets **2** and **2'** attached to the periphery of the rotor successively supply magnetic fields to induction primary cores **4** above, and magnetic field is accordingly generated in a path from one orbit of the rotor along induction primary core **4**, induction secondary core **5**, induction tertiary core **8**, induction secondary core **5'**, induction primary core **4'** to the other orbit of the rotor as shown in **Fig.2**.

Accordingly, current flows in the coils affected by this electric field to generate electric power. For example, if the generated power is used as generated output for switching on an electric light or for using it as motive energy, the current flowing through the coils generates the reverse magnetic fields. However, this reverse magnetic fields do not influence permanent magnets **2** and **2'** attached to the rotor in **Fig.2** since the reverse magnetic fields of the same magnitude respectively of S and N or N and S on both ends of magnetic induction secondary cores **5** and **5'** cancel out each other as shown in **Fig.4**. Because of this, the rotor is in a no-load state in which any resistance except the weight of the rotor itself and dynamic resistance is not exerted on the rotor.

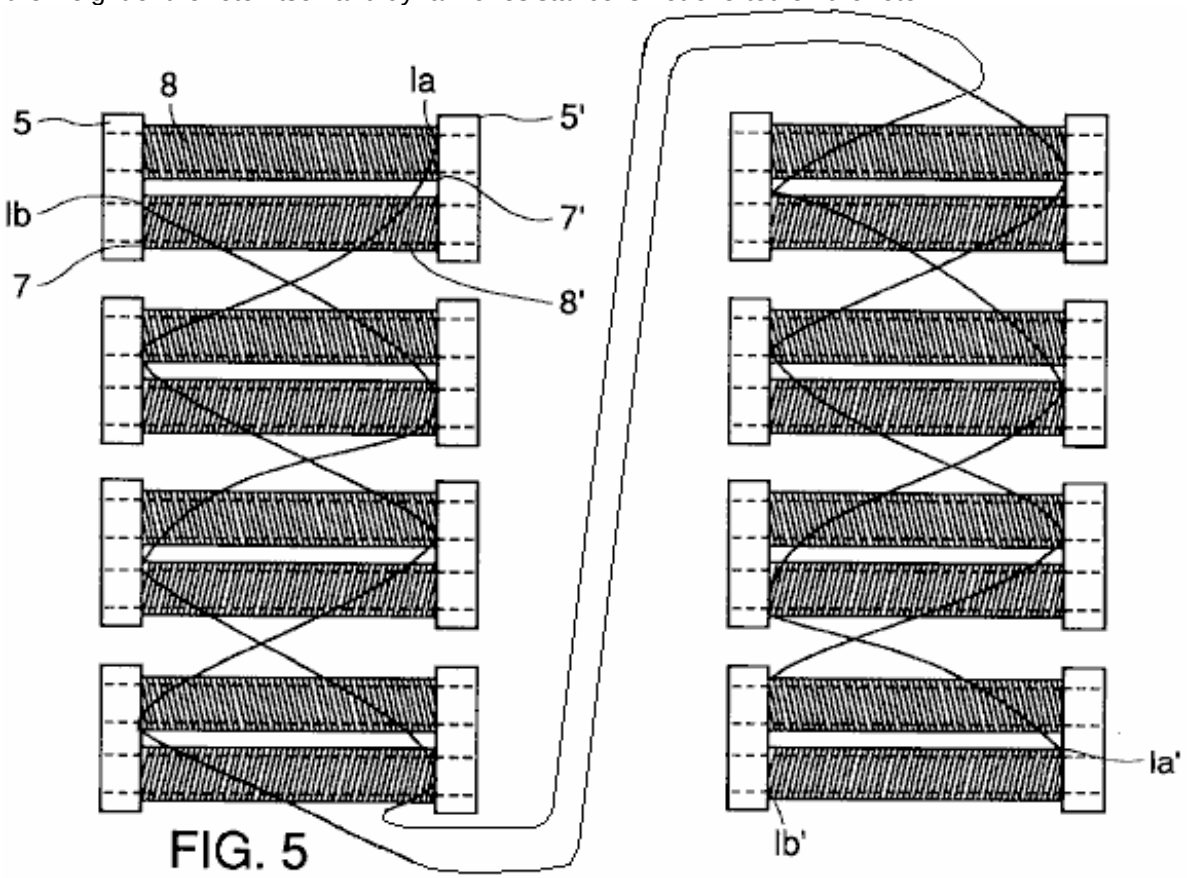

FIG. 5

Fig.5 illustrates a manner of connecting magnetically responsive coils **7** and **7'** wound around magnetic induction tertiary cores **8** and **8'** with eight poles.

Referring to **Fig.5**, according to a method of connecting magnetically responsive coils **7** and **7'** , line **1a1** of responsive coil **7'** (one drawn-out line of the wire coiled around a first magnetic induction core **8**) is connected to line **1a2'** (one drawn-out line of the wire coiled around a second magnetic induction core **8**), and then line **1a2** (the other drawn-out line of the wire coiled around a second magnetic induction core **8**) is connected to line **1a3'**, and subsequently lines **1a** and **1a'** are connected successively in zigzag manner to allow current to flow. Further, responsive coil **7** is arranged to connect lines represented by **1b1** in zigzag manner such that lines **1b** and **1b'** are successively connected. In this way, lines **1b**, **1b'** and lines **1a** and **1a'** of respective magnetically responsive coils **7** and **7'** are connected. As a whole, total four electric wires are drawn out for use.

When electric power is to be generated according to the present invention as described above, specifically, a closed circuit is formed by responsive coils **7** and **7'**, electric currents are induced in responsive coils **7** and **7'** wound around the magnetic induction cores of the generator, and the induced magnetic fields produced respectively by responsive coils **7** and **7'** could cause a great load which interferes the rotational force of the rotor. However, as shown in **Fig.4**, the direction of convolution of one coil **7** is opposite to that of the other coil **7'** so that the magnetic force generated by the reverse currents (induced currents) in responsive coils **7** and **7'** wound around magnetic induction core **4** is not transmitted to magnetic induction cores **8** and **8** accordingly no reverse magnetic force is transmitted to permanent magnets **2** and **2'**.

Therefore, each time the N poles and S poles alternate with each other because of the alternation of permanent magnets **2** and **2'** shown in **Fig.2**, the reverse magnetic forces in the right and left direction opposite to the direction of arrows denoted by **MA** and **MB** completely disappear as shown in **Fig.4**. Consequently, the reverse magnetic forces caused by the reverse currents are not influenced by permanent magnets **2** and **2'** and accordingly no load except the mechanical primary load is exerted on the generator of the invention.

As discussed above, the load-free generator of the present invention, secondary load except mechanical load of the generator, i.e. the load caused by the reverse currents flowing through the responsive coils can be nulled. With regard to this load-free generator, even if 100% of the current generated by magnetic induction (electromagnetic induction) is used, the magnetic secondary load due to the reverse currents except the mechanical primary load does not serve as load.

Although the number of poles of the rotor is described as **8** in the above description, the present invention is not limited to such a structure, and the invention can exhibit its effect when the smaller or greater number of poles is applied.

Further, although the magnet of the rotor is described as the permanent magnet in the above structure, the invention is not limited to such a case and the magnet of the rotor may be an electromagnet, for example.

In addition, although the description above is applied to the structure of the rotating-field type generator, the generator may be of the rotating-armature type.

EXPERIMENTAL EXAMPLE

More detailed description of the generator of the present invention is hereinafter given based on specific experimental examples of the invention.

The generator of the present invention and a conventional generator were used to measure the electric power production efficiency and the amount of load and compare the resultant measurements.

EXPERIMENTAL EXAMPLE 1

A 12-pole alternating current (AC) generator for battery charging was used, and the electricity output and the load when 50% of the electricity output was used as well as those when 100% of the electricity output was used were measured. The generator above is a single-phase AC motor and the employed power source was 220V, with 1750 rpm and the efficiency of 60%. The result of measurement using power of a motor of 0.5HP and ampere .times.volt gauge is shown in **Table 1**.

EXPERIMENTAL EXAMPLE 2

Measurement was done under the same conditions as those of experimental example 1 and a generator used was the one which was made according to the present invention to have the same conditions as those of the product of the existing model above. The result of measurement using ampere x volt gauge is shown in **Table 1**.

Table 1

	50% Electricity Used		100% Electricity Used	
Type of Generator	Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)
Conventional:	100	221	14	347
This invention:	100	220	183	200

(electricity output and load amount of the alternating current generators when 50% and 100% of the electricity were used)

From the result of Experimental Example 1 above, the reason for the remarkable reduction of the electricity output when the electricity consumption was 100% relative to the electricity consumption of 50% in the conventional generator is considered to be the significant increase of the repulsive load exerted on the generator when 100% of the electricity is used.

On the other hand, in the generator of the present invention, there was no appreciable difference in the amount of load between those cases in which 50% of the electricity was used and 100% thereof was used respectively. Rather, the amount of load slightly decreased (approximately 20W) when 100% of the electricity was used. In view of this, it can be understood that the amount of generated electric power of the generator of the present invention is approximately doubled as the electricity consumption increases, which is different from the conventional generator producing electric power which sharply decreases when the electricity consumption increases.

In conclusion, the amount of load above is supposed to be numerical value relative to the mechanical load of the generator as described above. Any secondary load except this, i.e. load due to the reverse currents generated in the armature responsive coils can be confirmed as zero.

EXPERIMENTAL EXAMPLE 3

12V direct current (DC) generators having similar conditions to those in experimental example 1 were used to make measurement under the same conditions (efficiency 80%). The result of the measurement is presented below.

Table 2

	50% Electricity Used		100% Electricity Used	
Type of Generator	Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)
Conventional:	103	290	21	298
This invention:	107	282	236	272

(electricity output and load amount of the alternating current generators when 50% and 100% of the electricity were used)

The DC generator has higher efficiency (80%) than that of the AC generator, while use of the brush increases the cost of the DC generator. When 100% of the electricity was used, the amount of load slightly decreased which was similar to the result shown in Table 1 and the electricity output was approximately at least 2.2 times that when 50% of the electricity was used.

EXPERIMENTAL EXAMPLE 4

A 220V single-phase alternating current (AC) generator (0.5HP) having similar conditions to those in experimental example 1 was used, and the rotation per minute (rpm) was changed to make measurement under the condition of 100% consumption of the generated electricity. The result of measurement is illustrated in the following **Table 3**.

Table 3

1750 rpm		3600 rpm		5100 rpm	
Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)
130	160	210	228	307	342

(amounts of generated electric power and load when the rotation per minute of the generator of the present invention was varied)

As shown in **Table 3** above, as the rotation per minute (rpm) increases as from 1750, 3600 to 5100, the amount of electric power increases respectively from 130, 210 to 307W and consequently the difference between the amount of generated electric power and the amount of load decreases to cause relative decrease of the amount of load as the rotation per minute (rpm) increases.

EXPERIMENTAL EXAMPLE 5

Measurement was done by changing the number of N and S poles of the permanent magnets of the invention under the same conditions as those of experimental example 1 and under the condition that 100% of the generated electricity was used.

The result of the measurement is illustrated below.

Table 4

2 poles		4 poles		8 poles	
Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)	Electricity Output (Watts)	Amount of Load (Watts)
80	152	130	200	265	296

(amounts of generated electric power and load when the number of poles of the permanent magnets of the generator of the invention was changed)

From **Table 4** above, it can be understood that as the number of poles increases, both of the amounts of generated electric power and load increase. However, the ratio of the amount of generated electric power to the amount of load monotonously increases. In the table above, in terms of the amount of load, only the mechanical primary load is exerted and electrical secondary is not exerted.

The increase of the number of poles causes increase, by the number of increased poles, in the number of lines of magnetic flux which coils traverse, and accordingly the electromotive force increases to increase the amount of generated electric power. On the other hand, the amount of mechanical load has a constant value regardless of the increase of the number of poles, so that the mechanical load amount relatively decreases to reduce the difference between the amount of load and the amount of generated electric power.

Detailed description of the present invention which has been given above is just for the purpose of presenting example and illustration, not for limitation. It will dearly be appreciated that the spirit and scope of the invention will be limited only by the attached scope of claims.

ALBERTO MOLINA-MARTINEZ

Patent Application US 20020125774 6th March 2002 Inventor: Alberto Molina-Martinez

CONTINUOUS ELECTRICAL GENERATOR

This patent application shows the details of a device which it is claimed, can produce sufficient electricity to power both itself and external loads. It also has no moving parts.

ABSTRACT

A stationary cylindrical electromagnetic core, made of one piece thin laminations stacked to desired height, having closed slots radially distributed, where two three-phase winding arrangements are placed together in the same slots, one to the centre, one to the exterior, for the purpose of creating a rotational electromagnetic field by temporarily applying a three-phase current to one of the windings, and by this means, inducting a voltage on the second one, in such a way that the outgoing energy is a lot greater than the input. A return will feedback the system and the temporary source is then disconnected. The generator will run by itself indefinitely, permanently generating a great excess of energy.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to electrical power generating systems. More specifically, the present invention relates to self-feeding electrical power generating units.

2. Description of Related Art

Since Nikola Tesla invented and patented his Polyphase System for Generators, Induction Motors and Transformers, no essential improvement has been made in the field. The generators would produce the polyphase voltages and currents by means of mechanical rotational movement in order to force a magnetic field to rotate across the generator's radially spaced windings. The basis of the induction motor system was to create an electro-magnetically rotating field, instead of a mechanically rotated magnetic field, which would induce voltages and currents to generate electromotive forces usable as mechanical energy or power. Finally, the transformers would manipulate the voltages and currents to make them feasible for their use and transmission for long distances.

In all present Electric Generators a small amount of energy, normally less than one percent of the outgoing power in big generators, is used to excite the mechanically rotated electromagnetic poles that will induce voltages and currents in conductors having a relative speed or movement between them and the polar masses.

The rest of the energy used in the process of obtaining electricity, is needed to move the masses and to overcome the losses of the system: mechanical losses; friction losses; brushes losses, windage losses; armature reaction losses; air gap losses; synchronous reactance losses; eddy current losses; hysteresis losses, all of which, in conjunction, are responsible for the excess in power input (mechanical power) required to generate always smaller amounts of electric power.

SUMMARY OF THE INVENTION

The **C**ontinuous **E**lectrical **G**enerator consists of a stationary cylindrical electromagnetic core made of one piece thin laminations stacked together to form a cylinder, where two three-phase windings arrangements are placed in the same slots not having any physical relative speed or displacement between them. When one of the windings is connected to a temporary three-phase source, an electromagnetic rotating field is created, and the field this way created will cut the stationary coils of the second winding, inducting voltages and currents. In the same way and extent as in common generators, about one percent or less of the outgoing power will be needed to keep the rotational magnetic field excited.

In the **C**ontinuous **E**lectrical **G**enerator there are no mechanical losses; friction losses; brush losses; windage losses; armature reaction losses; or air gap losses, because there is not any movement of any kind. There are: synchronous reactance losses, eddy current losses and hysteresis losses, which are inherent to the design, construction and the materials of the generator, but in the same extent as in common generators.

One percent or less of the total energy produced by present electric generators goes to create their own magnetic field; a mechanical energy that exceeds the total output of present generators is used to make them rotate in the process of extracting electrical currents from them. In the **C**ontinuous **E**lectrical **G**enerator there is no need for movement since the field is in fact already rotating electro-magnetically, so all that mechanical energy will not be needed. Under similar conditions of exciting currents, core mass and windings design, the **C**ontinuous **E**lectrical **G**enerator is significantly more efficient than present generators, which also means that it can produce significantly more than the energy it needs to operate. The **C**ontinuous **E**lectrical **G**enerator can feedback the system, the temporary source may be disconnected and the Generator will run indefinitely.

As with any other generator, the **C**ontinuous **E**lectrical **G**enerator may excite its own electromagnetic field with a minimum part of the electrical energy produced. The **C**ontinuous **E**lectrical **G**enerator only needs to be started up by connecting its inducting three-phase windings to a three-phase external source for an instant, and then to be disconnected, to start the system as described herein. Then, disconnected, it will run indefinitely generating a great excess of electric power to the extent of its design.

The **C**ontinuous **E**lectrical **G**enerator can be designed and calculated with all mathematical formulas in use today to design and calculate electrical generators and motors. It complies with all of the laws and parameters used to calculate electrical induction and generation of electricity today.

Except for the Law of Conservation of Energy, which, by itself, is not a mathematical equation but a theoretical concept and by the same reason does not have any role in the mathematical calculation of an electrical generator of any type, the **C**ontinuous **E**lectrical **G**enerator complies with all the Laws of Physics and Electrical Engineering. The **C**ontinuous **E**lectrical **G**enerator obligates us to review the Law of Conservation of Energy. In my personal belief, the electricity has never come from the mechanical energy that we put into a machine to move the masses against all oppositions. The mechanical system is actually providing the path for the condensation of electricity. The **C**ontinuous **E**lectrical **G**enerator provides a more efficient path for the electricity.

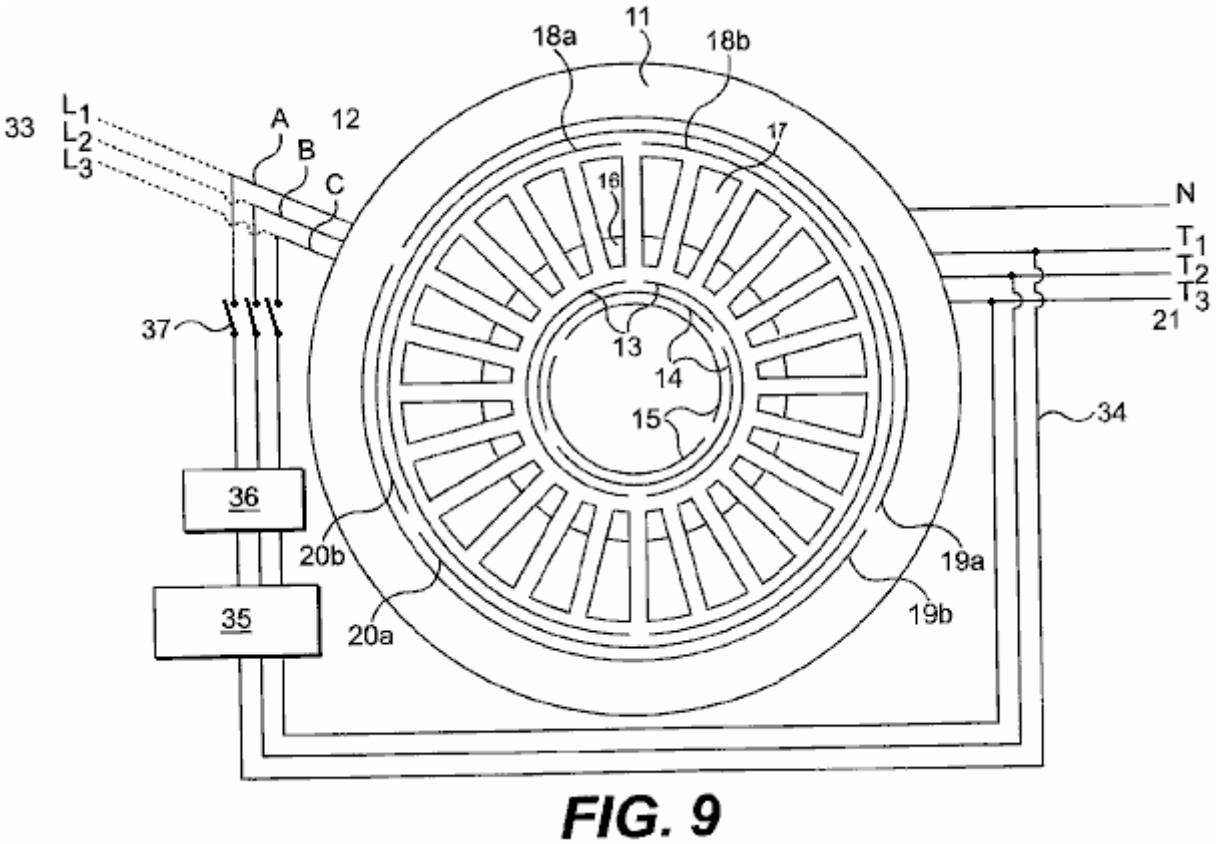

FIG. 9

DETAILED DESCRIPTION OF THE INVENTION

The present invention is a Continuous and Autonomous Electrical Generator, capable of producing more energy than it needs to operate, and which provides itself the energy needed to operate. The basic idea consists in the induction of electric voltages and currents without any physical movement by the use of a rotational magnetic field created by a three-phase stator connected temporarily to a three-phase source, and placing stationary conductors on the path of said rotational magnetic field, eliminating the need of mechanical forces.

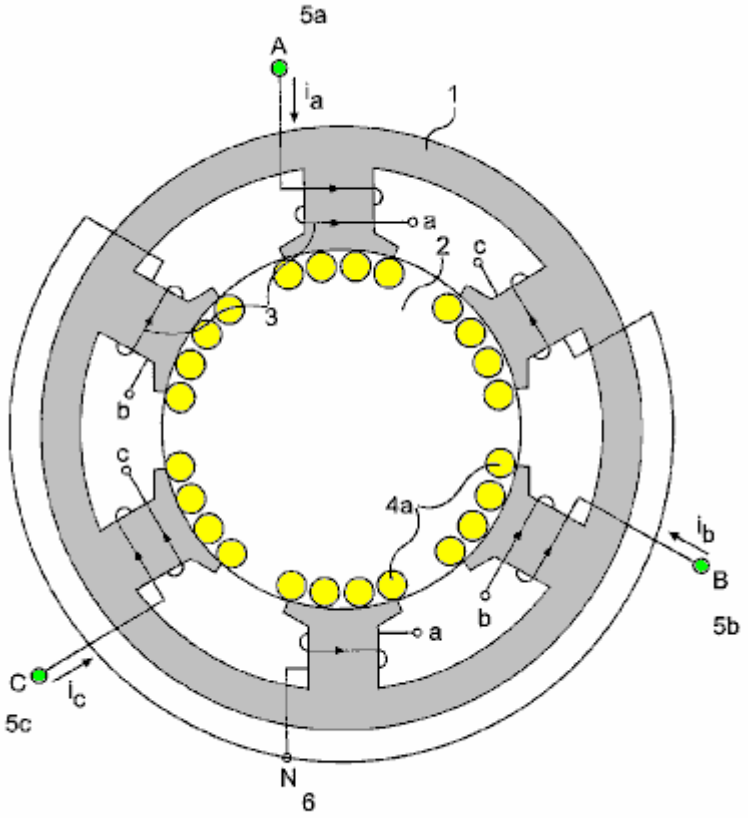

FIG. 1

The basic system can be observed in **Fig.1**, which shows one embodiment of the present invention. There is a stationary ferromagnetic core **1** with a three-phase inducting windings **3**, spaced 120 degrees and connected in Y **6** in order to provide a rotating electromagnetic field, when a three-phase voltage is applied; for the case, a two-pole arrangement. Inside this core **1** there is a second stationary ferromagnetic core **2**, with no space between them, this is, with no air-gap. This second core **2** has also a three-phase stationary winding arrangement (**4a** in **Fig.4b** and **4b** in **Fig.2**), aligned as shown in **Fig.1** and **Fig.2** with the external core inducting windings **3**. There is not any movement between the two cores, since there is no air-gap between them.

There is no shaft on either core since these are not rotating cores. The two cores can be made of stacked insulated laminations or of insulated compressed and bonded ferromagnetic powder. The system works either way, inducting three-phase voltages and currents on the stationary conductors **4a** of the internal windings **4b**, applying three-phase currents to terminals **A 5a**, **B 5b** and **C 5c** of the external windings **3**; or inducting three-phase voltages and currents on the external windings **3**, by applying three-phase currents to the terminals **T1 7a**, **T2 7b** and **T3 7c**, of the internal windings **4b**. When a three-phase voltage is applied to terminals **A 5a**, **B 5b** and **C 5c**, the currents will have the same magnitude, but will be displaced in time by an angle of 120 degrees. These currents produce magneto motive-forces, which, in turn, create a rotational magnetic flux. The arrangements may vary widely as they occur with present alternators and three-phase motors, but the basics remain the same, a stationary but electro-magnetically rotating magnetic field, inducting voltages and currents on the stationary conductors placed on the path of said rotating magnetic field. The diagram is showing a two-pole arrangement for both windings, but many other arrangements may be used, as in common generators and motors.

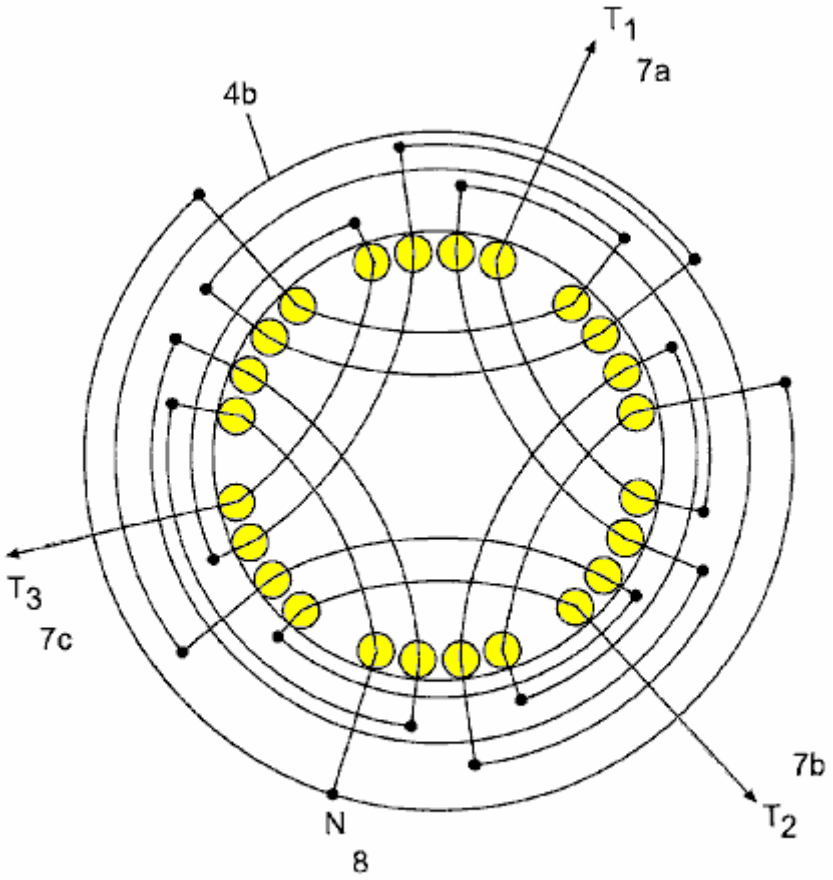

FIG. 2

Fig.2 shows the three-phase arrangement of the internal winding **4b** which has provided, in practice, symmetrical voltages and currents, due to a space angle of 120 degrees. It is similar to a two-pole arrangement. Many other three-phase or poly-phase arrangements may be used. Wherever a conductor is crossed by a rotational magnetic field, a voltage will be induced across its terminals. The interconnections depend on the use that we will give to the system. In this case, we will have a three-phase voltage in terminals **T1 7a, T2 7b** and **T3 7c** and a neutral **8**. The outgoing voltage depends on the density of the rotational magnetic flux, the number of turns of the conductor, the frequency (instead of the speed) and the length of the conductor crossed by the field, as in any other generator.

Fig.3 shows an alternate embodiment of the present invention in which the generator is made from multiple one-piece laminations **9**, stacked as a cylinder to the desired height. This embodiment can also be made of a one-piece block of compressed and bonded insulated ferromagnetic powder. The same slot **10** will accommodate the internal **4a/4b** and the external windings **3**, that is, the inducting and the induced windings (see **Fig.5**). In this case, a 24-slot laminate is shown, but the number of slots may vary widely according to the design and needs.

Fig.4 shows a two-piece single laminate for another alternate embodiment of the present invention. For practical effects the lamination can be divided into two pieces **9a, 9b**, as shown, to facilitate the insertion of the coils. Then, they are solidly assembled without separation between them, as if they were only one piece.

The laminates described above may be constructed with thin (0.15 mm thick or less) insulated laminations **9** or **9a** and **9b** of a high magnetic permeability material and low hysteresis losses such as Hiperco 50A, or similar, to reduce losses or with compressed electrically isolated ferromagnetic powder, which has lower eddy current losses and also may have low hysteresis losses, which can make the generator highly efficient.

OPERATING THE GENERATOR

The **C**ontinuous **E**lectrical **G**enerator as described and shown in the following drawings is designed and calculated to produce a strong rotating electromagnetic field with low exciting currents. By using a laminated material, such as the said Hiperco 50A, we can achieve rotating magnetic fields above two Teslas, since there are no air gap losses, mechanical losses, windage losses, armature reaction losses, etc. as said before. This may be obtained by applying a temporary three-phase current to the terminals **A**, **B** and **C 12** of the inducting coils **13, 14** and **15** (**5a, 5b** and **5c** in **Fig.1**), spaced 120 degrees from each other (see **Fig.5**).

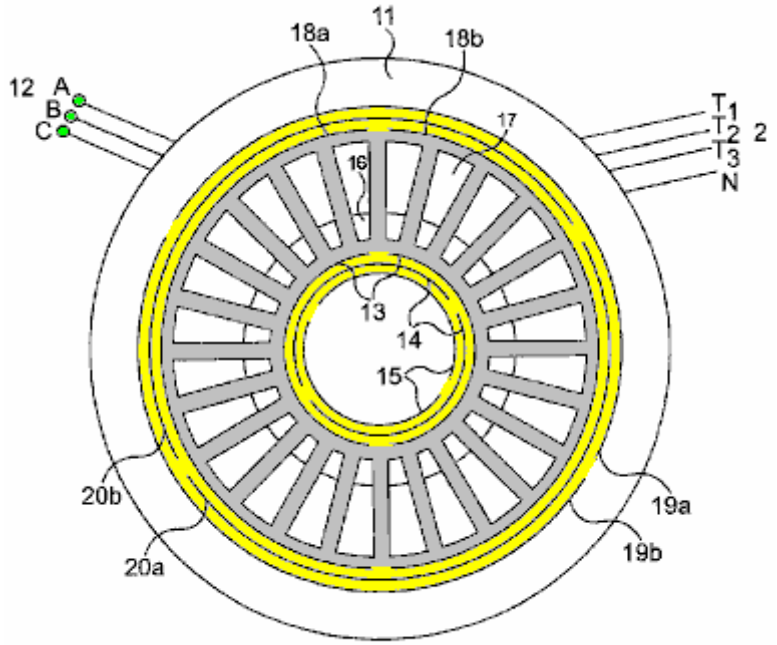

FIG. 5

Fig.5 shows the spatial distribution of the inducting windings **13, 14** and **15**, as well as the induced windings **18a, 18b, 19a, 19b, 20a** and **20b**. Both, the inducting and the induced windings are placed in the same slots **10** or **16** and **17**, with similar arrangements. Even though the system works in both directions, the better configuration seems to be to place the inducting windings **13, 14** and **15**, to the centre and the induced windings **18a, 18b, 19a, 19b, 20a** and **20b**, to the exterior, since small windings will be needed to induce a very strong rotational magnetic field, due to the small losses involved in the process, and in exchange, bigger and powerful windings will be needed to extract all the energy that the system will provide. Both windings are connected in Y (not shown), but they can be connected in different ways, as any other generator. These arrangements are equivalent to the arrangements shown for the embodiment in **Fig.1** and **Fig.2**.

The inducting coils **13, 14** and **15** are designed and calculated so that the generator may be started with common three-phase lines voltages (230 Volts 60 Hz per phase, for example). If the local lines voltages are not appropriate, we can control the voltage to the designed level by means of a three-phase variable transformer, an electronic variator or inverter etc. Once we have such strong magnetic field rotating and crossing the stationary induced coils **18a, 18b, 19a, 19b, 20a** and **20b**, a three-phase voltage will be induced across terminals **T1, T2, T3** and **N 21** in proportion to the magnetic flux density, the number of turns in the coils, the frequency used (instead of the speed), the length of the conductors cut by the rotating field, as in any other alternator. We can connect, as we desire in Y or delta, etc., as in any other alternator or generator. The outgoing currents will be three-phase currents (or poly-phase currents depending on the arrangement) and we can have a neutral **21** if we are using a Y connection, as in any other alternator.

The outgoing alternate voltages and currents are perfect sinusoidal waves, perfectly spaced in time, and totally symmetrical. The voltages and currents obtained by this method are usable in any conventional manner. Any voltage can be produced, depending on the design.

Fig.6 shows the magnetic flux pattern produced by the three-phase inducting windings **13, 14** and **15**. This pattern is similar to the pattern of an induction motor's stators. Since there is no air gap; the whole path for the magnetic flux is homogeneous with no change in materials. The core is made of thin insulated laminations of a high magnetic permeability and low hysteresis loss material; eddy current losses are minimal due to the thin lamination. There are no counter fluxes or armature reactions thus the magnetic flux may be near to saturation with a small exciting current or input energy. Due to the time differential between the three phases and the spatial distribution of the inducting windings, a rotational magnetic field will be created in the core, as shown in **Fig.7**.

Once the generator is started, a small part of the energy obtained is sent back (**Fig.8** and **Fig.9**) to feed the inducting coils **3** (in **Fig.1**) or **13, 14** and **15** (in **Fig.5**), as in any other auto-excited alternator or generator. Of course voltages and phases should be perfectly identical and aligned, and if necessary the feedback voltages should be controlled and handled by means of variable transformers, electronic variators, phase shifters (to align phases) or other type of voltage or phase controllers.

One possible method consists of the use of an electronic converter or variator **25** which initially converts two or three lines of alternating current **24** to direct current by an electronic rectifier **26** and then, electronically, converts the direct current **27** to three-phase current **28** to supply three-phase currents spaced in time 120 degrees for the electromagnetic fields **A, B** and **C 3**. Some variators or converters can accept two lines of voltage, while others will accept only a three-phase line voltage. This embodiment uses a variator of 3 kVA that accepts two 220-volt lines.

The rotational magnetic field created by the currents going through the inducting three-phase windings **13**, **14** and **15**, will induce a voltage across the terminals **T1, T2, T3, N, 29** (**7a, 7b, 7c, 8** in **Fig.2**). Then, from the outgoing current lines **29**, a derivation is made **30** to feed back the system, converting the feed back alternate currents, by means of electronic diode rectifiers **31**, to direct current **32** and then feed back the electronic converter or variator **25** to the DC terminals of the electronic rectifier **26** (See **Fig.8**). Once the feedback is connected, the **C**ontinuous **E**lectrical **G**enerator may be disconnected from the temporary source **24**, and will continue generating electric energy indefinitely.

In **Fig.9**, an alternate embodiment of the **C**ontinuous **E**lectrical **G**enerator can be observed. The basic principles remain the same as for the embodiment described above and shown in **Fig.1** and **Fig.2**. The basic differences are in the shape of the laminations and the physical distribution of the windings, as discussed and shown previously. A variation of the feedback, using a variable and shifting transformers is also shown.

The ferromagnetic core **11** is made of one-piece laminates **9** as shown in **Fig.3** (or two for convenience **9a**, **9b** as shown in **Fig.4**) stacked to the desired height. The slots **10**, as indicated before, will accommodate both the inducting **13, 14** and **15** and the induced **18a-b, 19a-b** and **20a-b** windings in the same slot **10** or **16** and **17**. The incoming three phase lines **12** feed the inducting three-phase windings **13, 14** and **15**. They are fed, initially by the temporary source **33** in the first instance, and by the three-phase return **34** once the generator is running by itself.

The inducting windings **13, 14** and **15** have a two-pole arrangement, but many other three-phase or poly-phase arrangements can be made to obtain an electromagnetic rotating field. These windings are connected in Y (not shown) in the same way shown for the embodiment shown in **Fig.1**, **Fig.2** and **Fig.8**, but may be connected in many different ways. The inducting windings **13, 14** and **15** are located in the internal portion **16** of the slot **10** (**Fig.5**).

The induced windings **18a-b**, **19a-b** and **20a-b** have a two-pole arrangement, exactly equal to the arrangement for the inducting windings **13, 14** and **15**, but many other arrangements can be made depending on the design and the needs. The induced windings must be calculated in a way that the generator will have the lowest possible synchronous reactance and resistance. In this way, most of the outgoing power will go to the charge instead of staying to overcome the internal impedance. These windings are connected in Y to generate a neutral **21**, in the same way shown in the embodiment of the present invention shown in **Fig.2**, but may be connected in different ways according to the needs. The induced windings **18a-b, 19a-b** and **20a-b** are located in the external portion **17** of the slot **10**.

The outgoing three-phase and neutral lines **21** come from the induced windings **18a-b, 19a-b** and **20a-b**. The rotational magnetic field created in the core (see **Fig.6** & **Fig.7**) by the inducting windings **13, 14** and **15**, induces a voltage across the terminals **T1, T2** and **T3**, plus a neutral, **29**. From each of the three-phase outgoing lines **21**, a return derivation **34** is made to feedback the system.

The temporary three-phase source **33** is temporarily connected to terminals **A, B** and **C 12**. The **C**ontinuous **E**lectrical **G**enerator must be started with an external three-phase source for an instant, and then disconnected.

Even though the return lines voltage can be calculated and obtained precisely by tabbing the induced windings at the voltage required by the inducting windings (according to the design), it may be convenient to place a three-phase variable transformer or other type of voltage controller **35** in the middle for more precise adjustment of the return voltage.

Placed after the variable transformer **35**, the three-phase shifting transformer **36** will correct and align any phase shift in the voltage and currents angles, before the return is connected. This system functions similarly to the system shown in **Fig.8** which uses a variator or a converter **25**.

Once the voltage and phases are aligned with the temporary source **33**, the return lines **34** are connected to the incoming lines **A, B** and **C 12** at feedback connection **37** and the temporary source **33** is then disconnected. The **C**ontinuous **E**lectrical **G**enerator will remain working indefinitely without any external source of energy, providing a great excess of energy permanently.

The outgoing electric energy provided by this system has been used to produce light and heat, run poly-phase motors, generate usable mono-phase and poly-phase voltages and currents, transform voltages and currents by means of transformers, convert the alternate outgoing poly-phase currents to direct current, as well as for other uses. The electricity obtained by the means described is as versatile and perfect as the electricity obtained today with common electric generators. But the **C**ontinuous **E**lectrical **G**enerator is autonomous and does not depend on any other source of energy but itself once it is running; may be carried anywhere with no limitations; it can be constructed in any size and provides any amount of electricity indefinitely, according to the design.

The **C**ontinuous **E**lectrical **G**enerator is and will be a very simple machine. The keystones of the systems reside in the ultra-low losses of a non-movement generation system, and in a very low synchronous reactance design.

The induced windings must be calculated in a way that the generator may have the lowest possible synchronous reactance and resistance. In this way, most of the outgoing power will go to the charge instead of staying to overcome the internal impedance.

MICHAEL OGNYANOV

Patent Application US 3,766,094 20th September 1971 Inventor: Michael Ognyanov

SEMICONDUCTOR COMPOSITIONS

This patent application shows the details of a device which it is claimed, can produce electricity via a solid-state oscillator. It should be noted that while construction details are provided which imply that the inventor constructed and tested several of these devices, this is only an application and not a granted patent.

ABSTRACT

A resonance oscillator electric power pack for operating a flash lamp, for example, or other electrically operated device, operates without moving mechanical parts or electrolytic action. The power pack is contained in a cylindrical metal envelope and in a preferred embodiment, is coupled to a relaxation oscillator and an incandescent lamp. Within the envelope, and insulated from it, is a semiconductor tablet having a metal base connected to the external circuit. A metal probe makes contact with a point on the semiconductor tablet and with a cylindrical ferrite rod, axially aligned with the envelope. Wound about the ferrite rod, are concentric helical coils designated as a 'primary' with many turns, and a 'secondary' with fewer turns than the primary.

One end of the primary coil is connected to the probe and the other end is connected to the secondary coil. the leads from the secondary coil are connected to the relaxation oscillator via an adjustable capacitor. Oscillation within the envelope is resonance amplified , and the induced voltage in the secondary coil is rectified for application to the relaxation oscillator and lamp. Selenium and germanium base semiconductor compositions including Te, Nd, Rb and Ga in varying proportions area used for the tablet.

BACKGROUND OF THE INVENTION

This is a continuation-in-part of my co-pending patent application Serial No. 77,452, filed 2nd October 1970, entitled "Electric Power Pack" now abandoned.

In many situations it is desirable to have a source of electric power which is not dependent on wires from a central generating station, and therefore, portable power supplies having no moving parts have been employed. typically, such portable power packs have been primary or secondary electrolytic cells which generate or store electrical energy for release by chemical action. Such batteries have a limited amount of contained energy and must often be replaced at frequent intervals to maintain equipment in operation.

Thus, as one example, flashing lights are commonly used along highways and other locations to warn of dangerous conditions. These flashing lights in remote locations are typically incandescent or gas-discharge lamps connected to some type of relaxation oscillator powered by a battery. The batteries employed in such blinking lights have a limited lifetime and must be periodically replaced, typically each 250 to 300 hours of operation. This involves a rather large labour cost in replacing the expended batteries with fresh ones and additional cost for primary cells or for recharging secondary cells. It is desirable to provide an electric power pack capable of providing a sufficient quantity of electrical energy over a prolonged period of time so that the requirement for periodic replacement of the electrolytic cells can be avoided. Such a power pack is valuable even if appreciably more expensive than batteries because of the greatly reduced labour costs required for periodic replacements.

BRIEF SUMMARY OF THE INVENTION

There is provided in practice of this invention according to a preferred embodiment, semiconductive compositions selected from the Group consisting of:

Selenium with, from 4.85% to 5.5% Tellurium, from 3.95% to 4.2% Germanium, from 2.85% to 3.2% Neodymium, and from 2.0% to 2.5% Gallium.

Selenium with, from 4.8% to 5.5% Tellurium, from 3.9% to 4.5% Germanium, from 2.9% to 3.5% Neodymium and from 4.5% to 5% Rubidium, and

Germanium with, from 4.75% to 5.5% Tellurium, from 4.0% to 4.5% Neodymium and from 5.5% to 7.0% Rubidium.

DRAWINGS

These and other features and advantages of the invention will be appreciated and better understood by reference to the following detailed description of a preferred embodiment when considered in conjunction with the following drawings:

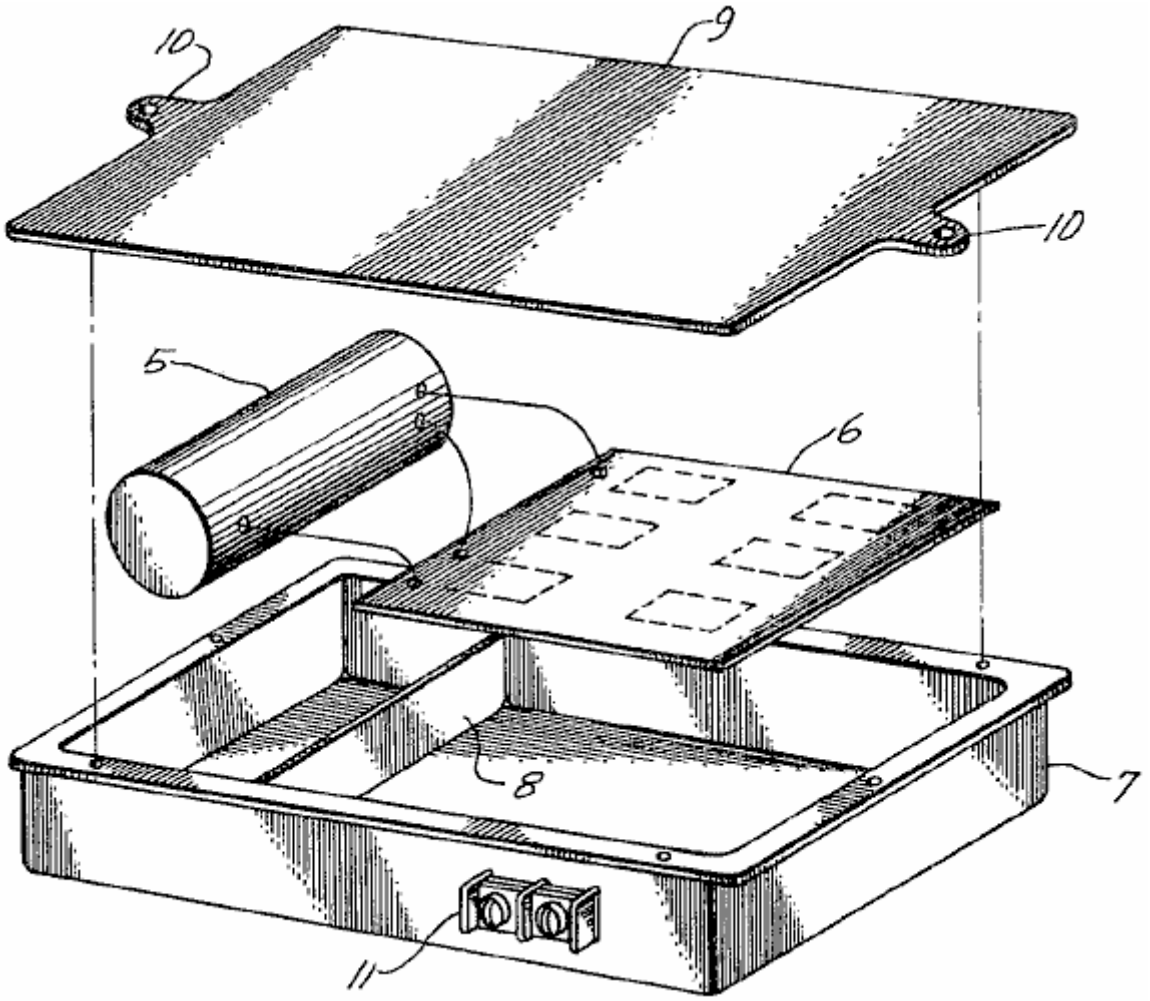

Fig.1 illustrates in exploded schematic, a flashing lamp connected to an electric power supply constructed according to the principles of this invention.

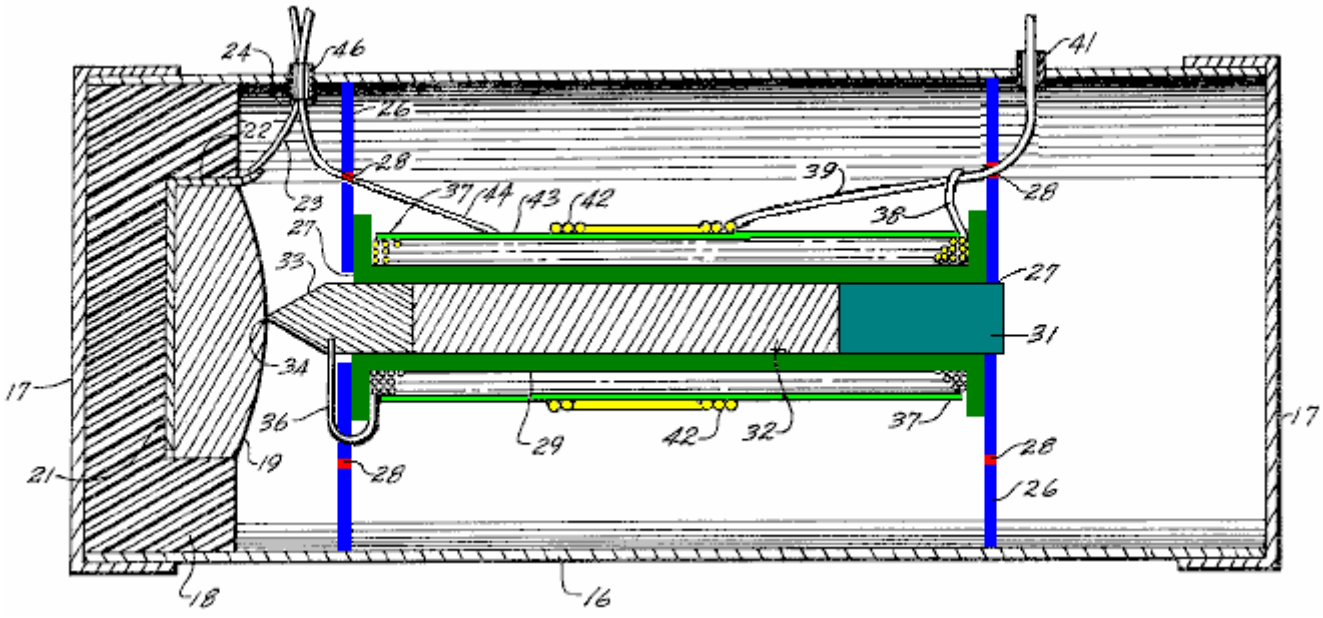

Fig.2 illustrates in longitudinal cross-section, the power pack of Fig.1

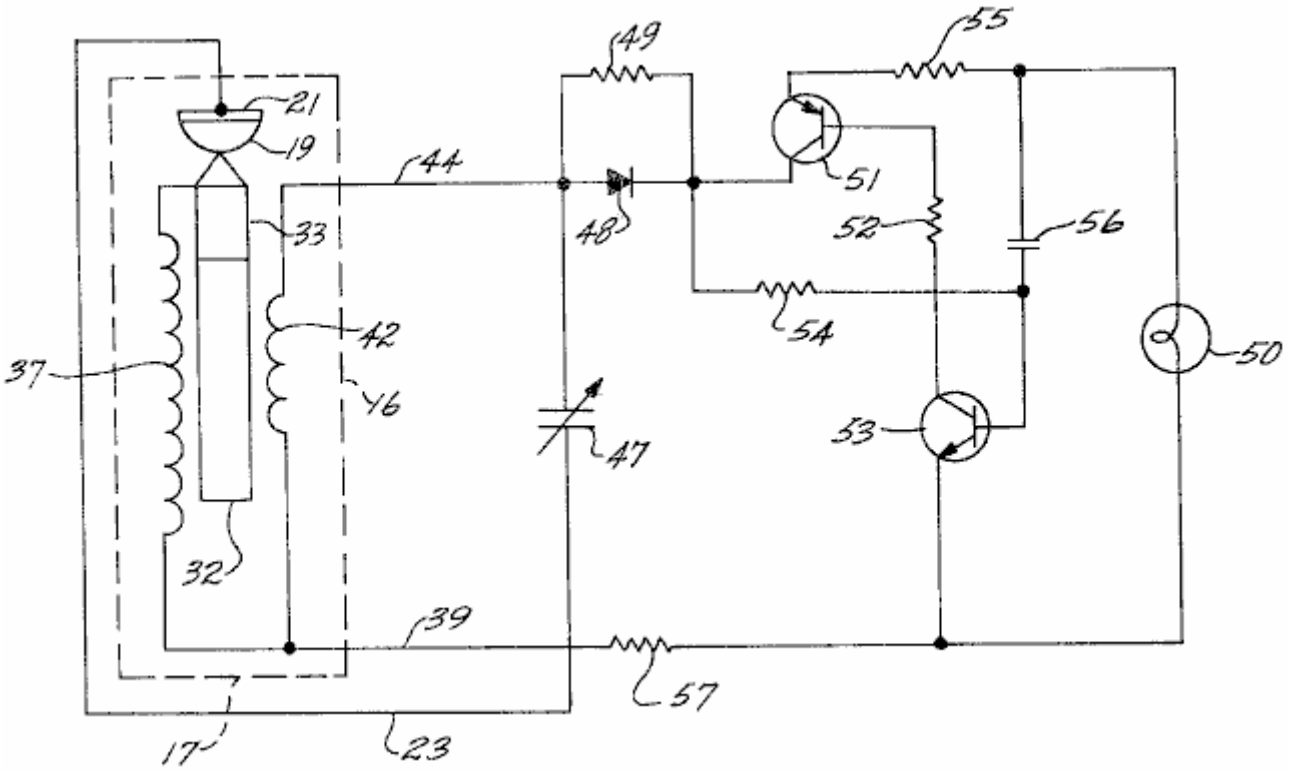

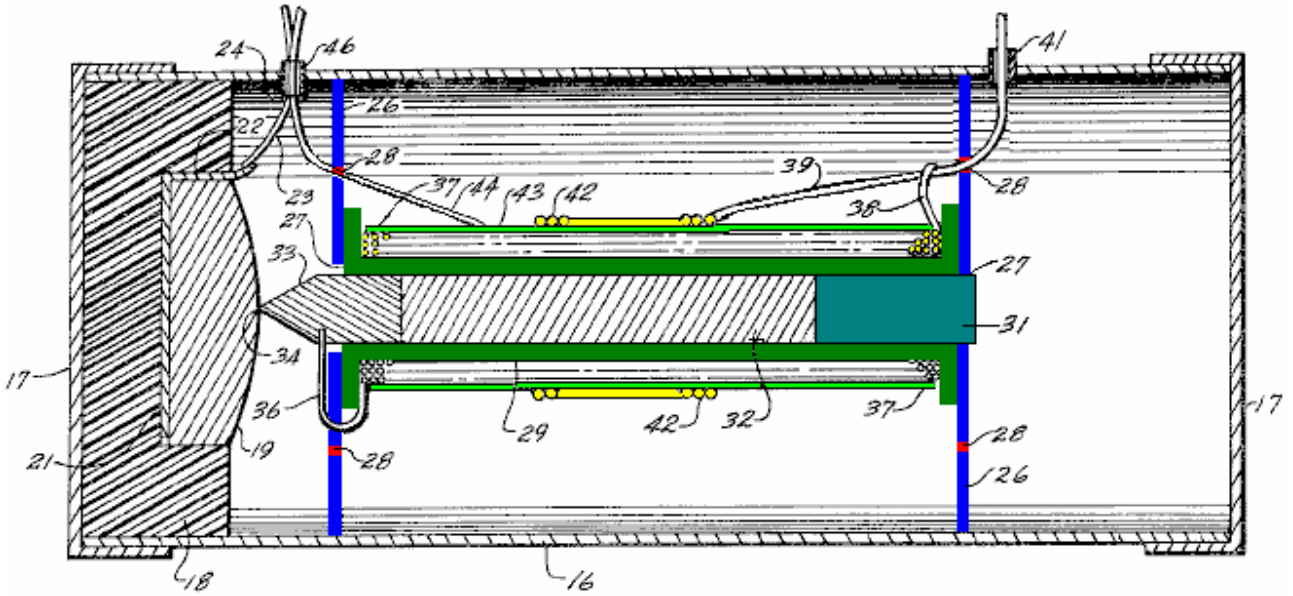

Fig.3 is an electric circuit diagram of the system.

DESCRIPTION

Fig.1 illustrates schematically, a typical flashing lamp having a power supply constructed according to the principles of this invention. As illustrated in this preferred embodiment, an electric power pack **5**, is connected electrically to a relaxation oscillator circuit (shown only schematically) on a conventional printed-circuit board **6**.

The power pack **5** and the printed-circuit board are mounted in a metal box **7**, which has a transverse partial partition **8**, which creates two spaces, one for the power pack and the other for the printed-circuit board which is prevented from contacting the metal box by any convenient insulating mounting. Preferably, these components are potted in place in a conventional manner.

A cover **9**, having mounting lugs **10**, is riveted on to the box after assembly. A small terminal strip **11**, mounted on one side of the box **7**, provides electrical contacts for connection to a load such as an incandescent lamp (not shown in Fig.1). the lamp provides a flash of light when the relaxation oscillator switches. Although the described system is employed for a flashing lamp, it will be apparent that other loads may be powered by the invention.

In **Fig.2**, the electric power pack **10**, is illustrated in longitudinal cross-section and has dimensions as follows: These dimensions are provided by way of example for powering a conventional flashing lamp and it will be clear that other dimensions may be used for other applications. In particular, the dimensions may be enlarged in order to obtain higher power levels and different voltage or current levels. The power pack is comprised of a cylindrical metal tube **16**, having closely fitting metal caps **17** at each end, which are preferably sealed to the tube after the internal elements are inserted in place. The metal tube **16** and caps **17**, which are preferably of aluminium, thus form a closed conductive envelope, which in a typical embodiment, has an inside diameter of about 0.8 inch and a length of about 2.25 inches.

Mounted within one end of the envelope is a plastic cup **18**, the dimensions of which are not critical, however, a wall thickness of at least 1/16 inch is preferred. Mounted within the plastic cup **18** is a semiconductor tablet **19** having a flat base and somewhat domed opposite side. The composition of the semiconductor tablet **19** is set out in greater detail below. Typically, the semiconductor tablet has a mass of about 3.8 grams. A metal disc **21** is positioned beneath the base of the tablet **19** in the cup **18**, and is preferably adhesively bonded inside the cup. The metal disc is tightly fitted to the base of the tablet so that good electrical contact is obtained over a substantial area of the semiconductor.

An ear **22** on one edge of the disc is soldered to a wire **23**, which extends through a short insulating sleeve **24** which passes through a hole in the side of the metal envelope. The insulating sleeve **24** acts as a grommet and ensures that there is no damage to the insulation of wire **23** and subsequent accidental short circuiting between the wire and the metal envelope. Preferably, the insulating sleeve **24** is sealed with a small amount of plastic cement or the like, in order to maintain clean air within the cylindrical envelope. Two other openings for leads through the tube **16**, as mentioned below, are also preferably sealed to maintain cleanliness within the envelope.

A pair of circular metal discs **26**, are fitted inside tube **16** and are preferably cemented in place to prevent shifting. The two discs **26**, are equally spaced from the opposite ends of the envelope and are spaced apart by slightly more than 1.15 inches. Each of the discs has a central aperture **27**, and there is a plurality of holes **28**, extending through the disc in a circular array midway between the centre of the disc and it's periphery. The holes **28** are preferably in the size range of about 0.01 to 0.06 inch in diameter and there are 12 on each disc located at 30^0 intervals around the circle.

The two discs **26** divide the interior of the cylindrical envelope into three chambers, and the pattern of holes **28** provides communication between the chambers and affects the electrical properties of the cavity. It is believed that the pattern of holes affects the inductive coupling between the cavities inside the envelope and influences the oscillations in them.

Although an arrangement of 12 holes at 30^0 centres has been found particularly advantageous in the illustrated embodiment, it is found in other arrangements that a pattern of 20 holes at 18^0 centres or a pattern of 8 holes at 45^0 centres, provides optimum operation. In either case, the circle of holes **28** is midway between the centre and the periphery of the disc.

Mounted between the discs **26** is a plastic spool **29** which has an inside distance of 1.1 inches between its flanges. The plastic spool **29** preferably has relatively thin walls and an internal bore diameter of 1/8 inch. A plastic mounting plug **31**, is inserted through the central aperture **27** of the disc **26** farthest from the semiconductor table **19**, and into the bore of the spool **29**. The plastic plug **31** is preferably cemented to the disc **26** in order to hold the assembly together.

Also mounted inside the bore of spool **29** is a cylindrical ferrite core **32**, about 1/8 inch diameter and 3/4 inch long. Although a core of any magnetic ferrite is preferred, other ferromagnetic materials having similar properties can be used if desired. The core **32**, is in electrical contact with a metal probe **33** about 1/4 inch long. half of the length of the probe **33** is in the form of a cylinder positioned within the spool **29**, and the other half is in the form of a cone ending in a point **34** in contact with the domed surface of the semiconductor tablet **19** where it makes an electrical contact with the semiconductor in a relatively small point.

Electrical contact is also made with the probe **33** by a lead **36**, which passes through one of the holes **28** in the disc **26** nearer to the semiconductor tablet and thence to a primary coil **37**, wound on the plastic spool **29**. The primary coil **37** is in the form of 800 to 1000 turns wound along the length of the spool, and the lead **38** at the opposite end of the coil **37** is soldered to one of the external leads **39** of the power pack. This lead **39** proceeds through one of the holes **28** in the disc farthest from the semiconductor tablet **19**, and through an insulating sleeve **41** in the metal tube **16**.

The lead **39** is also connected to one end of a secondary coil **42** which is composed of 8 to 10 turns around the centre portion of the primary coil **37**. A thin insulating sheet **43** is provided between the primary and secondary coils. The other lead **44** from the secondary coil passes through one of the holes **28** in the disk nearer the semiconductor tablet and thence through an insulating sleeve **46** through the wall of the tube **16**.

Fig.3 illustrates schematically, the electrical circuit employing an electric power pack constructed according to the principles of this invention. At the left hand side of **Fig.3**, the arrangement of elements is illustrated in a combination of electrical schematic and mechanical position inside tube **16** for ready correlation with the embodiment illustrated in **Fig.2**. Thus, the semiconductor tablet **19**, probe **33** and ferrite core **32** are shown in both their mechanical and electrical arrangement, the core being inductively coupled to the coils **37** and **42**. The lead **23** from the metal base of the semiconductor tablet **19**, is connected to a variable capacitor **47**, the other side of which is connected to the lead **44** from the secondary coil **42**. The lead **44** is also connected to a rectifying diode **48** shunted by a high value resistor **49**.

It will be seen that the variable capacitor **47** is in a tank circuit with the inductive coils **37** and **42** which are coupled by the ferrite core **32**, and this circuit also includes the semiconductor tablet **19** to which point contact is made by the probe **33**. The mechanical and electrical arrangement of these elements provides a resonant cavity in which resonance occurs when the capacitor 47 is properly trimmed. The diode **48**, rectifies the oscillations in this circuit to provide a suitable DC for operating an incandescent lamp **50** or similar load.

The rectifying diode **48** is connected to a complementary-symmetry relaxation circuit for switching power to the load **50**. The diode is connected directly to the collector of a PNP transistor **51** which is in an inverted connection. the emitter of the PNP transistor is connected to one side of the load **50** by way of a timing resistor **55**. The base of the transistor **51** is connected by way of a resistor **52** and a capacitor **56** to the collector of an NPN transistor **53**, the emitter of which is connected to the other side of the load **50**. The base of the NPN transistor **53** is coupled to the diode by a resistor **54**. The emitter of the PNP transistor **51** is fed back to the base of the NPN transistor **53** by the resistor **55**. Current flow through the lamp **50** is also limited by a resistor **57** which couples one side of the lamp and the emitter of the NPN transistor **53** to the two coils **37** and **42** by way of the common lead **39**.

The electrical power pack is believed to operate due to a resonance amplification once an oscillation has been initiated in the cavity, particularly the central cavity between the discs **26**. This oscillation, which apparently rapidly reaches amplitudes sufficient for useful power, is then half-wave rectified for use by the diode **48**. With such an arrangement, a voltage level of several volts has been obtained, and power sufficient for intermittent operation of a lamp requiring about 170 to 250 milliwatts has been demonstrated. The resonant amplification is apparently due to the geometrical and electrical combination of the elements, which provide inductive coupling of components in a suitable resonant circuit. This amplification is also, at least in part, due to unique semiconductor properties in the tablet **19**, which has electronic properties due to a composition giving a unique atomic arrangement, the exact nature of which has not been measured.

The semiconductor tablet has electronic properties which are determined by it's composition and three such semiconductors satisfactory for use in the combination have been identified. In two of these, the base semiconductor material is selenium provided with suitable dopant elements, and in the third, the base element is germanium, also suitably doped. The semiconductor tablets are made by melting and casting in an arrangement which gives a large crystal structure. It has not been found necessary to provide a selected crystal orientation in order to obtain the desired effects.

A preferred composition of the semiconductor includes about 5% by weight of tellurium, about 4% by weight of germanium, about 3% by weight of neodymium and about 4.7% by weight of rubidium, with the balance of the composition being selenium. Such a composition can be made by melting these materials together or by dissolving the materials in molten selenium.

Another highly advantageous composition has about 5% by weight of tellurium, about 4% by weight of germanium, about 3% by weight of neodymium, and about 2.24% by weight of gallium, with the balance being selenium. In order to make this composition, it is found desirable to add the very low melting point gallium in the form of gallium selenide rather than elemental gallium.

A third suitable composition has about 5% by weight of tellurium, about 4% by weight of neodymium, about 6% by weight of rubidium, with the balance being germanium. These preferred compositions are not absolute and it has been found that the level of dopant in the compositions can be varied within limits without significant loss of performance. Thus, it is found that the proportion of tellurium in the preferred composition can range from about 4.8% to about 5.5% by weight; the germanium can range from about 3.9% to 4.5% by weight; neodymium can range from about 2.9% to 3.5% by weight, and rubidium can vary from about 4.5% to 5.0% by weight. The

balance of the preferred composition is selenium although it has also been found that nominal impurity levels can be tolerated and no great care is required in preventing minor contamination.

The other selenium base composition useful in practice of this invention can have a tellurium concentration in the range of from about 4.85% to 5.5% by weight, germanium in the range of from about 3.95% to 4.2% by weight, neodymium in the range of from about 2.85% to 3.2% by weight, and gallium in the range of from about 2.0% to 2.5% by weight. As in the preferred composition, the balance is selenium and nominal impurity levels can be tolerated. It is preferred to add the gallium in the form of gallium selenide rather than as elemental gallium with a corresponding decrease in the selenium used to make up the composition.

The above selenium base compositions are easier to make and less expensive than the germanium base composition and are therefore preferable for most applications. It is found that these are particularly suited for relatively small semiconductor tablets up to about 1 inch or a little less. For relatively large tablets, it is preferred to use the germanium base composition.

The germanium base composition has a tellurium level in the range of from about 4.75% to 5.5% by weight, neodymium in the range of from about 4.0% to 4.5% by weight, and rubidium in the range of from about 5.5% to 7.4% by weight. It is also found that it is of greater importance to maintain purity of the germanium base compositions than the selenium base compositions. Although the exact purity levels have not been ascertained, it is in excess of 99%.

It has been found that it is not necessary to have single crystals in the semiconductor tablets and any convenient grain size in excess of about 1 millimetre appears satisfactory. In the above compositions, when the recited ranges are exceeded, oscillation in the power pack drops off rapidly and may cease altogether.

The reasons that these compositions are satisfactory in the arrangement providing resonance amplification has not been determined with certainty. It is possible that the semiconductor serves as a source of electrons for providing an oscillating current in the circuit. This is, of course, combined with a relatively large area contact to one side of the semiconductor tablet, and a point contact on another area. Any resonant current in the coils wound on the ferrite rod, induces a varying magnetic field in the resonant cavity, and the electrical connection between the ferrite rod and the metal probe, provides a feedback of this oscillation to the semiconductor tablet.

it should particularly be noted that the oscillation in the circuit does not commence until it is initiated by an oscillating signal. In order to accomplish this, it is only necessary to apply a few millivolts of AC for a few seconds to the semiconductor tablet and the associated coils coupled to it. The initial signal applied to the base of the semiconductor tablet and the lead **39** is preferably in the frequency range of 5.8 to 18 Mhz and can be as high as 150 Mhz. Such a signal can be applied from any conventional source and no great care appears necessary to provide a single frequency signal or to eliminate noise. Once such energisation has been applied to the circuit and oscillations initiated, it does not appear to be necessary to apply such a signal again. This is apparently due to the feedback provided by the ferrite rod to the probe which makes contact with the semiconductor tablet.

Energy is, of course, dissipated in the lamp, or other utilisation device, as the combination operates. Such energy may come from deterioration of the semiconductor tablet as oscillations continue; however, if there is any such deterioration, it is sufficiently slow that a power source may be operated for many months without attendance. Such a source of energy may be augmented by ambient Radio Frequency radiation, coupled into the resonant cavity by the external leads. This is a surprising phenomenon because the leads are small compared to what would normally be considered an adequate antenna, and it is therefore postulated that stimulated amplification may also be a consequence of the unique electronic configuration of the semiconductors having the compositions specified above.

Although only one embodiment of electric power pack constructed according to principles of this invention has been described and illustrated here, many modifications and variations will be apparent to one skilled in the art. Thus, for example, a larger power pack may be axially arranged in a cylindrical container with various electronic elements arranged in the annular space. It is therefore to be understood that other configurations are included within the scope of the invention.

EDWIN GRAY

US Patent 3,890,548 June 17, 1975 Inventor: Edwin V. Gray snr.

PULSED CAPACITOR DISCHARGE ELECTRIC ENGINE

Please note that this is a re-worded extract from Edwin Gray's Patent 3,890,548. It describes his high voltage motor and the circuitry used to drive it. This motor was shown to have 80 horsepower of excess energy.

SUMMARY OF THE INVENTION:

This invention relates to electric motors or engines, and more particularly to a new electric machine including electromagnetic poles in a stator configuration and electromagnetic poles in a rotor configuration, wherein in one form thereof, the rotor is rotatable within the stator configuration and where both are energised by capacitor discharges through rotor and stator electromagnets at the instant of the alignment of a rotor electromagnet with a stator electromagnet. The rotor electromagnet is repelled from the stator electromagnet by the discharge of the capacitor through the coils of both the rotor and stator electromagnets at the same instant.

In an exemplary rotary engine according to this invention, rotor electromagnets may be disposed 120 degrees apart on a central shaft and major stator electromagnets may be disposed 40 degrees apart in the motor housing about the stator periphery. Other combinations of rotor elements and stator elements may be utilised to increase torque or rate of rotation.

In another form, a second electromagnet is positioned to one side of each of the major stator electromagnets on a centreline 13.5 degrees from the centreline of the stator magnet, and these are excited in a predetermined pattern or sequence. Similarly, to one side of each rotor electromagnet, is a second electromagnet spaced on a 13.5 degree centreline from the major rotor electromagnet. Electromagnets in both the rotor and stator assemblies are identical, the individual electromagnets of each being aligned axially and the coils of each being wired so that each rotor electromagnetic pole will have the same magnetic polarity as the electromagnet in the stator with which it is aligned and which it is confronting at the time of discharge of the capacitor.

Charging of the discharge capacitor or capacitors is accomplished by an electrical switching circuit wherein electrical energy from a battery or other source of d-c potential is derived through rectification by diodes.

The capacitor charging circuit comprises a pair of high frequency switchers which feed respective automotive-type ignition coils employed as step-up transformers. The "secondary" of each of the ignition coils provides a high voltage square wave to a half-wave rectifier to generate a high voltage output pulse of d-c energy with each switching alternation of the high frequency switcher. Only one polarity is used so that a unidirectional pulse is applied to the capacitor bank being charged.

Successive unidirectional pulses are accumulated on the capacitor or capacitor bank until discharged. Discharge of the bank of capacitors occurs across a spark gap by arc-over. The gap spacing determines the voltage at which discharge or arc-over occurs. An array of gaps is created by fixed elements in the engine housing and moving elements positioned on the rotor shaft. At the instant when the moving gap elements are positioned opposite fixed elements during the rotor rotation, a discharge occurs through the coils of the aligned rotor and stator electromagnets to produce the repulsion action between the stator and rotor electromagnet cores.

A plurality of fixed gap elements are arrayed in a motor housing to correspond to the locations of the stator electromagnets in the housing. The rotor gap elements correspond to the positions of the rotor electromagnets on the rotor so that at the instant of correct alignment of the gaps, the capacitors are discharged to produce the necessary current through the stator and rotor coils to cause the electromagnets to repel one another.

The charging circuits are arranged in pairs, and are such that the discharge occurs through both rotor and stator windings of the electromagnets, which are opposite one another when the spark gap elements are aligned and arc-over.

The speed of the rotor can be changed by means of a clutch mechanism associated with the rotor. The clutch shifts the position of the rotor gap elements so that the discharge will energise the stator coils in a manner to advance or retard the time of discharge with respect to the normal rotor/stator alignment positions. The discharge through the rotor and stator then occurs when the rotor has passed the stator by 6.66 degrees for speed advance.

By causing the discharge to occur when the rotor position is approaching the stator, the repulsion pulse occurs 6.66 degrees before the alignment position of the rotor and stator electromagnets, thus reducing the engine speed.

The clutch mechanism for aligning capacitor discharge gaps for discharge is described as a control head. It may be likened to a firing control mechanism in an internal combustion engine in that it “fires” the electromagnets and provides a return of any discharge overshoot potential back to the battery or other energy source.

The action of the control head is extremely fast. From the foregoing description, it can be anticipated that an increase in speed or a decrease in speed of rotation can occur within the period in which the rotor electromagnet moves between any pair of adjacent electromagnets in the stator assembly. These are 40 degrees apart so speed changes can be effected in a maximum of one-ninth of a revolution.

The rotor speed-changing action of the control head and its structure are believed to be further novel features of the invention, in that they maintain normal 120 degree firing positions during uniform speed of rotation conditions, but shift to 6.66 degree longer or shorter intervals for speed change by the novel shift mechanism in the rotor clutch assembly.

Accordingly, the preferred embodiment of this invention is an electric rotary engine wherein motor torque is developed by discharge of high potential from a bank of capacitors, through stator and rotor electromagnet coils when the electromagnets are in alignment. The capacitors are charged from batteries by a switching mechanism, and are discharged across spark gaps set to achieve the discharge of the capacitor charge voltage through the electromagnet coils when the gaps and predetermined rotor and stator electromagnet pairs are in alignment.

Exemplary embodiments of the invention are herein illustrated and described. These exemplary illustrations and description should not be construed as limiting the invention to the embodiments shown, because those skilled in the arts appertaining to the invention may conceive of other embodiments in the light of the description within the ambit of the appended claims.

BRIEF DESCRIPTION OF THE DRAWINGS:

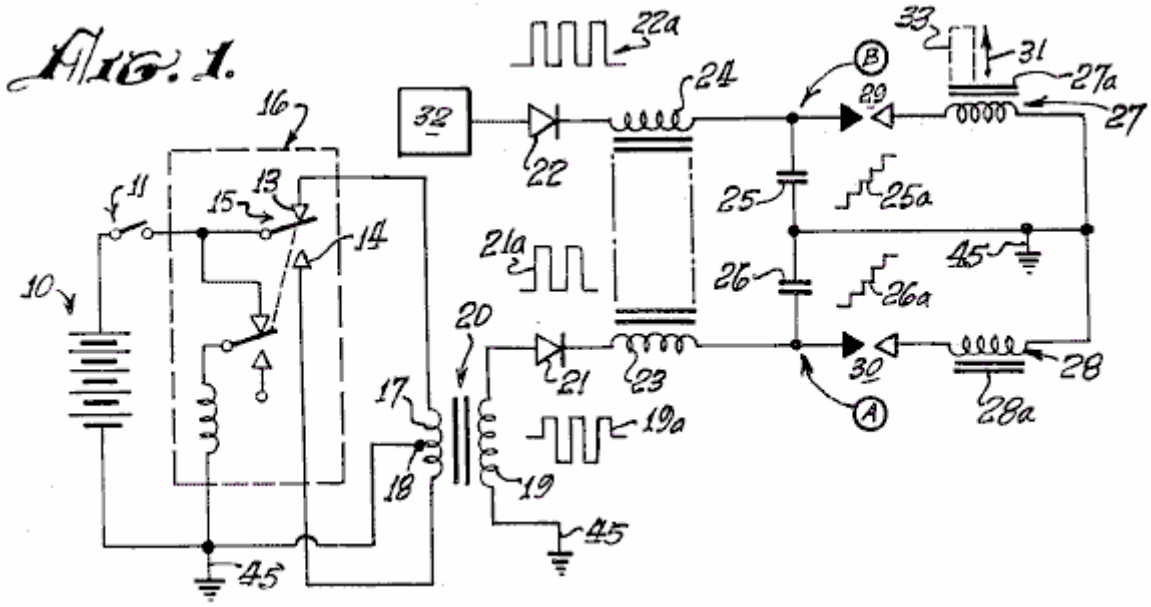

Fig.1 is an explanatory schematic diagram of a capacitor charging and discharging circuit utilised in the present invention.

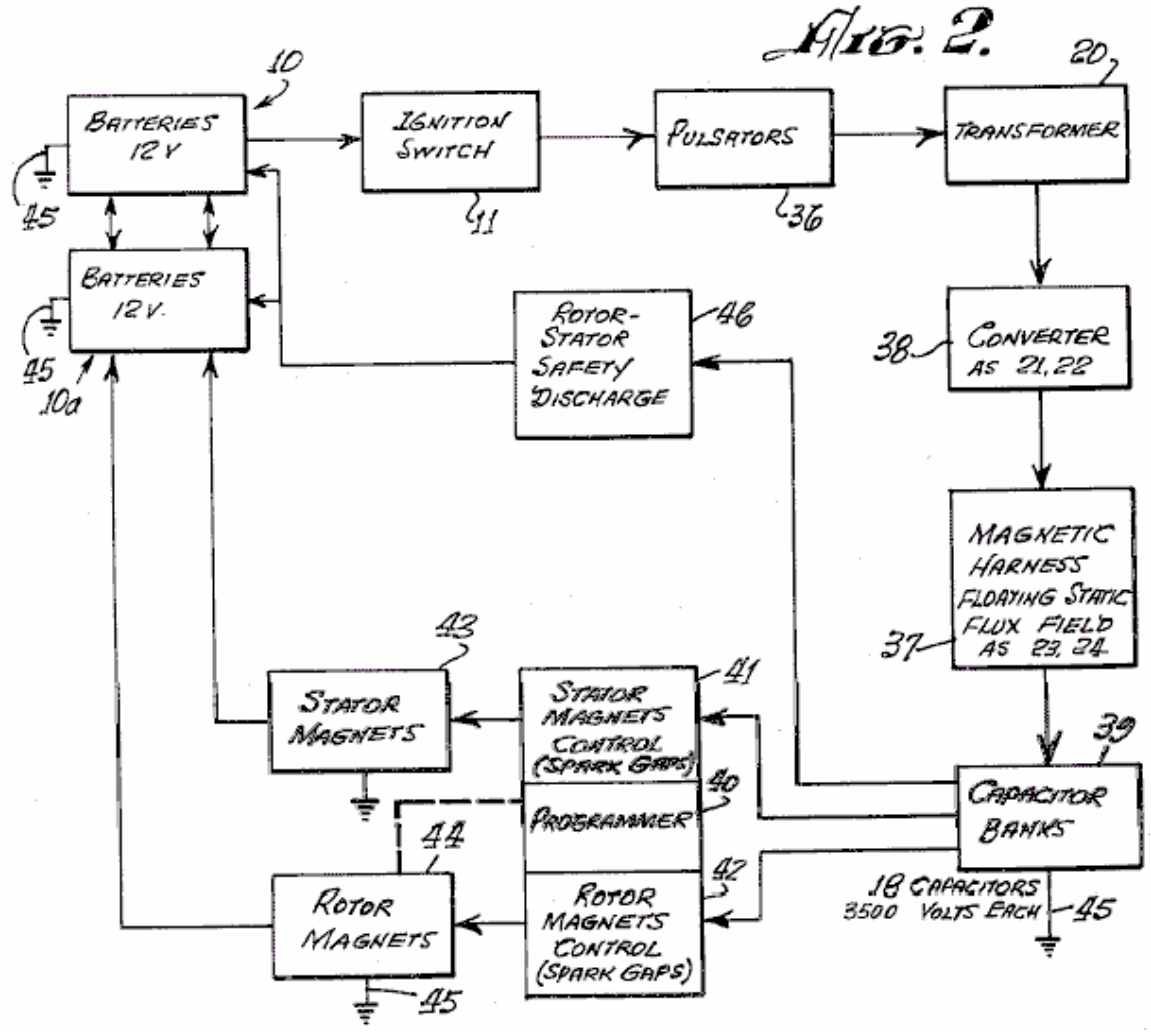

Fig.2 is a block diagram of an exemplary engine system according to the invention.

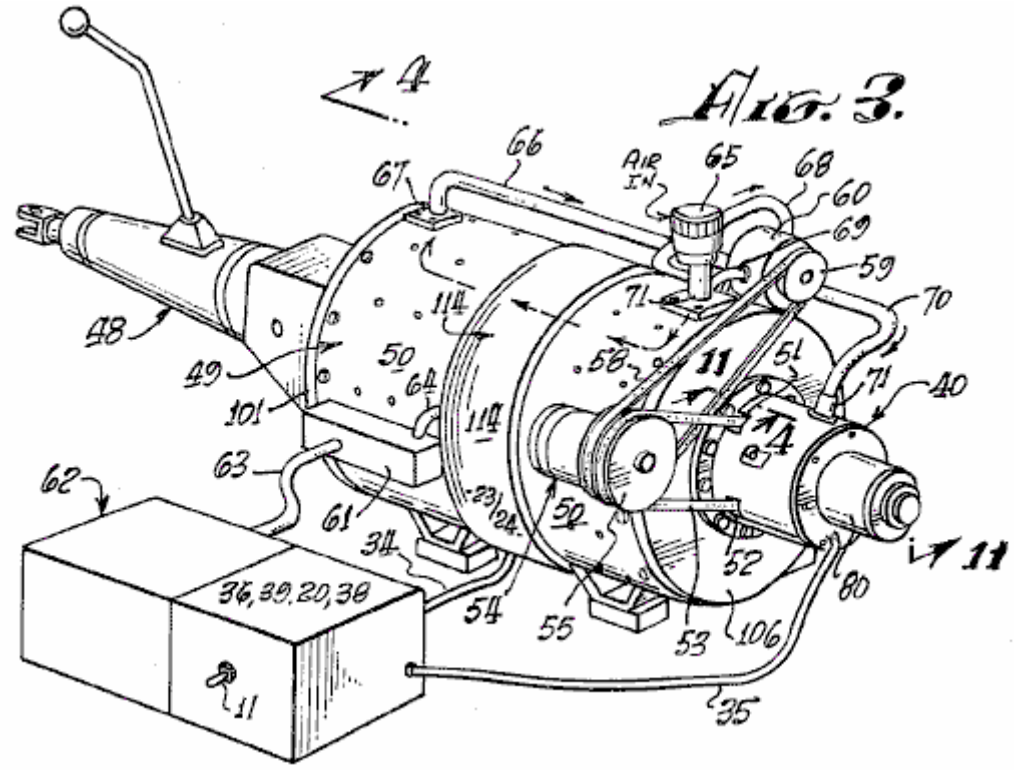

Fig.3 is a perspective view of a typical engine system according to the invention, coupled to an automotive transmission.

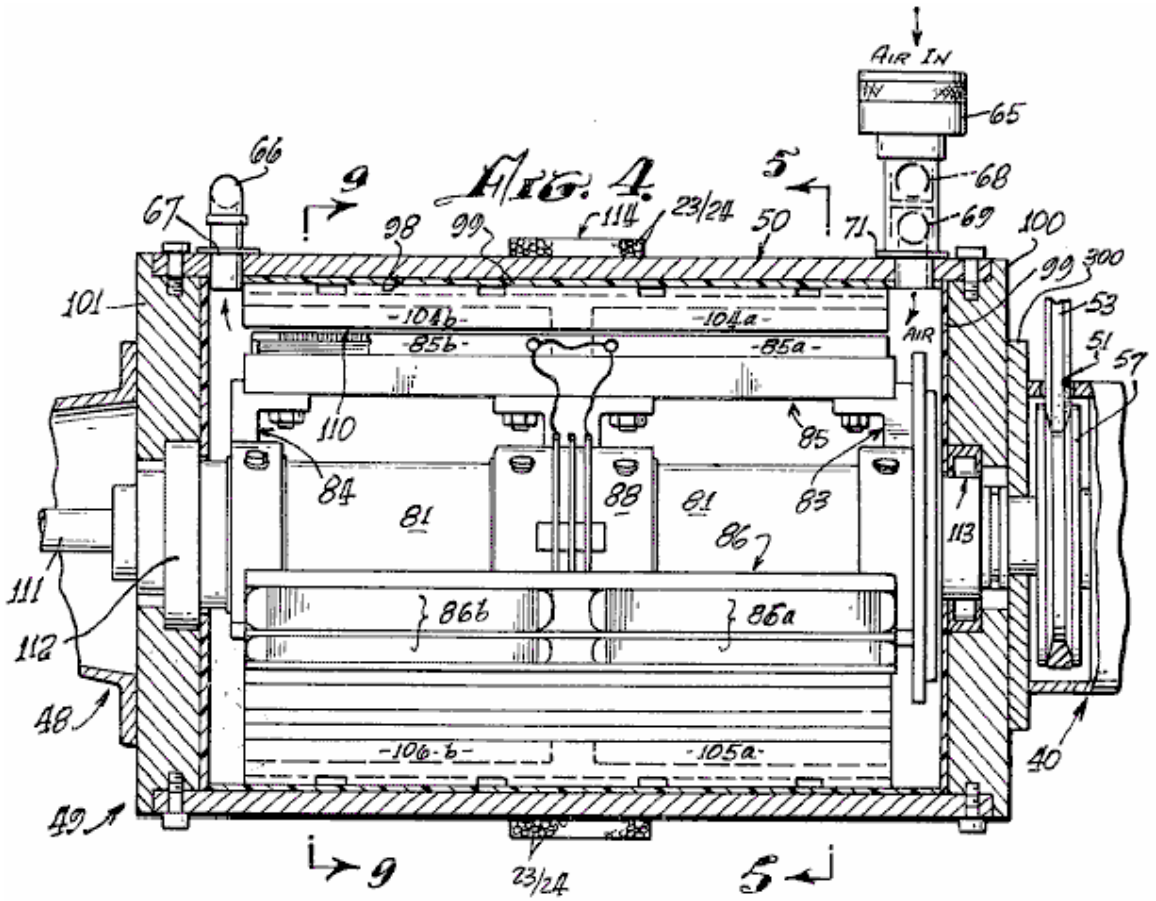

Fig.4 is an axial sectional view taken at line 4---4 in Fig.3

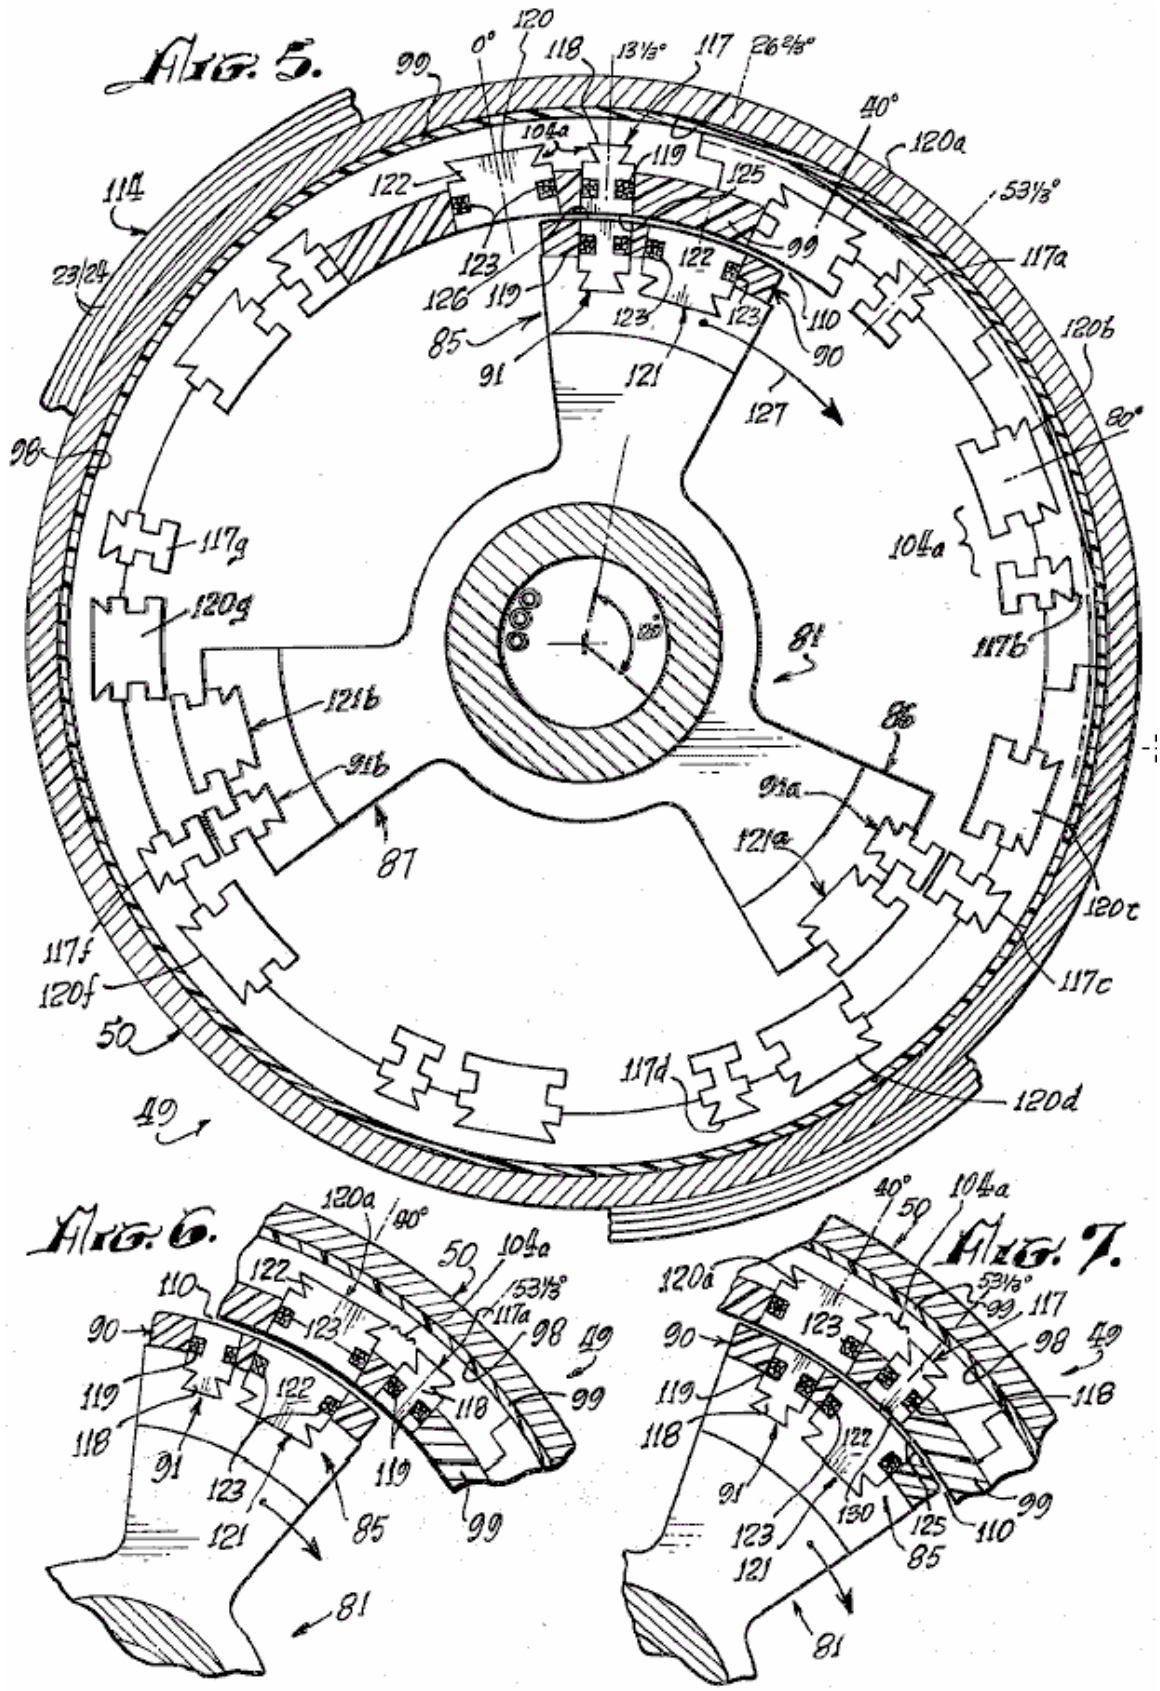

Fig.5 is a sectional view taken at line 5---5 in Fig.4

Fig.6 and **Fig.7** are fragmentary sectional views, corresponding to a portion of Fig.5, illustrating successive advanced positions of the engine rotor therein.

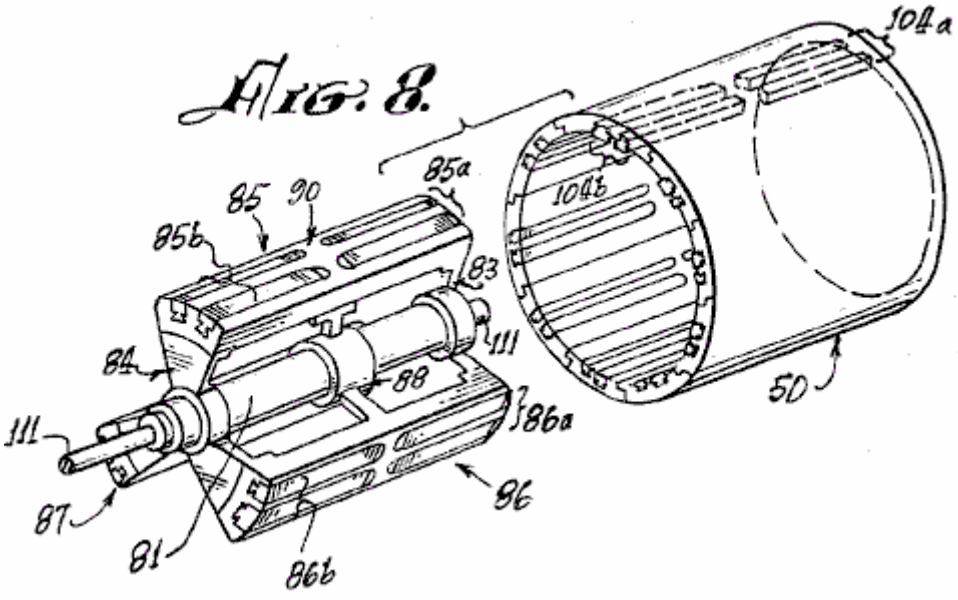

Fig.8 is an exploded perspective view of the rotor and stator of the engine of Fig.3 and Fig.4

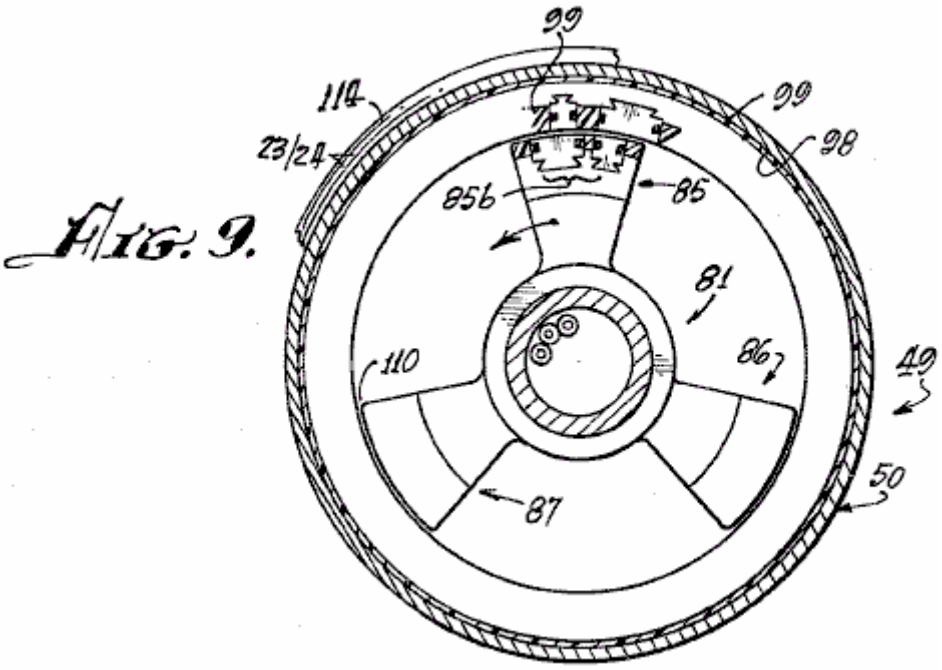

Fig.9 is a cross-sectional view taken at line 9---9 of Fig.4

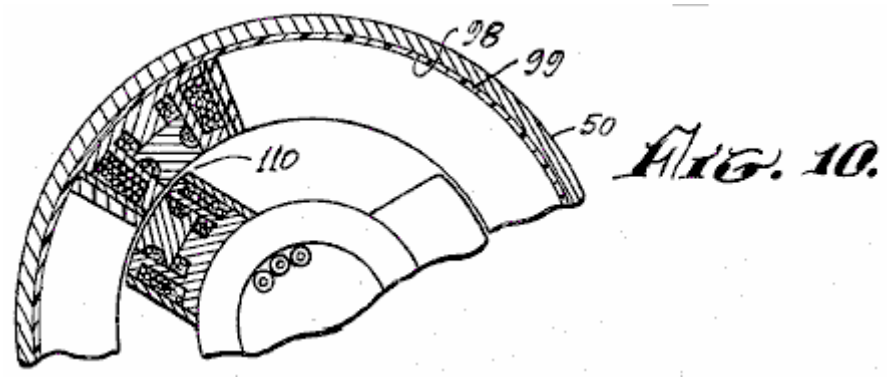

Fig.10 is a partial sectional view, similar to the view of Fig.9, illustrating a different configuration of electromagnets in another engine embodiment of the invention.

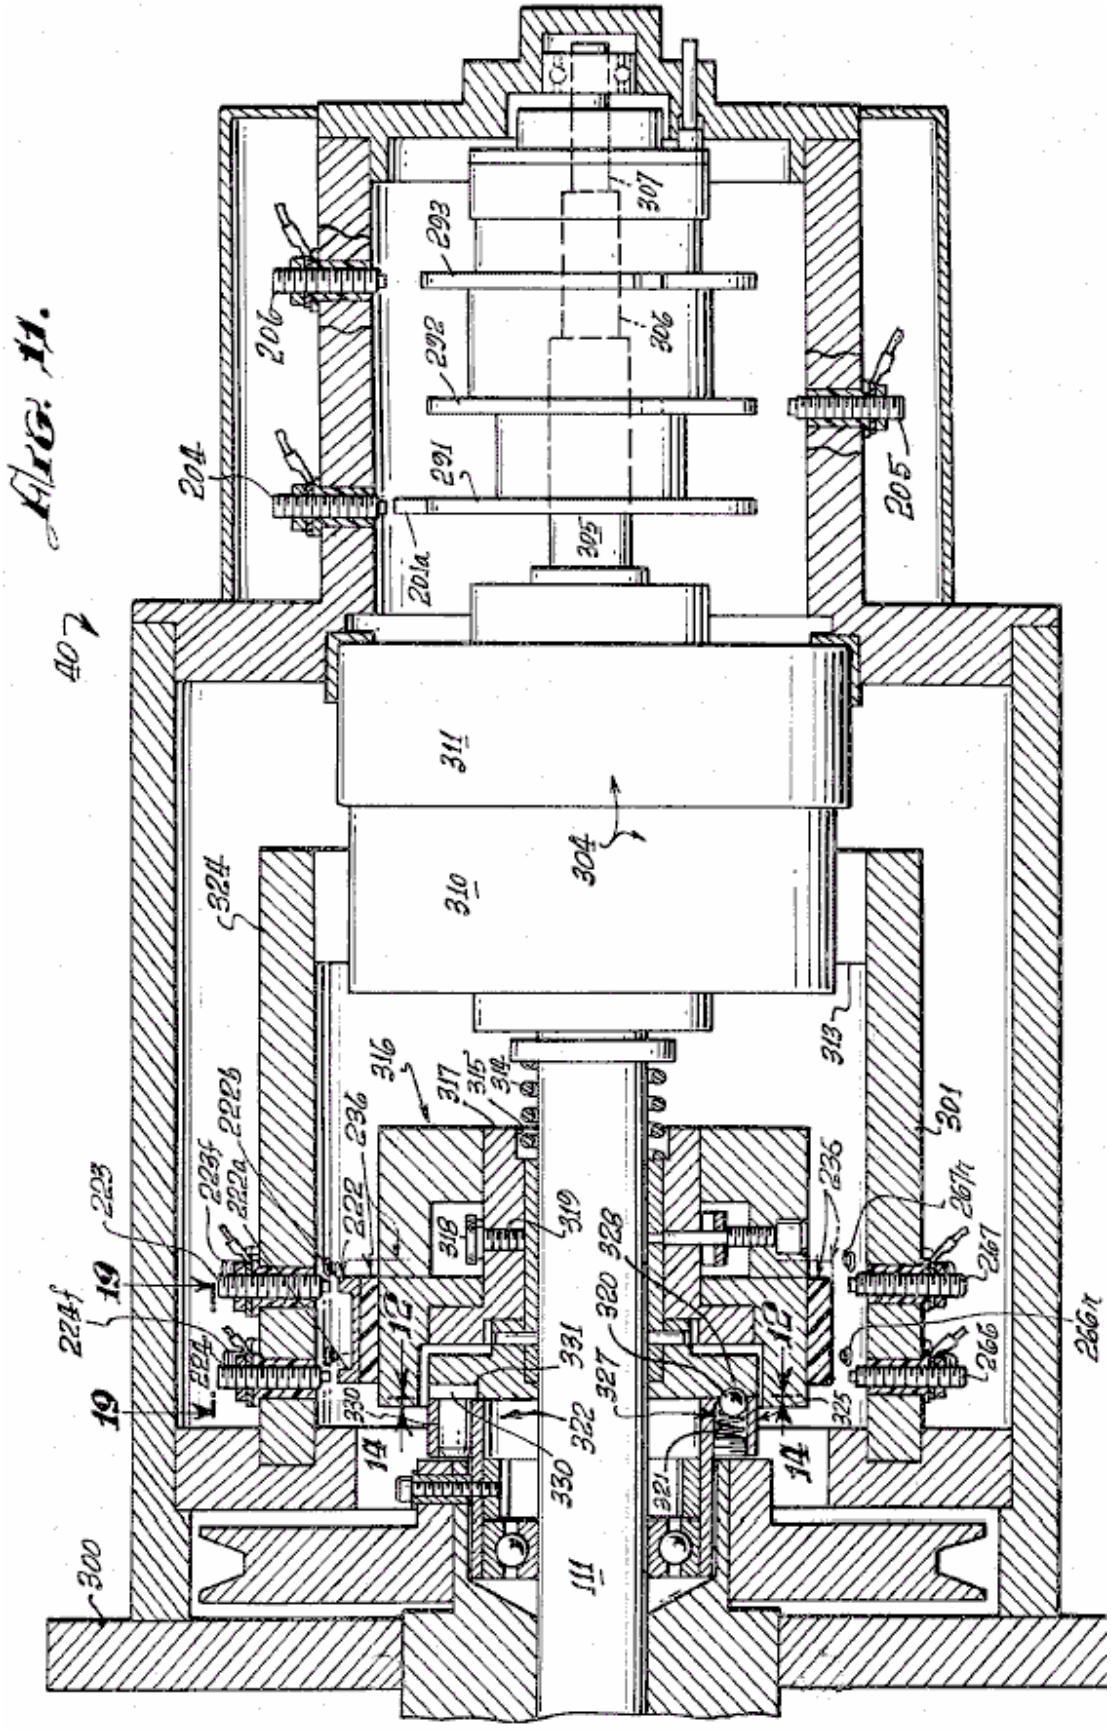

Fig.11 is a sectional view taken at line 11---11 in Fig.3, illustrating the control head or novel speed change controlling system of the engine.

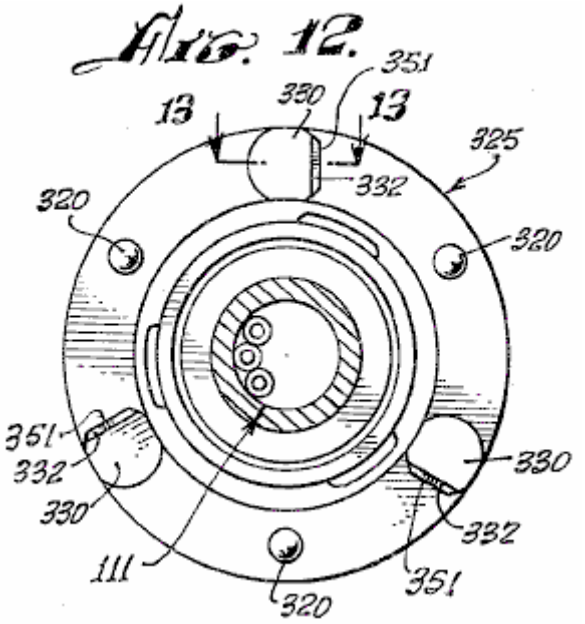

Fig.12 is a sectional view, taken at line 12---12 in Fig.11, showing a clutch plate utilised in the speed change control system of Fig.11

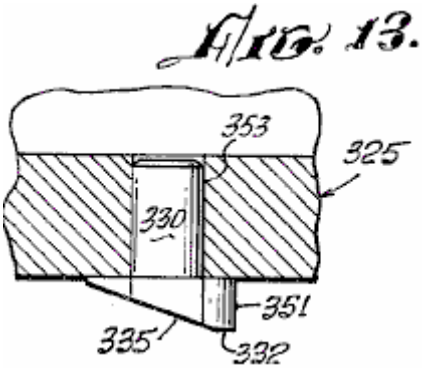

Fig.13 is a fragmentary view, taken at line 13---13 in Fig.12

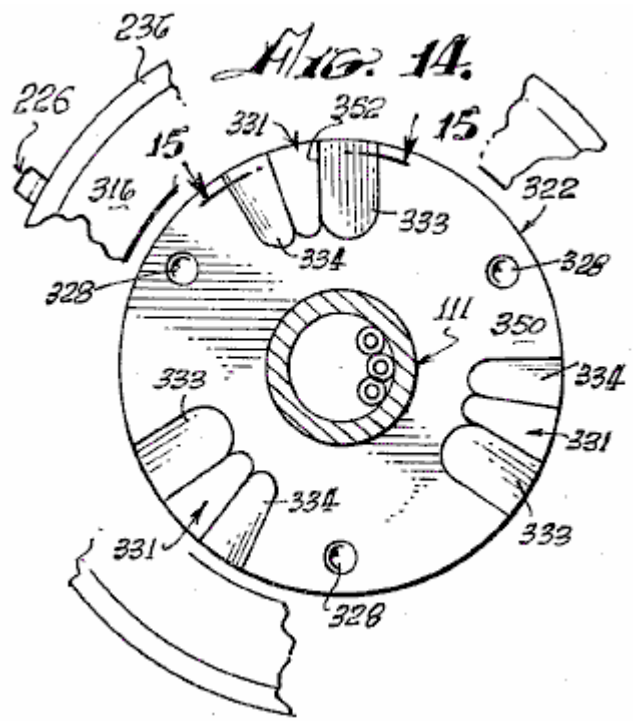

Fig.14 is a sectional view, taken at line 14---14 in Fig.11, showing a clutch plate which co-operates with the clutch plate of Fig.12

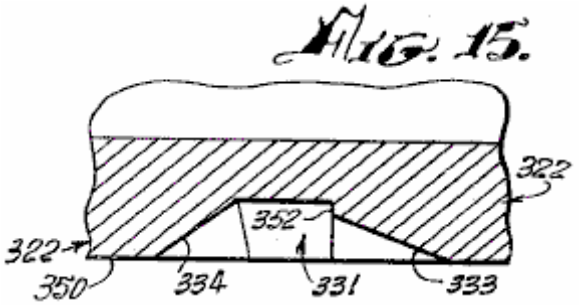

Fig.15 is a fragmentary sectional view taken at line 15---15 of Fig.13

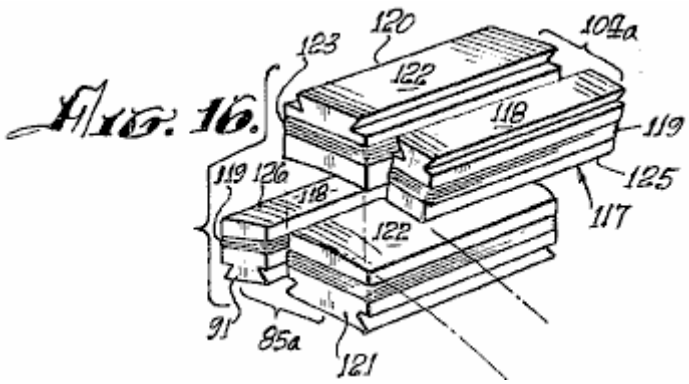

Fig.16 is a perspective view of electromagnets utilised in the present invention.

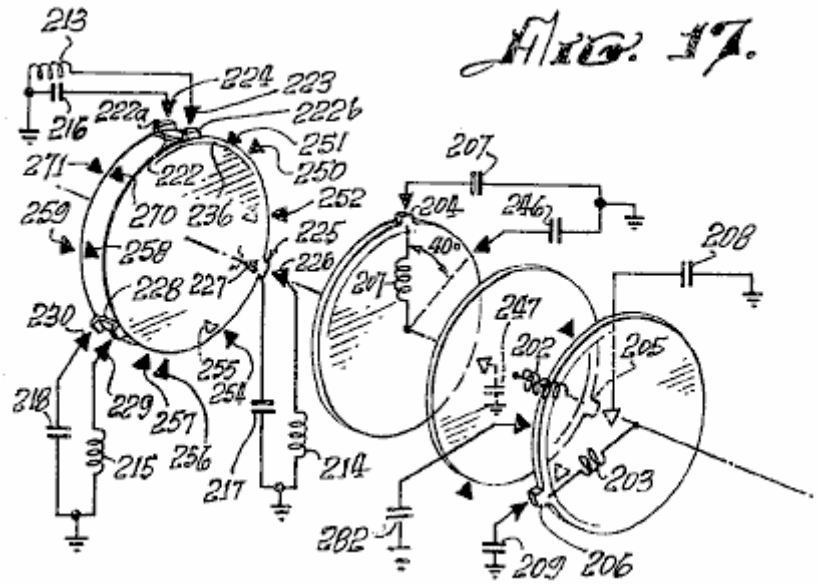

Fig.17 is a schematic diagram showing co-operating mechanical and electrical features of the programmer portion of the invention.

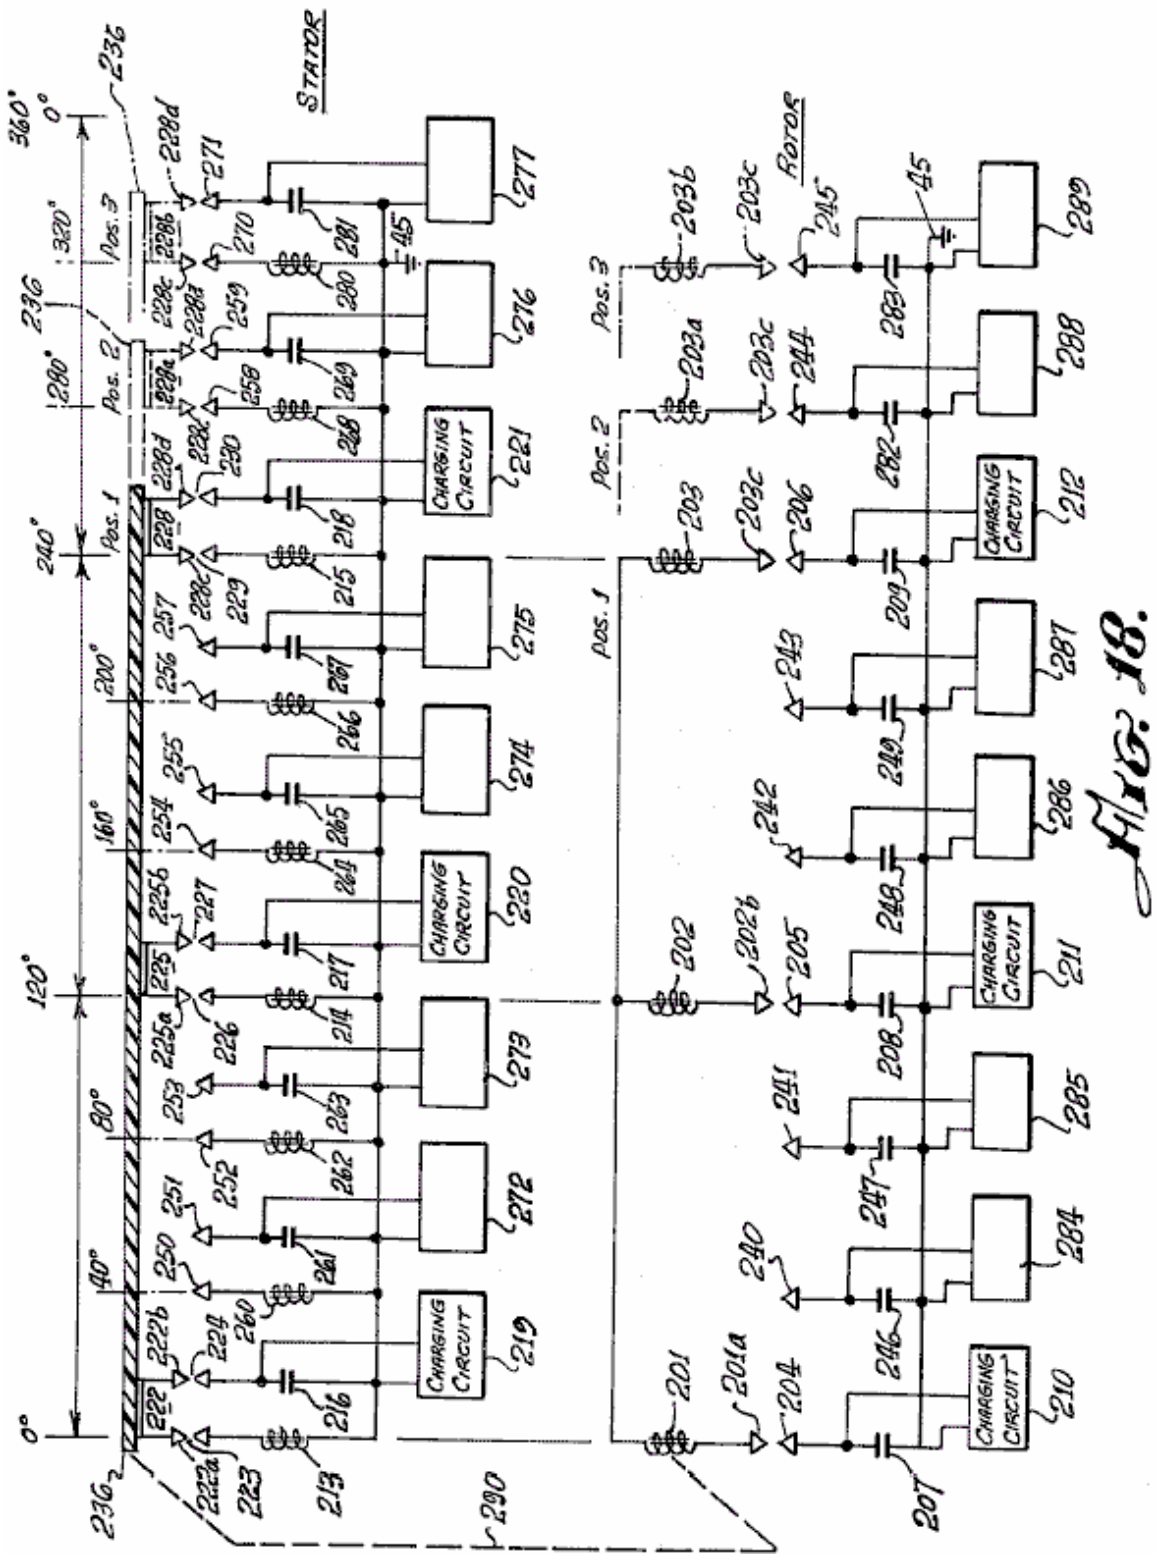

Fig.18 is an electrical schematic diagram of an engine according to the invention, showing the electrical relationships of the electromagnetic components embodying a new principle of the invention, and

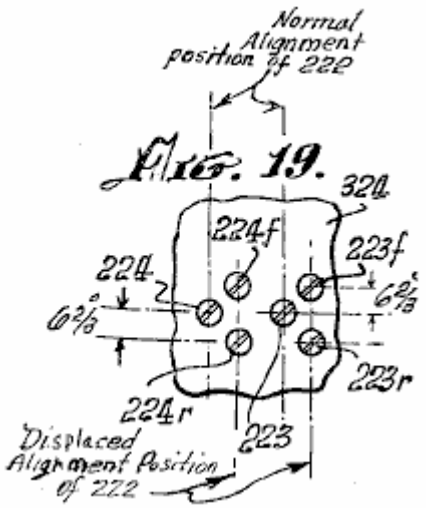

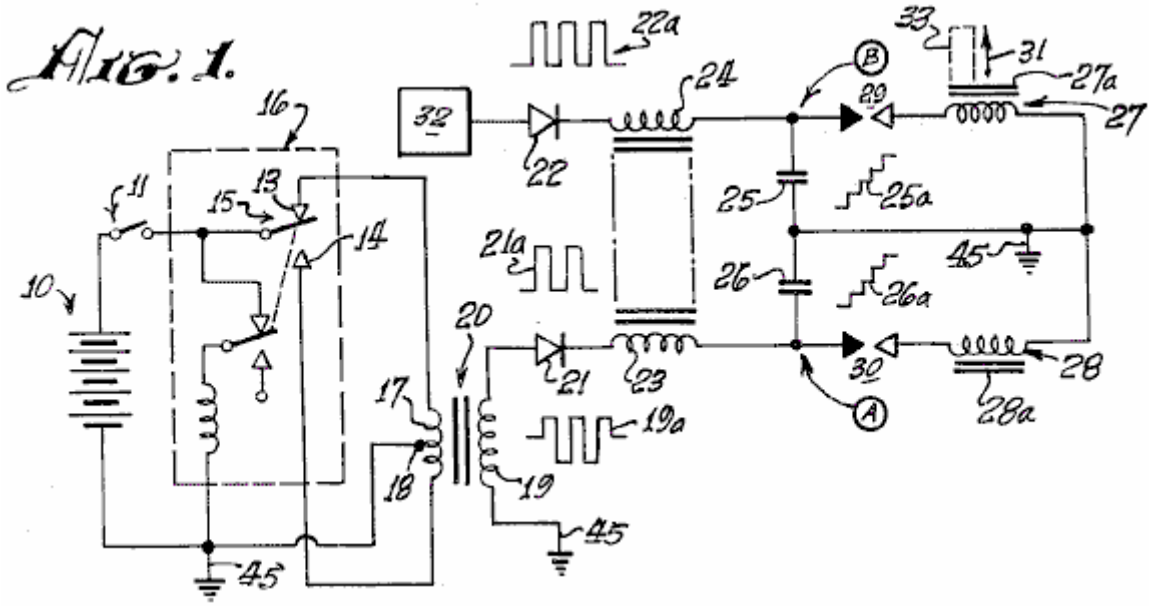

Fig.19 is a developed view, taken at line 19---19 of Fig.11, showing the locations of displaced spark gap elements of the speed changing mechanism of an engine according to the invention.

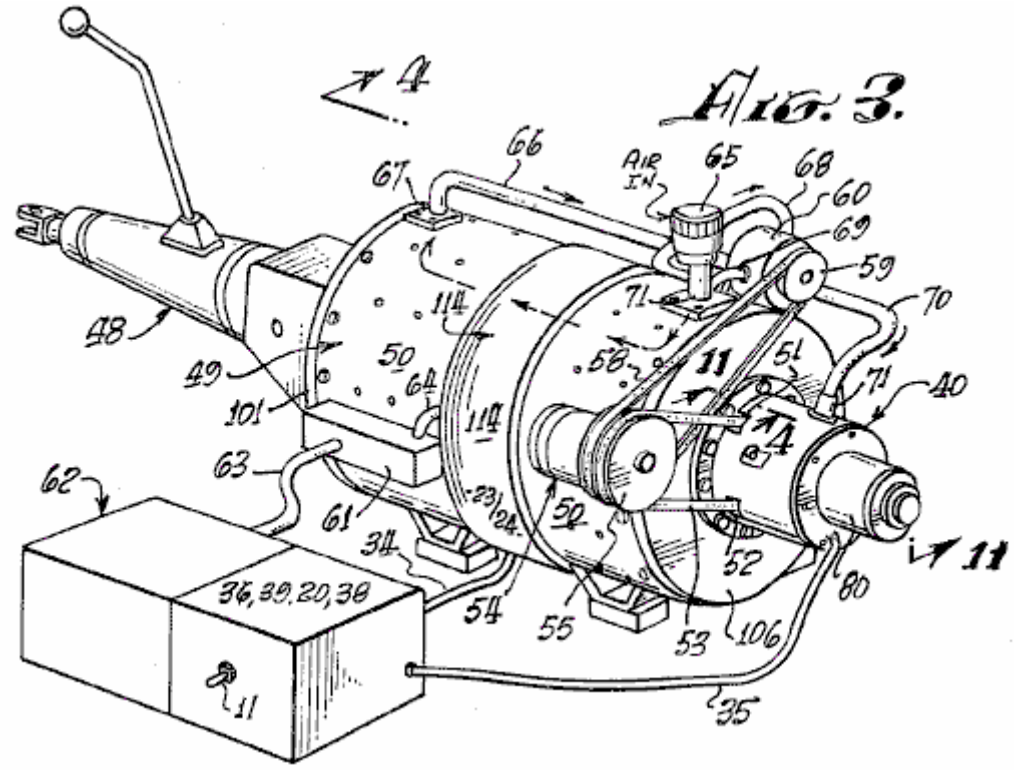
DESCRIPTION OF THE PREFERRED EMBODIMENT

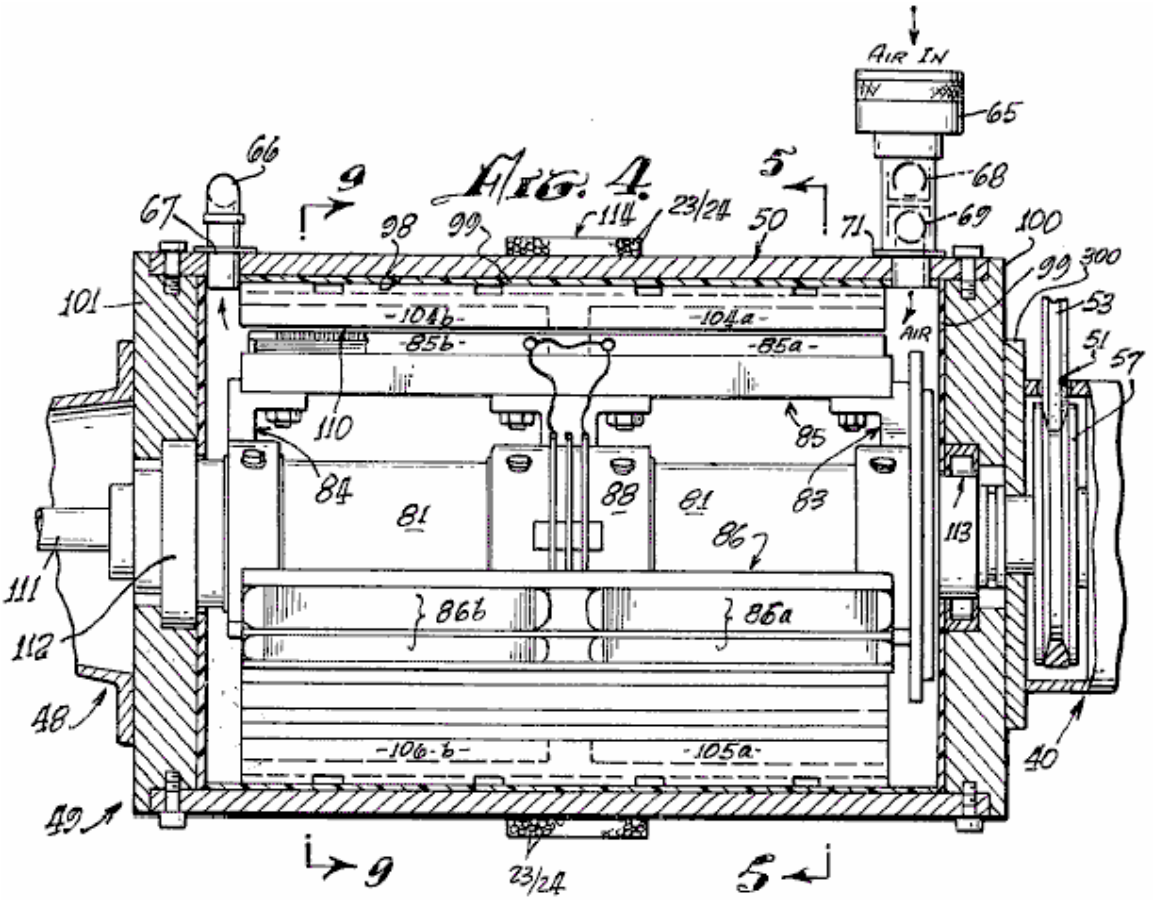
As mentioned earlier, the basic principle of operation of the engine of the invention, is the discharge of a capacitor across a spark gap and through an inductor. When a pair of inductors is used, and the respective magnetic cores thereof are arranged opposite one another and arranged in opposing magnetic polarity, the discharge through them causes the cores to repel each other with considerable force.



Referring to the electrical schematic diagram of **Fig.1**, a battery **10** energises a pulse-producing vibrator mechanism **16**, which may be of the magnetic type, incorporating an armature **15** moving between contacts **13** and **14**, or of the transistor type (not shown) with which a high frequency bipolar pulsed output is produced in primary **17** of transformer **20**. The pulse amplitude is stepped up in secondary **19** of transformer **20**. Wave form **19a** represents the bi-directional or bi-polar pulsed output. A diode rectifier **21** produces a unidirectional pulse train, as indicated at **21a**, to charge capacitor **26**. Successive unidirectional pulses of wave **21a** charge capacitor **26** to high level, as indicated at **26a**, until the voltage at point **A** rises high enough to cause a spark across the spark gap **30**. Capacitor **26** discharges via the spark gap, through the electromagnet coil **28**. A current pulse is produced which magnetises core **28a**. Simultaneously, another substantially identical charging system **32** produces a discharge through inductor **27** across spark gap **29**, to magnetise core **27a**. Cores **27a** and **28a** are wound with coils **27** and **28** respectively, so that their magnetic polarities are the same. As the cores **27a** and **28a** confront one another, they tend to fly apart when the discharge occurs through coils **27** and **28** because of repulsion of identical magnetic poles, as indicated by arrow **31**. If core **28a** is fixed or stationary, and core **27a** is moveable, then core **27a** may have tools **33** attached to it to perform work when the capacitor discharges.

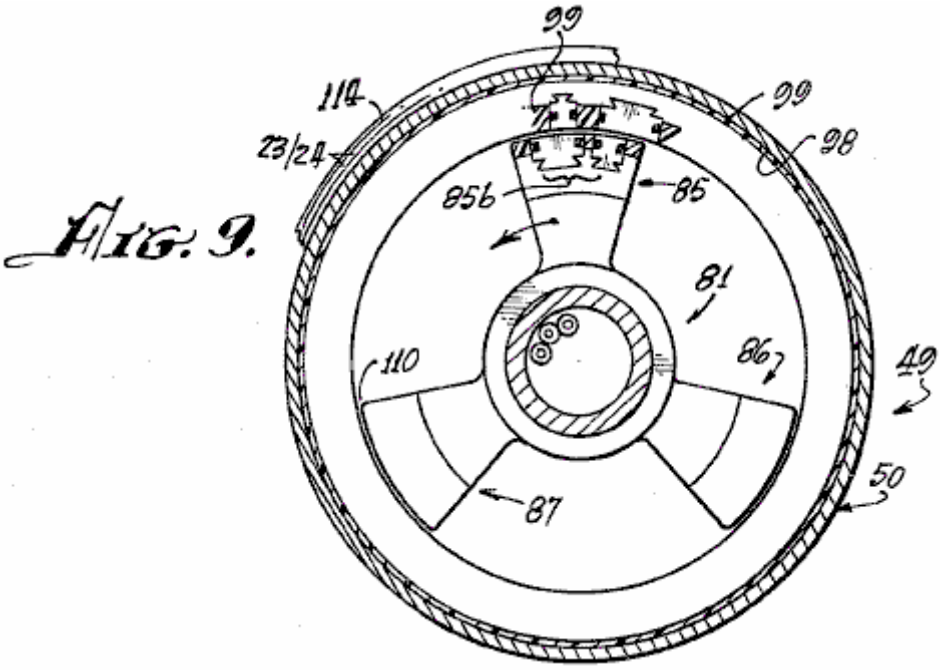
Referring to **Fig.1** and **Fig.2**, a d-c electrical source or battery **10**, energises pulsators **36** (including at least two vibrators **16** as previously described) when switch 11 between the battery **10** and pulsator **36** is closed, to apply

relatively high frequency pulses to the primaries of transformers **20**. The secondaries of transformers **20** are step-up windings which apply bipolar pulses, such as pulses **19a** (Fig.1) to the diodes in converter **38**. The rectified unidirectional pulsating output of each of the diodes in converter **38** is passed through delay coils **23** and **24**, thus forming a harness **37**, wound about the case of the engine, as herein after described, which is believed to provide a static floating flux field. The outputs from delay lines **37**, drive respective capacitors in banks **39**, to charge the capacitors therein, to a relatively high charge potential. A programmer and rotor and stator magnet control array **40**, **41**, **42**, is formed by spark gaps positioned, as hereinafter described, so that at predetermined positions of the rotor during rotation of the engine, as hereinafter described, selected capacitors of the capacitor banks **39** will discharge across the spark gaps through the rotor and stator electromagnets **43** and **44**. The converters **38**, programmer **40**, and controls **41** and **42**, form a series circuit path across the secondaries of transformers **20** to the ground, or point of reference potential, **45**. The capacitor banks **39** are discharged across the spark gaps of programmer **40** (the rotor and stator magnet controls **41** and **42**). The discharge occurs through the coils of stator and rotor electromagnets **43** and **44** to ground **45**. Stator and rotor electromagnets are similar to those shown at **27**, **27a**, **28** and **28a** in **Fig.1**.



The discharge through the coils of stator and rotor electromagnets **43** and **44** is accompanied by a discharge overshoot or return pulse, which is applied to a secondary battery **10a** to store this excess energy. The overshoot pulse returns to battery **10a** because, after discharge, the only path open to it is that to the battery **10a**, since the gaps in **40**, **41** and **42** have broken down, because the capacitors in banks **39** are discharged and have not yet recovered the high voltage charge from the high frequency pulsers **36** and the converter rectifier units **38**.

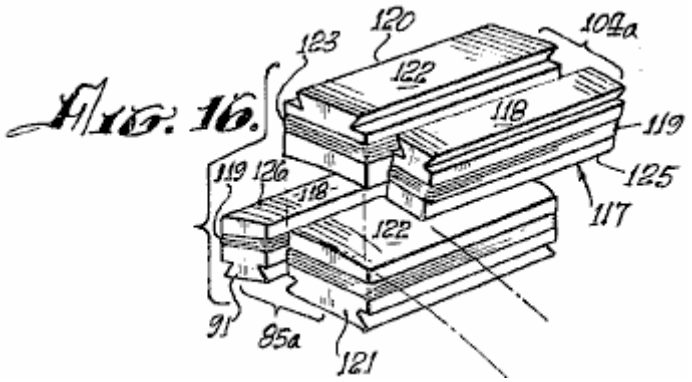
In the event of a misfire in the programmer control circuits **40**, **41** and **42**, the capacitors are discharged through a rotor safety discharge circuit **46** and returned to batteries **10-10a**, adding to their capacity. The circuit **46** is connected between the capacitor banks **39** and batteries **10**, **10a**.



Referring to **Fig.3**, a motor or engine **49** according to the present invention is shown connected with an automotive transmission **48**. The transmission **48**, represents one of many forms of loads to which the engine may be applied. A motor housing **50**, encases the operating mechanism hereinafter described. The programmer 40 is axially mounted at one end of the housing. Through apertures **51** and **52**, a belt **53** couples to a pulley **57** (not shown in this view) and to an alternator **54** attached to housing **50**. A pulley **55** on the alternator, has two grooves, one for belt **53** to the drive pulley **58** on the shaft (not shown) of the engine **49**, and the other for a belt **58** coupled to a pulley **59** on a pump **60** attached to housing **50**, A terminal box **61** on the housing, interconnects between the battery assembly **62** and motor **49** via cables **63** and **64**.

An intake **65** for air, is coupled to pump **60** via piping **68** and **69** and from pump **60** via tubing or piping **66** and **70** to the interior of housing **50** via coupling flanges **67** and **71**. The air flow tends to cool the engine and the air may preferably be maintained at a constant temperature and humidity so that a constant spark gap discharge condition is maintained. A clutch mechanism **80** is provided on programmer **40**.

Referring to **Fig.4**, **Fig.5** and **Fig.9**, rotor **81** has spider assemblies **83** and **84** with three electromagnet coil assembly sets mounted thereon, two of which are shown in **Fig.4**, on **85**, at **85a** and **85b** and on **86** at **86a** and **86b**. One of the third electromagnet coil assemblies, designated **87a**, is shown in **Fig.5**, viewed from the shaft end. As more clearly shown in the perspective view of **Fig.8**, a third spider assembly **88** provides added rigidity and a central support for the rotor mechanism on shaft **81**.

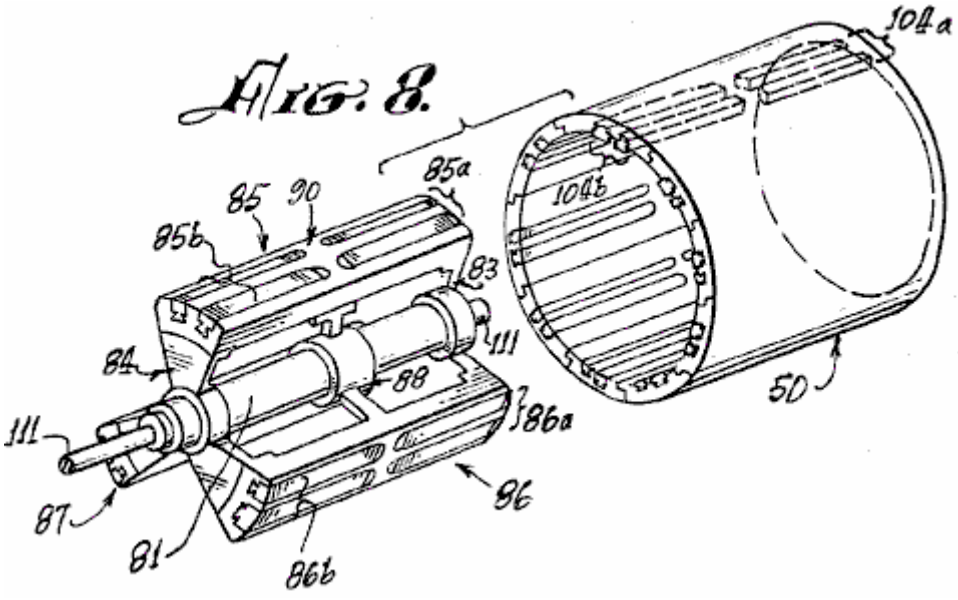


The electromagnet sets **85a**, **85b**, **86a**, **86b**, **87a** and **87b**, disposed on rotor **81** and spiders **83**, **84** and **88**, each comprise pairs of front units **85a**, **86a** and **87a** and pairs of rear units **85b**, **86b** and **87b**. Each pair consists of a major electromagnet and a minor electromagnet, as hereinafter described, which are imbedded in an insulating

material **90**, which insulates the electromagnet coil assemblies from one another and secures the electromagnets rigidly in place on the spider/rotor cage **81**, **83**, **84** and **88**.

The interior wall **98**, of housing **50**, is coated with an electrically insulating material **99** in which are imbedded electromagnet coils, as hereinafter described, and the interiors of end plates **100** and **101** of the housing **50**. On the insulating surface 98 of housing **50** is mounted a series of stator electromagnet pairs **104a**, identical with electromagnet pairs **85a**, **86a**, **87a**, etc. Electromagnet pairs such as **104a** or **105a** are disposed every **40** degrees about the interior of housing **50** to form a stator which co-operates with the rotor **81-88**. An air gap **110** of very close tolerance is defined between the rotor and stator electromagnets and air from pump **65** flows through this gap.

As shown in **Fig.8**, the electromagnet assemblies, such as **85** through **87**, of the rotor and magnet assemblies, such as **104a** in the stator, are so embedded in their respective insulating plastic carriers (rotor and stator) that they are smoothly rounded in a concave contour on the rotor to permit smooth and continuous rotation of rotor **81** in stator housing **50**. The air gap **110** is uniform at all positions of any rotor element within the stator assembly, as is clearly shown in **Fig.16**.



The rotor **81** and spiders **83**, **84** and **88** are rigidly mounted on shaft **111** journaled in bearing assemblies **112** and **113** which are of conventional type, for easy rotation of the rotor shaft **111** within housing **50**.

Around the central outer surface of housing **50**, are wound a number of turns of wire **23** and **24** to provide a static flux coil **114** which is a delay line, as previously described. **Figs. 5, 6, 7** and **9** are cross-sectional views of the rotor assembly **81-88**, arranged to show the positioning and alignment of the rotor and stator electromagnet coil assemblies at successive stages of the rotation of the rotor **81-88** through a portion of a cycle of operation thereof. For example, in **Fig.5** the rotor assembly **81-88** is shown so positioned that a minor rotor electromagnet assembly **91** is aligned with a minor stator electromagnet assembly **117**.

As shown in further detail in **Fig.16**, minor electromagnet assembly **117** consists of an iron core **118**, grooved so that a coil of wire **119** may be wound around it. Core **118** is the same in stator electromagnet **117** as it is in rotor electromagnet **91**.

As a position 13.33 degrees to the right of rotor electromagnet **91**, as viewed in **Fig.5** and **Fig.16**, there is a second or major rotor electromagnet **121** which has a winding **123** about its core **122**. The electromagnets **91** and **121** are the pair **85a** of **Fig.4** and **Fig.8**.

At a position 13.33 degrees to the left of stator electromagnet **117**, as viewed in **Fig.5**, there is a second or major stator electromagnet **120** whose core **122** is of the same configuration as core **122** of rotor electromagnet **121**. A winding **123** about core **122** of electromagnet **120** is of the same character as winding **123** on electromagnet **121**.

Electromagnet assembly pair **85a** on the rotor is identical in configuration to that of the electromagnet stator assembly pair **104a** except for the position reversal of the elements **117-120** and **91-121** of the respective pairs.

There are none pairs of electromagnets **120-117** (**104a**) located at 40 degree intervals about the interior of housing **50**. The centreline of core **122** of electromagnet **120** is positioned 13.33 degrees to the left of the centreline of the core **118** of electromagnet **117**. Three pairs of electromagnets **85a**, **86a** and **87a** are provided on rotor assembly **81-88** as shown in **Fig.5**.

Other combinations are possible, but the number of electromagnets in the rotor should always be in integral fraction of the number of electromagnets in the stator. As shown in **Fig.8**, for the rotor assembly **85a** and **85b**, there are three of each of the front and back pairs of electromagnetic assemblies. Similarly, as shown in **Fig.4** and **Fig.8**, there are nine front and back pairs of electromagnets in the stator such as **104a** and **104b**.

In order to best understand the operation of the rotor **81-88** rotating within the stator housing **50** of an engine according to this invention, the positions of rotor electromagnets **91** and stator electromagnets **117** are initially exactly in line at the 13.33 degree peripheral starting position marked on the vertical centreline of **Fig.5**. The winding direction of the coils of these magnets is such that a d-c current through the coils **119** will produce a particular identical magnet polarity on each of the juxtaposed surfaces **125** of magnet **117** and **126** of magnet **91** (**Fig.5**). **Fig.16** and **Fig.6** illustrate the next step in the motion wherein the two major electromagnets, **120** in the stator and **121** in the rotor, are in alignment.

When the d-c discharges from the appropriate capacitors in banks **39** occur simultaneously across spark gaps through the coils **119** of electromagnets **117** and **91**, at the instant of their alignment, their cores **118**, will repel one another to cause rotor assembly **81-88** to rotate clockwise in the direction indicated by arrow **127**. The system does not move in the reverse direction because it has been started in the clockwise direction by the alternator motor **54** shown in **Fig.3**, or by some other starter means. If started counterclockwise, the motor will continue to rotate counterclockwise.

As noted earlier, the discharge of any capacitor occurs over a very short interval via its associated spark gap and the resulting magnetic repulsion action imparts motion to the rotor. The discharge event occurs when electromagnets **117** and **91** are in alignment. As shown in **Fig.5**, rotor electromagnet **91a** is aligned with stator electromagnet **117c**, and rotor electromagnet **91b** is aligned with stator electromagnet **117e** at the same time that similar electromagnets **117** and **91** are aligned. A discharge occurs through all six of these electromagnets simultaneously (that is, **117**, **91**, **117c**, **91a**, **117e** and **91b**). A capacitor and a spark gap are required for each coil of each electromagnet. Where, as in the assembly shown in **Fig.8**, front and back pairs are used, both the axial in-line front and back coils are energised simultaneously by the discharge from a single capacitor or from a bank of paralleled capacitors such as **25** and **26** (**Fig.1**). Although **Fig.4** and **Fig.8** indicate the use of front and back electromagnets, it should be evident that only a single electromagnet in any stator position and a corresponding single electromagnet in the rotor position, may be utilised to accomplish the repulsion action of the rotor with respect to the stator. As stated, each electromagnet requires a discharge from a single capacitor or

capacitor bank across a spark gap for it to be energised, and the magnetic polarity of the juxtaposed magnetic core faces must be the same, in order to effect the repulsive action required to produce the rotary motion.

Referring to **Fig.5** and **Fig.6**, the repulsion action causes the rotor to move 13.33 degrees clockwise, while electromagnets **91**, **91a** and **91b** move away from electromagnets **117**, **117c** and **117e** to bring electromagnets **121**, **121a** and **121b** into respective alignment with electromagnets **120a**, **120d** and **120f**. At this time, a capacitor discharge across a spark-gap into their coils **123** occurs, thus moving the rotor. Another 13.33 degrees ahead, as shown in **Fig.7**, major electromagnets 121, 121a and 121b come into alignment with minor electromagnets **117a**, **117d** and **117f**, at which time a discharge occurs to repeat the repulsion action, this action continuing as long as d-c power is applied to the system to charge the capacitor banks.

Fig.18 further illustrates the sequencing of the capacitor discharges across appropriate spark gap terminal pairs. Nine single stator coils and three single rotor coils are shown with their respective interconnections with the spark gaps and capacitors with which they are associated for discharge. When the appropriate spark gap terminals are aligned, at the points in the positioning of the rotor assembly for most effective repulsion action of juxtaposed electromagnet cores, the discharge of the appropriate charged capacitors across the associated spark gap occurs through the respective coils. The capacitors are discharged is sets of three, through sets of three coils at each discharge position, as the rotor moves through the rotor positions. In **Fig.18**, the rotor electromagnets are positioned linearly, rather than on a circular base, to show the electrical action of an electric engine according to the invention. These motor electromagnets **201**, **202** and **203** are aligned with stator electromagnets **213**, **214** and **215** at 0 degrees, 120 degrees and 240 degrees respectively. The stator electromagnets are correspondingly shown in a linear schematic as if rolled out of the stator assembly and laid side by side. For clarity of description, the capacitors associated with the rotor operation **207**, **208**, **209** and **246**, **247**, **248**, **249**, **282** and **283**, are arranged in vertical alignment with the respective positions of the rotor coils **201**, **202** and **203** as they move from left to right, this corresponding to clockwise rotation of the rotor. The stator coils **213, 214, 215, 260, 261, 262, 263, 264, 265, 266,** etc. and capacitor combinations are arranged side by side, again to facilitate description.

An insulative disc **236** (shown in **Fig.17** as a disc but opened out linearly in **Fig.18**) has mounted thereon, three gap terminal blocks **222**, **225** and **228**. Each block is rectangularly U-shaped, and each interconnects two terminals with the base of the U. Block **222** has terminals **222a** and **222b**. Block **225** has terminals **225a** and **225b**. Block **228** has terminals **228c** and **228d**. When insulative disc **230** is part of the rotor as indicated by mechanical linkage **290**, it can be seen that terminal U **222** creates a pair of gaps with gap terminals **223** and **224** respectively. Thus, when the voltage on capacitor **216** from charging unit **219**, is of a value which will arc over the air spaces between **222a** and **223**, and between **222b** and **224**, the capacitor **216** will discharge through the coil of electromagnet **213** to ground. Similarly, gap terminal U 225 forms a dual spark gap with gap terminals **226** and **227** to result in arc-over when the voltage on capacitor **217**, charged by charging circuit **220**, discharges into the coil of electromagnet **214**. Also, U-gap terminal **228** with terminals **228c** and **228d**, creates a spark gap with terminals **229** and **230** to discharge capacitor **218**, charged by charging circuit **221**, into coil **215**. At the same time, rotor coils, **201**, **202** and **203** across gaps **201a - 204**, **202b - 205** and **203c - 206** each receives a discharge from respective capacitors **207**, **208** and **209**.

When the electromagnet coils **213**, **214** and **215** and **201**, **202** and **203** are energised, the repulsion action causes the rotor assembly to move to position 2 where a new simultaneous group of discharges occurs into rotor coils **201**, **202** and **203** from capacitors **246**, **248** and **282** across gaps **201a - 240**, **202b - 242** and **203c - 244**. Simultaneously, because gap-U-elements **222**, **225** and **228** have also moved to position 2 with the rotor assembly, capacitor **261** is discharged through electromagnet coil **260**, capacitor **265** is discharged through electromagnet coil **264**, and capacitor **269** is discharged through electromagnet coil **268** in alignment with position 2 of the rotor electromagnet coils, thus to cause the rotor electromagnets to move to position 3 where the discharge pattern is repeated now with capacitors **247**, **249** and **283** discharging through the rotor electromagnet coils **201**, **202** and **203**, and the capacitors **263**, **267** and **281** discharging respectively through stator electromagnet coils **262**, **266** and **280**.

After each discharge, the charging circuits **219 - 221** and **272 - 277** for the stator capacitors, and **210 - 212** and **284 - 289** for the rotor capacitors, are operated continuously from a battery source as described earlier with reference to **Fig.1**, to constantly recharge the capacitors to which each is connected. Those versed in the art will appreciate that, as each capacitor discharges across an associated spark gap, the resulting drop in potential across the gap renders the gap an open circuit until such time as the capacitor can recharge to the arc-over level for the gap. This recharge occurs before a rotor element arrives at the next position in the rotation.

The mechanical schematic diagram of **Fig.17**, further clarifies the operation of the spark-gap discharge programming system. A forward disc **236** of an electrically insulative material, has thereon the set of U-shaped gap terminal connectors previously described. These are positioned at 0 degrees, 120 degrees and 240 degrees respectively. In **Fig.17**, schematic representations of the position of the coil and capacitor arrangements at the

start of a cycle are shown to correspond to the above description with reference to **Fig.18**. Accordingly, the coil and capacitor combinations **213/216, 214/217** and **215/218** are shown connected with their gap terminals, respectively, **223/224, 226/227** and **229/230**. On the rotor coil and capacitor connection, three separate discs **291, 292** and **293** are shown, each with a single gap terminal. The discs **291 - 293** are rotated so as to position their respective gap terminals 201a, 201b and 201c, at 120 degree increments, with the 0 degrees position corresponding to the 0 degrees position of U-gap terminal **222** on disc **230**.

Representative gap terminals are shown about the peripheries of discs **230, 291 - 293** to indicate clearly how, as the discs turn in unison, the gap alignments correspond so that three rotor coils always line up with three stator coils at 120 degree intervals about the rotary path, producing an alignment every 40 degrees, there being nine stator coils. Thus, there are three simultaneous discharges into stator coils and three into rotor coils at each 40 degree position. Nine positions displaced 40 degrees apart provide a total of 27 discharge points for capacitors into the rotor coils and 27 discharge points for capacitors into the stator coils in one revolution of the rotor.

It will be understood that, as illustrated in **Fig.17** and **Fig.18**, nine individual electromagnet coils are shown in the stator and three in the rotor, in order to show in its simplest form, how the three rotor electromagnets are stepped forward from alignment with three of the stator electromagnets, when the appropriate spark gaps are in alignment, to effect the discharge of capacitors through juxtaposed pairs of rotor/stator electromagnets. The repulsion moves the rotor electromagnet from the stator electromagnet to the next alignment position 40 degrees further on. In the interval, until another rotor electromagnet, 120 degrees removed, is aligned with the stator electromagnet which had just been pulsed, the associated capacitor is recharged. Thus, the rotor moves from one position to the next, with capacitor discharges occurring each 40 degrees of rotation, a total of nine per revolution. It should be obvious that, with other rotor/stator combinations, the number of electromagnet coincidences and spark-gap discharges will vary. For example, with the coil pairs shown in **Figs 4 through 8**, a total of 27 discharges will occur. Although there are 18 stator electromagnets and 3 rotor electromagnets, the discharge pattern is determined by the specific spark gap arrangement.

The rotor/stator configuration of **Fig.5** and **Fig.8**, involving the major and minor pairs of electromagnets, such as **85a** and **104a** (the terms “minor” and “major” referring to the difference in size of the elements), include nine pairs of electromagnets in the stator, such as **104a**, with three electromagnet pairs of the rotor, such as **85a**. Because of the 13.33 degree separation between the major and minor electromagnets in the rotor pair **85a**, with the same separation of minor and major electromagnets of the stator pair **104a**, the sequence of rotation and discharge described above, with respect to the illustrative example of **Fig.5**, involves the following:
1. A minor element **117** of stator pair **104a** is aligned with the minor element **91** of rotor pair **85a**. On the discharge, this moves the rotor ahead 13.33 degrees.
2. the major rotor element **122** of the pair **85a**, now is aligned with the major stator element **120b** of the next stator electromagnet pair, in the stator array as shown in **Fig.6**. On the discharge, the rotor moves ahead 13.33 degrees.
3. This brings the minor rotor electromagnet **91** into alignment with the major stator electromagnet **120b** of pair **104d**, and the major electromagnet **122** (just discharged) of pair **85a** into alignment with minor electromagnet **117b** of pair **104d**, and the rotor spark gap elements into alignment with a different position of gap elements connected with capacitors not discharged in the previous position of the rotor. It should be remembered at this point that it is the positioning of a rotatable spark gap array, similar to that illustrated in **Fig.17** and **Fig.18**, which controls the time of discharge of capacitors connected to these gap terminals. Therefore, any electromagnet can be energised twice, successively, from separate capacitors as the rotor brings appropriate gap terminals into alignment with the coil terminals of a particular electromagnet.

Thus, although major electromagnet **120b** of pair **104d** has just been energised as described above, it can now be energised again along with minor rotor electromagnet **91** in step 3, because the rotor moved to a new set of terminals of the spark gap arrays connected to capacitors which have not yet been discharged. These capacitors now discharge through rotor electromagnet **91** and stator electromagnet **120b**, causing the rotor to move ahead another 13.33 degrees, thus again aligning two minor electromagnets again, these being **117b** of stator pair **104d** and **91** of rotor pair **85a**. The rotor has now moved 40 degrees since step 1 above. The sequence is now repeated indefinitely. It is to be noted that at each 13.33 degree step, the discharges drive the rotor another 13.33 degrees. There are 27 steps per revolution with nine stator coil pairs. The discharge sequence is not uniform, as is shown in Table 1. In the stator, three major electromagnets 120 degrees apart are energised twice in sequence, followed by a hiatus of one step while three minor electromagnets of the stator, 120 degrees apart, are energised during the hiatus. In the rotor the major electromagnets are energised during a hiatus step following two minor electromagnet energisation steps. A total of 27 energisations are this accomplished in the nine pairs of coils of the stator.

In Table 1, the leftmost column shows the location of each rotor arm **85, 86** and **87** at an arbitrarily selected step No. 1 position. For example, in step 1, rotor arm **85** has a minor stator and minor rotor electromagnet in alignment for capacitors to discharge through them simultaneously at the 13.33 degree position.

TABLE I

CAPACITOR DISCHARGE SEQUENCE FOR ONE REVOLUTION OF ROTOR IN SYSTEM OF FIGS. 5 AND 8

Step No. Rotor Arm 87	85	86	Rotor Angle	Rotor Electro-magnet Minor	Rotor Electro-magnet Major	Stator Electro-magnet Minor	Stator Electro-magnet Major
10	1	19	13 1/3°	x		x	
11	2	20	26 2/3°		x		x
12	3	21	40°	x			x
13	4	22	53 1/3°	x		x	
14	5	23	66 2/3°		x		x
15	6	24	80°	x			x
16	7	25	93 1/3°	x		x	
17	8	26	106 2/3°		x		x
18	9	27	120°	x			x
19	10	1	133 1/3°	x		x	
20	11	2	146 2/3°		x		x
21	12	3	160°	x			x
22	13	4	173 1/3°	x		x	
23	14	5	186 2/3°		x		x
24	15	6	200°	x			x
25	16	7	213 1/3°	x		x	
26	17	8	226 2/3°		x		x
27	18	9	240°	x			x
1	19	10	253 1/3°	x		x	
2	20	11	266 2/3°		x		x
3	21	12	280°	x			x
4	22	13	293 1/3°	x		x	
5	23	14	306 2/3°		x		x
6	24	15	320°	x			x
7	25	16	333 1/3°	x		x	
8	26	17	346 2/3°		x		x
9	27	18	360°	x			x

Similarly, in step 1, rotor arm **86** is at the 133.33 degree position which has two minor electromagnets in alignment, ready for discharge. Simultaneously, rotor arm 87 is at the 253.33 degree position with two minor electromagnets aligned for capacitor discharge. The other steps of the sequence are apparent from Table 1, for each position of the three rotor arms at any step and the juxtapositions of respective stator and rotor electromagnet elements at that position.

In the simplified motor arrangement shown in schematic form in **Fig.18**, with single electromagnet configuration, the alignment is uniform and the discharge sequences follow sequentially.

As mentioned before, a change in speed is effected by displacing the stator spark gap terminals on the rotor (shown at **236** in **Fig.17** and **Fig.18**) either counterclockwise or clockwise 6.66 degrees so that the discharge position of the stator electromagnets is displaced. Referring to **Figs. 11 to 15**, the simultaneous discharge of selected capacitors into the displaced electromagnets results in a deceleration if the rotor electromagnet is approaching the stator electromagnet at the time of discharge, or an acceleration if the rotor electromagnet is leaving the stator electromagnet at the time of the discharge pulse. In each event, there is a repulsive reaction between the stator and rotor electromagnets which effects this change in speed.

Referring to **Fig.11**, clutch mechanism **304** about shaft **111** is operated electromagnetically in conventional manner, to displace the spark-gap mechanism **236** which is operated normally in appropriate matching alignment with the rotor spark-gap discs **291, 292** and **293**. Clutch **304** has a fixed drive element **311**, containing an electromagnetic drive coil (not shown) and a motor element **310** which, when the electromagnetic drive coil is energised, can be operated by a direct current. The operation of motor element 310, brings into operation, spark gap elements **224r, 223r** or **223f, 224f** of the system shown in **Figs. 4, 5 and 8,** as illustrated in **Fig.19**.

The fixed stator coil spark gap terminal pairs **223, 224** and **266, 267** are arrayed about a cylindrical frame **322** which is fabricated in insulative material. In the illustrative example of **Fig.17** and **Fig.18**, there are nine such spark gap terminal pairs positioned around the periphery of the cylinder frame **324**. In the engine of **Figs. 4 to 8**, a total of 27 such spark gap pairs are involved. In addition, although not shown in the drawing, there are also pairs of terminals, such as **223r or 223f**, **224r or 224f** and **226r or 226f**, **267r or 267f**, displaced 6.66 degrees on either side of the pairs **223, 224** or **266, 267** and all other pairs in the spark gap array, the letters “r” and “f” denoting “retard” or “faster”. The latter displaced pairs are used in controlling the speed of the engine rotor. The displaced pairs not shown are involved in the operation of the clutch **304**, the speed-changing control element.

Clutch **304** is associated with shaft **111** in that the movable element **310** draws clutch disc element **316** on shaft **111**, away from clutch disc element **322** when energised by a voltage of appropriate polarity applied to its motor electromagnet **311**. Such clutch drives are well known in the art.

The clutch mechanism **304** of **Fig.11** and **Fig.19**, when not energised, is in the configuration shown in **Fig.11**. The energised configuration of clutch **304** is not specifically illustrated. Upon energisation, spark-gap element **222** on disc **236** is displaced rightward, as viewed in **Fig.11**, by broken lines **236X**, into alignment with the positions of fixed spark-gap terminals **223f, 224f** and **267r, 266r**. When the disc is in position **236X**, the flattened edge **332** of pin **330** in disc **325** rides on surface **350** of disc **322**. Normally, the flattened edges **351** of pins **330** are engaged against the flat edge **352** in recess **331** of disc **322**. The displacement of disc **322** on shaft **111** is effected by the action of clutch **304** against spring **314** (Fig.11). An electric switch (not shown) of clutch mechanism **304** energises it from a d-c power source, and has two positions, one for deceleration and one for acceleration. In either position, clutch **304** is engaged to pull clutch disc **322** from clutch disc **325**, momentarily. For the decelerate or the accelerate position, the displaced alignment of spark gap elements **222** is with the **224f, 223f** and the **224r, 223r** spark-gap terminal elements. However, only the **224f, 223f** spark-gap elements are switched into operation with appropriate capacitors for the accelerate position, while in the decelerate position, only the **223r and 224r** spark-gap elements are switched into the circuit with their associated capacitors.

Of course, when insulative disc **236** is displaced by clutch **304**, its gap terminals **222, 225** and **228** (**Fig.14** and **Fig.18**) are all displaced into the alignment position of **236X** so as to engage the "r" and "f" lines of fixed spark gap elements. Although the accelerate and decelerate positions of disc **236** are the same, it is the switching into operation of the **223, 224** or **266, 267** exemplary "r" or "f" pairs of terminals which determines whether the rotor will speed up or slow down.

The momentary displacement of clutch disc **322** from clutch disc **325** results in rotation of disc **325** about disc **322** through an angle of 120 degrees. The detent ball and spring mechanism **320, 321** in disc **325**, positions itself between one detent dimple **328** and a succeeding one **328** at a position 120 degrees away on disc **325**.

As stated, flat **332** of pin **330** rides on surface **350** of disc **322**, and pin **330** leaves the pin-holding groove **331/352** along ramp **333** in disc **322** during the momentary lifting of disc **322** by clutch **304**. Pin **330** falls back into the next groove **331** at a point 120 degrees further on about disc **322**. Pin **330** falls into place in groove **331** on ramp **334**. Pins **330** are rotatable in their sockets **353**, so that for either clockwise or counterclockwise rotation, the flat **351** will engage the flat **352** by the particular ramp it encounters.

The deceleration or acceleration due to the action of clutch **304** thus occurs within a 120 degree interval of rotation of disc **325**. During this interval, disc **322** may only move a fraction of this arc.

There has been described earlier, an electromotive engine system wherein at least one electromagnet is in a fixed position and a second electromagnet of similar configuration is juxtaposed with it in a magnetic polarity relationship such that, when the cores of the electromagnets are energised, the juxtaposed core faces repel each other. One core being fixed, and the second core being free to move, any attachments to the second electromagnet core will move with it. Hence, if a plurality of fixed cores are positioned about a circular confining housing, and, within the housing, cores on a shaft are free to move, the shaft is urged rotationally each time the juxtaposed fixed and rotatable cores are in alignment and energised. Both the fixed and the movable cores are connected to spark gap terminal elements and the associated other terminal elements of the spark gaps are connected to capacitors which are charged to high voltage from pulsed unipolar signal generators. These capacitors are discharged through the electromagnets across the spark gaps. By switching selected groups of capacitors into selected pairs of spark gap elements for discharge through the electromagnets, the rotor of the circular array systems is accelerated and decelerated.

By confining a fixed electromagnet array in a linear configuration, with a linearly movable electromagnet to which a working tool is attached, exciting the juxtaposed pairs of electromagnets by capacitor discharge, results in the generation of linear force for such tools as punch presses, or for discharging projectiles with considerable energy.

CLAIMS:

1. An electric engine comprising:

A housing;

An array of electromagnets uniformly spaced in said housing to form a stator;

A rotor cage on a shaft journaled in and rotatable within said stator, said rotor cage having thereon a spaced array of electromagnets similar to said stator electromagnets and in number, comprising an integral fraction of the number of electromagnets in said stator array;

Each of the electromagnets of said stator and of said rotor, having a core which can be magnetised and of a particular configuration and each being wound with a coil such that a pulses of unidirectional electric current through said coil, magnetises the respective core thereof to a particular magnetic polarity, and the faces of rotor cores juxtaposing selected stator cores are magnetised to the same polarity, the juxtaposed cores thereby tending to repel one another, one lead of each of the stator and rotor coils being connected to a common terminal, the other lead of each of said coils being connected to a gap terminal, the gap terminals of said rotor coils being on the rotor and equal in number to the number of coils thereon and matching the positions of said rotor electromagnets thereon, the gap terminals of said stator being equal in number to the number of coils on the stator and disposed uniformly about said stator to match the positions of said stator electromagnets within said housing;

A first array of capacitors, each having a terminal in common with the common coil terminal of said stator electromagnets, and each capacitor having its other terminal connected to a gap terminal arrayed adjacent the gap terminal of an electromagnet associated therewith;

A second array of capacitors, each having a terminal in common with said common terminal of said rotor electromagnet coils but equal in number to the number of capacitors in said stator array, the other terminals of said capacitors in said second array being connected to gap terminals arrayed about said housing so as to be in axial alignment with said stator gap terminal positions and being alignable with said rotor gap terminals as said rotor is rotated in said housing and respective gap terminals of said rotor coils pass each second array capacitor gap terminals at a predetermined gap distance;

Gap coupling terminals on said rotor equal in number to the number of rotor electromagnet coils and positioned to match the rotor electromagnet positions on said rotor, the gap coupling terminals being rotatable with said rotor so as to pass said adjacent stator coil and associated stator capacitor gap terminal at a predetermined distance therefrom;

A plurality of capacitor charging circuits connected respectively across each of said capacitors in both said first and said second arrays of capacitors for charging each of said capacitors to a predetermined high d-c potential;

A first source of unidirectional electric potential connected to each of said capacitor charging circuits for energising said charging circuits; and

A second unidirectional electric potential source connected to said electromagnets of said rotor and said stator of such polarity as to receive a charge from the inverse inductive discharge of the electromagnet coils as their fields collapse following the discharge of each capacitor through a rotor or stator electromagnet coil,

Whereby, whenever a rotor electromagnet is aligned opposite a stator electromagnet, the rotor coil gap terminal of that electromagnet is opposite an associated second capacitor array gap terminal, and a gap coupling terminal of said rotor is aligned opposite the stator electromagnet coil gap terminal and associated first capacitor gap terminal, the capacitors discharge the charge thereon across the gaps through their associated electromagnet coils to magnetise their respective juxtaposed electromagnet cores to cause them to repel one another, thus aligning a succeeding pair of rotor and stator electromagnets for capacitor discharge across their respective gaps, to cause them to repel one another, alignments rotor rotation within the housing continuously bringing successive rotor-stator electromagnets into alignment for discharge of the capacitors through them to produce continuous rotary motion of the rotor on said rotor shaft, so long as energy is applied to said charging circuits to recharge said capacitors after each discharge.

2. In an electric engine having a rotor comprising electromagnetic coil means roatatable within a stator comprising similar electromagnetic coil means, said electromagnetic coil means being polarised for magnetic repulsion;

Capacitor means electrically coupled across successive spark gaps to selected ones of said stator and all of the coils of said rotor;

Charging means connected to said capacitor means for charging said capacitor means to an electrical charge potential sufficient to cause arcing across said spark gaps to result in the discharge of said capacitor means through the electromagnetic coil means repel one another; and

A unidirectional electric power source connected to said charging means to energise said charging means to continue charging said capacitor means following each discharge whereby the rotor of said engine is maintained

in rotation by the successive discharges of said capacitor means across successive spark gaps into said electromagnetic coil means.

3. An electric engine according to claim 2, wherein:

The charging means includes electronic square core oscillators connected to said unidirectional electric power source and includes step-up means and a rectifier to produce a substantial voltage step up from the voltage of said power source.

4. An electric engine according to claim 2, wherein:

The charging means includes a vibrator connected to said power source, and step-up transformer and rectifier means to provide a high voltage for charging said capacitor means.

5. A motive force-producing means comprising:

At least a first electromagnet means including at least one coil wound about a core,

At least a second electromagnet means including at least one coil wound about a core similar to said first core,

The respective cores being positioned adjacent to one another so that the magnetic polarities of the adjacent core surfaces are the same when a unidirectional electric current is passed through the coils,

At least one capacitor means having one terminal thereof connected to one terminal of both of said electromagnet coils,

The other terminal of said capacitor means being connected to one terminal of a spark gap means, the other terminals of the coils of both said first and said second electromagnet means being connected to the other terminal of said spark gap means,

At least one unidirectional pulse charging means connected to said capacitor means to charge said capacitor means to a relatively high potential sufficient to arc across said spark gap means at predetermined spacing of said gap terminals, and

A source of unidirectional potential connected to said charging circuit to energise said charging means,

Whereby upon application of current from said potential source to said charging means the successive pulses generated thereby charge said capacitor means to a voltage level sufficient to arc across said spark gap means to produce a discharge path for said capacitor means through said coils to cause said electromagnet means to repel one another with a substantial force.

6. A motive force-producing means according to claim 5, wherein:

Said first electromagnet means is secured in a relatively stable housing, and said second electromagnet means is connected with and freely movable relative to said stable housing, and has utilisation means connected thereto for performing work therewith when said capacitor means discharges through said coils of said electromagnet means.

7. A motive force-producing means according to claim 6, wherein said utilisation means is a motor rotor coupled with said second electromagnet means and said first electromagnet means is a stator.

8. A motive force-producing means according to claim 6, wherein said utilisation means is a piston attached to said second electromagnet means and is movable therewith to produce hammer-like blows when said capacitor means discharges through said electromagnet means.

9. In an electromotive force-generating system as disclosed, means for accelerating or decelerating the motion of a force-generating system, said means comprising:

At least two juxtaposed electromagnetic core elements, one fixed and one movable, including coils wound around it to provide a repulsion tendency when said cores are energised,

Spark gap terminals connected with said coils,

Capacitor means connected with said spark gap terminals to discharge across said spark gap terminals through said coils when a charge of sufficient voltage level appears across said capacitor means, thus to energise said juxtaposed electromagnets to induce said juxtaposed electromagnet cores to repel one another,

Charging means connected to said capacitors for charging them to said sufficient voltage level, and selective positioning means coupled with said spark gap terminals and with at least said movable electromagnet core to cause selective displacement of said movable core with respect to said fixed core.

10. An electromotive force-generating system according to claim 9, wherein:

Said juxtaposed electromagnetic cores include a plurality of fixed cores and a smaller number of movable cores, said smaller number being an integral fraction of the number of fixed cores, and

Said selective positioning means is an electromagnetic clutch coupled with said smaller number of movable cores for movement therewith, and includes selective displacement means coupled with said spark gap terminals connected with said capacitors in said capacitor means and selected combinations of coils in said plurality of fixed electromagnets.

11. The method of generating motive power comprising the steps of:

a. positioning similar electromagnets in juxtaposed relationship with their respective cores arranged for repulsion when said electromagnets are energised,

b. charging capacitors to a relatively high potential, and

c. discharging said capacitors simultaneously through said electromagnets across spark gaps set to break down at said relatively high potential, thereby to cause said similar electromagnets to repel one another with considerable force.

12. The method of generating motive power defined in claim 11, wherein, in said positioning step at least one of said electromagnets is maintained in a fixed position and another electromagnet is free to move relative to said fixed electromagnet.

13. The method of generating motive power according to claim 11, wherein:

The charging step includes the charging of capacitors to a relatively high potential from a pulsed unipolar source of electrical energy.

14. in an electromagnetic capacitor discharge engine including movable electromagnets and fixed electromagnets, said movable electromagnets being movable into polar alignment with said fixed electromagnets, capacitor means, means for charging said capacitor means, and means for discharging said charged capacitor means through said fixed and movable electromagnets to polarise aligned fixed and movable electromagnets for magnetic repulsion, an acceleration and deceleration control means comprising:

First selective means for momentarily delaying the discharge of the capacitors until the movable electromagnets in said engine have begun to recede from the fixed electromagnets, in order to accelerate the motion of said movable electromagnets by the added impetus of the repulsion, and

Second selective means for momentarily accelerating the discharge of the capacitors to occur at a point in the motion of the movable electromagnets where said movable electromagnets are approaching said fixed electromagnets to decelerate the motion of said movable electromagnets by the tendency to repel the approaching electromagnets by the fixed electromagnets.

15. An electric engine, comprising:

Fixed electromagnets;

Movable electromagnets, movable into alignment with said fixed electromagnets;

Capacitor means;

Means for charging said capacitor means, and

Means for discharging said charged capacitor means through said fixed and movable electromagnets to polarise said aligned fixed and movable electromagnets for magnetic repulsion.

16. An electric engine as recited in claim 15, wherein: said means for discharging said charged capacitor means comprises voltage breakdown switch means.

17. An electric engine as recited in claim 16, wherein:

Said voltage breakdown switch means includes at least one terminal movable with at least one of said movable electromagnets for breaking down when said at least one of said movable electromagnets is in alignment with a said fixed electromagnet.

18. An electric engine as recited in claim 17, wherein:

Said voltage breakdown switch means comprises a spark gap means.

EDWIN GRAY

US Patent 4,595,975 June 17, 1986 Inventor: Edwin V. Gray snr.

EFFICIENT POWER SUPPLY SUITABLE FOR INDUCTIVE LOADS

Please note that this is a re-worded excerpt from this patent. It describes the circuitry used with Edwin Gray's unique tube which picks up external power to drive his 80 horsepower electric motor.

Fig.1 is a schematic circuit diagram of the electrical driving system.
Fig.2 is an elevational sectional view of the electrical conversion element.
Fig.3 is a plan sectional view taken along line 3---3 of Fig.2.
Fig.4 is a plan sectional view taken along line 4---4 of Fig.2.
Fig.5 is a schematic circuit diagram of the alternating-current input circuit.

SUMMARY OF THE INVENTION

The present invention provides a more efficient driving system comprising a source of electrical voltage; a vibrator connected to the low-voltage source for forming a pulsating signal; a transformer connected to the vibrator for receiving the pulsating signal; a high-voltage source, where available, connected to a bridge-type rectifier; or the bridge-type rectifier connected to the high voltage pulse output of the transformer; a capacitor for receiving the voltage pulse output; a conversion element having first and second anodes, electrically conductive means for receiving a charge positioned about the second anode and an output terminal connected to the charge receiving means, the second anode being connected to the capacitor; a commutator connected to the source of electrical voltage and to the first anode; and an inductive load connected to the output terminal whereby a high energy discharge between the first and second anodes is transferred to the charge receiving means and then to the inductive load.

As a sub-combination, the present invention also includes a conversion element comprising a housing; a first low voltage anode mounted to the housing, the first anode adapted to be connected to a voltage source; a second high voltage anode mounted to the housing, the second anode adapted to be connected to a voltage source; electrically conductive means positioned about the second anode and spaced therefrom for receiving a charge, the charge receiving means being mounted to the housing; and an output terminal communicating with the charge receiving means, said terminal adapted to be connected to an inductive load.

The invention also includes a method for providing power to an inductive load comprising the steps of providing a voltage source, pulsating a signal from said source; increasing the voltage of said signal; rectifying said signal; storing and increasing the signal; conducting said signal to a high voltage anode; providing a low voltage to a second anode to form a high energy discharge; electrostatically coupling the discharge to a charge receiving element; conducting the discharge to an inductive load; coupling a second capacitor to the load; and coupling the second capacitor to the source.

It is an aim of the present invention to provide a system for driving an inductive load which system is substantially more efficient than any now existing. Another object of the present invention is to provide a system for driving an inductive load which is reliable, is inexpensive and simply constructed.

The foregoing objects of the present invention together with various other objects, advantages, features and results thereof which will be evident to those skilled in the art in light of this disclosure may be achieved with the exemplary embodiment of the invention described in detail hereinafter and illustrated in the accompanying drawings.

DESCRIPTION OF THE PREFERRED EMBODIMENT

While the present invention is susceptible of various modifications and alternative constructions, an embodiment is shown in the drawings and will herein be described in detail. It should be understood however that it is not the intention to limit the invention to the particular form disclosed; but on the contrary, the invention is to cover all modifications, equivalents and alternative constructions falling within the spirit and scope of the invention as expressed in the appended claims.

There is disclosed herein an electrical driving system which, on theory, will convert low voltage electric energy from a source such as an electric storage battery to a high potential, high current energy pulse that is capable of developing a working force at the inductive output of the device that is more efficient than that which is capable of being developed directly from the energy source. The improvement in efficiency is further enhanced by the capability of the device to return that portion of the initial energy developed, and not used by the inductive load in the production of mechanical energy, to the same or second energy reservoir or source for use elsewhere, or for storage.

This system accomplishes the results stated above by harnessing the “electrostatic” or “impulse” energy created by a high-intensity spark generated within a specially constructed electrical conversion switching element tube. This element utilises a low-voltage anode, a high-voltage anode, and one or more “electrostatic” or charge receiving grids. These grids are of a physical size, and appropriately positioned, as to be compatible with the size of the tube, and therefore, directly related to the amount of energy to be anticipated when the device is operating.

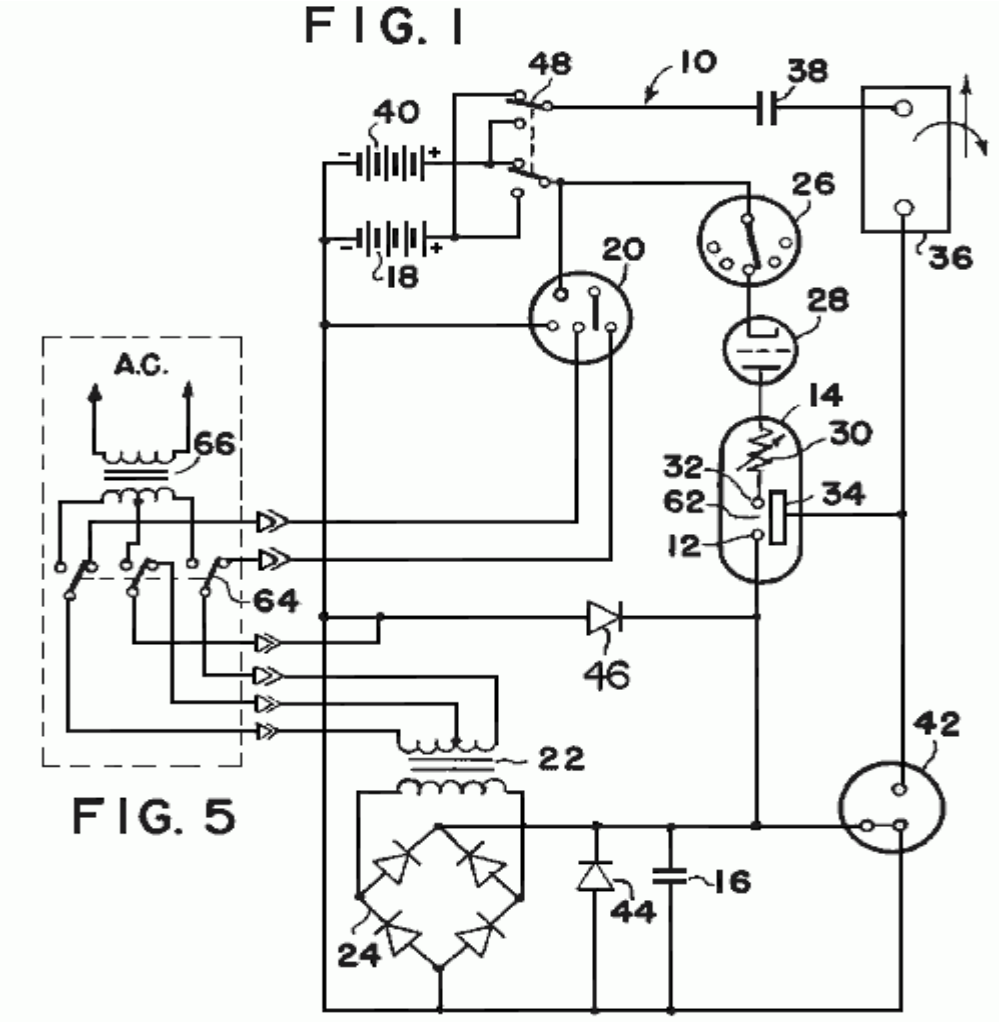
The low-voltage anode may incorporate a resistive device to aid in controlling the amount of current drawn from the energy source. This low-voltage anode is connected to the energy source through a mechanical commutator or a solid-state pulser that controls the timing and duration of the energy spark within the element. The high-voltage anode is connected to a high- voltage potential developed by the associated circuits. An energy discharge occurs within the element when the external control circuits permit. This short duration, high-voltage, high-current energy pulse is captured by the “electrostatic” grids within the tube, stored momentarily, then transferred to the inductive output load.

The increase in efficiency anticipated in converting the electrical energy to mechanical energy within the inductive load is attributed to the utilisation of the most optimum timing in introducing the electrical energy to the load device, for the optimum period of time.

Further enhancement of energy conservation is accomplished by capturing a significant portion of the energy generated by the inductive load when the useful energy field is collapsing. This energy is normally dissipated in load losses that are contrary to the desired energy utilisation, and have heretofore been accepted because no suitable means had been developed to harness this energy and restore it to a suitable energy storage device.

The present invention is concerned with two concepts or characteristics. The first of these characteristics is observed with the introduction of an energising cur- rent through the inductor. The inductor creates a contrary force (counter-electromotive force or CEMP) that opposes the energy introduced into the inductor. This CEMF increases throughout the time the introduced energy is increasing.

In normal applications of an alternating-current to an inductive load for mechanical applications, the useful work of the inductor is accomplished prior to terminating the application of energy. The excess energy applied is thereby wasted.



Previous attempts to provide energy inputs to an inductor of time durations limited to that period when the optimum transfer of inductive energy to mechanical energy is occurring, have been limited by the ability of any such device to handle the high current required to optimise the energy transfer.

The second characteristic is observed when the energising current is removed from the inductor, As the current is decreased, the inductor generates an EMF that opposes the removal of current or, in other words, produces an energy source at the output of the inductor that simulates the original energy source, reduced by the actual energy removed from the circuit by the mechanical load. This “regenerated”, or excess, energy has previously been lost due to a failure to provide a storage capability for this energy.

In this invention, a high-voltage, high-current, short duration energy pulse is applied to the inductive load by the conversion element. This element makes possible the use of certain of that energy impressed within an arc across a spark-gap, without the resultant deterioration of circuit elements normally associated with high energy electrical arcs.

This invention also provides for capture of a certain portion of the energy induced by the high inductive kick produced by the abrupt withdrawal of the introduced current. This abrupt withdrawal of current is attendant upon the termination of the stimulating arc. The voltage spike so created is imposed upon a capacitor that couples the attendant current to a secondary energy storage device.

A novel, but not essential, circuit arrangement provides for switching the energy source and the energy storage device. This switching may be so arranged as to actuate automatically at predetermined times. The switching may be at specified periods determined by experimentation with a particular device, or may be actuated by some control device that measures the relative energy content of the two energy reservoirs.

Referring now to **Fig.1**, the system **10** will be described in additional detail. The potential for the high- voltage anode, **12** of the conversion element **14** is developed across the capacitor **16**. This voltage is produced by drawing a low current from a battery source **18** through the vibrator **20**. The effect of the vibrator is to create a pulsating input to the transformer **22**. The turns ratio of the transformer is chosen to optimise the volt- age applied to a bridge-type rectifier **24**. The output of the rectifier is then a series of high-voltage pulses of modest current. When the available source is already of the high voltage, AC type, it may be coupled directly to the bridge-type rectifier.

By repetitious application of these output pulses from the bridge-type rectifier to the capacitor **16**, a high-voltage, high-level charge is built up on the capacitor.

Control of the conversion switching element tube is maintained by a commutator **26**. A series of contacts mounted radially about a shafts or a solid-state switching device sensitive to time or other variable may be used for this control element. A switching element tube type one-way energy path **28** is introduced between the commutator device and the conversion switching element tube to prevent high energy arcing at the commutator current path. When the switching element tube is closed, current from the voltage source **18** is routed through a resistive element **30** and a low voltage anode **32**. This causes a high energy discharge between the anodes within the conversion switching element tube **14**.

The energy content of the high energy pulse is eletrostatically coupled to the conversion grids **34** of the conversion element. This electrostatic charge is applied through an output terminal **60** (**Fig.2**) across the load inductance **36**, inducing a strong electromagnetic field about the inductive load. The intensity of this electromagnetic field is determined by the high electromotive potential developed upon the electrostatic grids and the very short time duration required to develop the energy pulse.

If the inductive load is coupled magnetically to a mechanical load, a strong initial torque is developed that may be efficiently utilised to produce physical work

Upon cessation of the energy pulse (arc) within the conversion switching element tube the inductive load is decoupled, allowing the electromagnetic field about the inductive load to collapse. The collapse of this energy field induces within the inductive load a counter EMF. This counter EMF creates a high positive potential across a second capacitor which, in turn, is induced into the second energy storage device or battery **40** as a charging current. The amount of charging current available to the battery 40 is dependent upon the initial conditions within the circuit at the time of discharge within the conversion switching element tube and the amount of mechanical energy consumed by the workload.

A spark-gap protection device **42** is included in the circuit to protect the inductive load and the rectifier elements from unduly large discharge currents. Should the potentials within the circuit exceed predetermined values, fixed by the mechanical size and spacing of the elements within the protective device, the excess energy is dissipated (bypassed) by the protective device to the circuit common (electrical ground).

Diodes **44** and **46** bypass the excess overshoot generated when the “Energy Conversion Switching Element Tube” is triggered. A switching element U allows either energy storage source to be used as the primary energy source, while the other battery is used as the energy retrieval unit. The switch facilitates interchanging the source and the retrieval unit at optimum intervals to be determined by the utilisation of the conversion switching element tube. This switching may be accomplished manually or automatically, as determined by the choice of switching element from among a large variety readily available for the purpose.

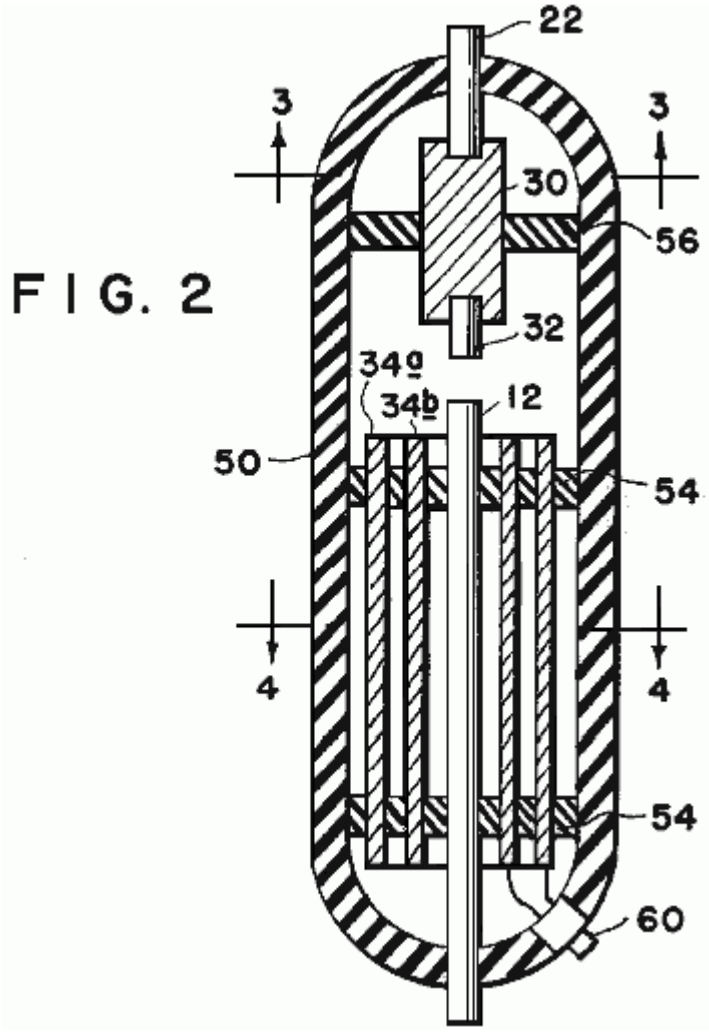


FIG. 2

FIG. 3

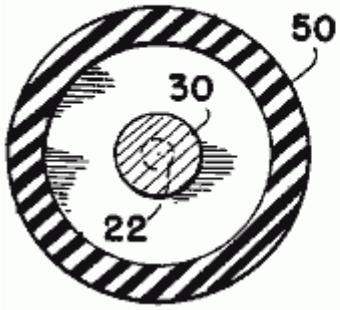

FIG. 4

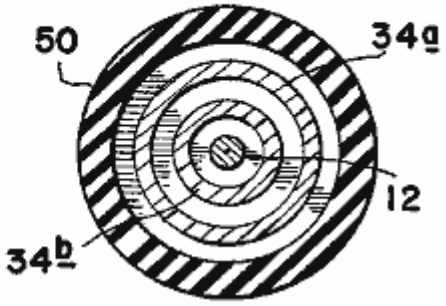

Fig.2, Fig.3, and **Fig.4** show the mechanical structure of the conversion switching element tube **14**. An outer housing **50** may be of any insulative material such as glass. The anodes **12** and **22** and grids **34a** and **34b** are firmly secured by nonconductive spacer material **54**, and **56**. The resistive element **30** may be introduced into the low-voltage anode path to control the peak currents through the conversion switching element tube. The resistive element may be of a piece, or it may be built of one or more resistive elements to achieve the desired result.

The anode material may be identical for each anode, or may be of differing materials for each anode, as dictated by the most efficient utilisation of the device, as determined by appropriate research at the time of production for the intended use. The shape and spacing of the electrostatic grids is also susceptible to variation with application (voltage, current, and energy requirements).

It is the contention of the inventor that by judicious mating of the elements of the conversion switching element tube, and the proper selection of the components of the circuit elements of the system, the desired theoretical results may be achieved. It is the inventor's contention that this mating and selection process is well within the capabilities of intensive research and development technique.

Let it be stated here that substituting a source of electric alternating-current subject to the required cur- rent and/or voltage shaping and/or timing, either prior to being considered a primary energy source, or there- after, should not be construed to change the described utilisation or application of primary energy in any way. Such energy conversion is readily achieved by any of a multitude of well established principles. The preferred embodiment of this invention merely assumes optimum utilisation and optimum benefit from this invention when used with portable energy devices similar in principle to the wet-cell or dry-cell battery.

This invention proposes to utilise the energy contained in an internally generated high-voltage electric spike (energy pulse) to electrically energise an inductive load.: this inductive load being then capable of converting the energy so supplied into a useful electrical or mechanical output.

In operation the high-voltage, short-duration electric spike is generated by discharging the capacitor **16** across the spark-gap in the conversion switching element tube. The necessary high-voltage potential is stored on the capacitor in incremental, additive steps from the bridge-type rectifier **24**. When the energy source is a direct-current electric energy storage device, such as the battery **12**, the input to the bridge rectifier is provided by the voltage step-up transformer **22**, that is in turn energised from the vibrator **20**, or solid-state chopper, or similar device to properly drive the transformer and rectifier circuits.

When the energy source is an alternating-current, switches **64** disconnect transformer **22** and the input to the bridge-type rectifier **24** is provided by the voltage step-up transformer **66**, that is in turn energised from the vibrator **20**, or solid-state chopper, or similar device to properly drive the transformer and rectifier circuits.

The repetitions output of the bridge rectifier incrementally increases the capacitor charge toward its maximum. This charge is electrically connected directly to the high-voltage anode **12** of the conversion switching element tube. When the low-voltage anode **32** is connected to a source of current, an arc is created in the spark-gap designated **62** of the conversion switching element tube equivalent to the potential stored on the high-voltage anode, and the current available from the low-voltage anode.

Because the duration of the arc is very short, the instantaneous voltage, and instantaneous current may both be very high. The instantaneous peak apparent power is therefore, also very high. Within the conversion switching element tube, this energy is absorbed by the grids **34a** and **34b** mounted circumferentially about the interior of the tube.

Control of the energy spike within the conversion switching element tube is accomplished by a mechanical, or

solid-state commutator, that closes the circuit path from the low-voltage anode to the current source at that moment when the delivery of energy to the output load is most auspicious. Any number of standard high-accuracy, variable setting devices are available for this purpose. When control of the repetitive rate of the system's output is required, it is accomplished by controlling the time of connection at the low-voltage anode.

Thus there can be provided an electrical driving system having a low-voltage source coupled to a vibrator, a transformer and a bridge-type rectifier to provide a high voltage pulsating signal to a first capacitor. Where a high-voltage source is otherwise available, it may be coupled direct to a bridge-type rectifier, causing a pulsating signal to a first capacitor. The capacitor in turn is coupled to a high-voltage anode of an electrical conversion switching element tube. The element also includes a low-voltage anode which in turn is connected to a voltage source by a commutator, a switching element tube, and a variable resistor. Mounted around the high-voltage anode is a charge receiving plate which in turn is coupled to an inductive load to transmit a high-voltage discharge from the element to the load. Also coupled to the load is a second capacitor for storing the back EMF created by the collapsing electrical field of the load when the current to the load is blocked. The second capacitor in turn is coupled to the voltage source.

ELECTRICAL MOTOR / GENERATOR

This version of the patent has been re-worded in an attempt to make it easier to read and understand. It describes the design of a pulsed electromagnet / permanent magnet motor which is capable of a higher power output than it's own power input.

ABSTRACT

An electrodynamic motor-generator has a salient pole permanent magnet rotor interacting with salient stator poles to form a machine operating on the magnetic reluctance principle. The intrinsic ferromagnetic power of the magnets provides the drive torque by bringing the poles into register whilst current pulses demagnetise the stator poles as the poles separate. In as much as less power is needed for stator demagnetisation than is fed into the reluctance drive by the thermodynamic system powering the ferromagnetic state, the machine operates regeneratively by virtue of stator winding interconnection with unequal number of rotor and stator poles. A rotor construction is disclosed (**Fig.6** and **Fig.7**). The current pulse may be such as to cause repulsion of the rotor poles.

FIELD OF THE INVENTION

This invention relates to a form of electric motor which serves a generating function in that the machine can act regeneratively to develop output electrical power or can generate mechanical drive torque with unusually high efficiency in relation to electrical power input.

The field of invention is that of switched reluctance motors, meaning machines which have salient poles and operate by virtue of the mutual magnetic attraction and/or repulsion as between magnetised poles.

The invention particularly concerns a form of reluctance motor which incorporates permanent magnets to establish magnetic polarisation.

BACKGROUND OF THE INVENTION

There have been proposals in the past for machines in which the relative motion of magnets can in some way develop unusually strong force actions which are said to result in more power output than is supplied as electrical input.

By orthodox electrical engineering principles such suggestions have seemed to contradict accepted principles of physics, but it is becoming increasingly evident that conformity with the first law of thermodynamics allows a gain in the electromechanical power balance provided it is matched by a thermal cooling.

In this sense, one needs to extend the physical background of the cooling medium to include, not just the machine structure and the immediate ambient environment, but also the sub-quantum level of what is termed, in modern physics, the zero-point field. This is the field activity of the vacuum medium which exists in the space between atomic nuclei and atomic electrons and is the seat of the action which is that associated with the Planck constant. Energy is constantly being exchanged as between that activity and coextensive matter forms but normally these energy fluctuations preserve, on balance, an equilibrium condition so that this action passes unnoticed at the technology level.

Physicists are becoming more and more aware of the fact that, as with gravitation, so magnetism is a route by which we can gain access to the sea of energy that pervades the vacuum. Historically, the energy balance has been written in mathematical terms by assigning 'negative' potential to gravitation or magnetism. However, this is only a disguised way of saying that the vacuum field, suitably influenced by the gravitating mass of a body in the locality or by magnetism in a ferromagnet has both the capacity and an urge to shed energy.

Now, however, there is growing awareness of the technological energy generating potential of this field background and interest is developing in techniques for 'pumping' the coupling between matter and vacuum field to derive power from that hidden energy source. Such research may establish that this action will draw on the

2.7K cosmic background temperature of the space medium through which the Earth travels at some 400 km/s. The effect contemplated could well leave a cool 'vapour trail' in space as a machine delivering heat, or delivering a more useful electrical form of energy that will revert to heat, travels with body Earth through that space.

In pure physics terms, relevant background is of recent record in the August 1993 issue of Physical Review E, vol. 48, pp. 1562-1565 under the title: 'Extracting energy and heat from the vacuum', authored by D. C. Cole and H. E. Puthoff. Though the connection is not referenced in that paper, one of its author's presented experimental evidence on that theme at an April 1993 conference held in Denver USA. The plasma power generating device discussed at that conference was the subject of U. S. Patent No. 5,018,180, the inventor of record being K. R. Shoulders.

The invention, to be described below, operates by extracting energy from a magnetic system in a motor and the relevant scientific background to this technology can be appreciated from the teachings of E. B. Moullin, a Cambridge Professor of Electrical Engineering who was a President of the Institution of Electrical Engineers in U. K. That prior art will be described below as part of the explanation of the operation of the invention.

The invention presented here concerns specific structural design features of a machine adapted for robust operation, but these also have novelty and special merit in a functional operation. What is described is quite distinct from prior art proposals, one being a novel kind of motor proposed by Gareth Jones at a 1988 symposium held in Hull, Canada under the auspices of the Planetary Association for Clean Energy. Jones suggested the adaptation of an automobile alternator which generates three-phase AC for rectification and use as a power supply for the electrics in the automobile. This alternator has a permanent magnet rotor and Jones suggested that it could be used, with high efficiency gain and torque performance, by operating it as a motor with the three-phase winding circuit excited so as to promote strong repulsion between the magnet poles and the stator poles after the poles had come into register.

However, the Jones machine is not one exploiting the advantages of the invention to be described, because it is not strictly a reluctance motor having salient poles on both stator and rotor. The stator poles in the Jones machine are formed by the winding configuration in a slotted stator form, the many slots being uniformly distributed around the inner circumference of the stator and not constituting a pole system which lends itself to the magnetic flux actions to be described by reference to the E. B. Moullin experiment.

The Jones machine operates by generating a rotating stator field which, in a sense, pushes the rotor poles forward rather than pulling them in the manner seen in the normal synchronous motor. Accordingly, the Jones machine relies on the electric current excitation of the motor producing a field system which rotates smoothly but has a polarity pattern which is forced by the commutation control to keep behind the rotor poles in asserting a continuous repulsive drive.

Another prior art proposal which is distinguished from this invention is that of one of the applicants, H. Aspden, namely the subject of U.K. Patent No. 2,234,863 (counterpart U.S. Patent Serial No.4,975,608). Although this latter invention is concerned with extracting energy from the field by the same physical process as the subject invention, the technique for accessing that energy is not optimum in respect of the structure or method used. Whereas in this earlier disclosure, the switching of the reluctance drive excited the poles in their approach phase, the subject invention, in one of its aspects, offers distinct advantages by demagnetisation or reversal of magnetisation in the pole separation phase of operation.

There are unexpected advantages in the implementation proposed by the subject invention, inasmuch as recent research has confirmed that it requires less input power to switch off the mutual attraction across an air gap between a magnet and an electromagnet than it does to switch it on. Usually, in electromagnetism, a reversal symmetry is expected, arising from conventional teaching of the way forward and back magnetomotive forces govern the resulting flux in a magnetic circuit.

This will be further explained after describing the scope of the invention.

BRIEF DESCRIPTION OF THE INVENTION

According to one aspect of the invention, an electrodynamic motor/generator machine comprises a stator configured to provide a set of stator poles, a corresponding set of magnetising windings mounted on the stator pole set, a rotor having two sections each of which has a set of salient pole pieces, the rotor sections being axially spaced along the axis of rotation of the rotor, rotor magnetisation means disposed between the two rotor sections arranged to produce a unidirectional magnetic field which magnetically polarises the rotor poles, whereby the pole faces of one rotor section all have a north polarity and the pole faces of the other rotor section all have a south polarity and electric circuit connections between an electric current source and the stator magnetising windings arranged to regulate the operation of the machine by admitting current pulses for a duration determined according

to the angular position of the rotor, which pulses have a direction tending to oppose the polarisation induced in the stator by the rotor polarisation as stator and rotor poles separate from an in-register position, whereby the action of the rotor magnetisation means provides a reluctance motor drive force to bring stator and rotor poles into register and the action of the stator magnetisation windings opposes the counterpart reluctance braking effect as the poles separate.

According to a feature of the invention, the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide demagnetisation of the stator poles as the stator and rotor poles separate from an in-register position.

In this regard it is noted that in order to suppress the reluctance drive torque or brake torque, depending upon whether poles are converging or separating, a certain amount of electrical power must be fed to the magnetising windings on the stator. In a sense these windings are really 'demagnetising windings' because the polarity of the circuit connections admit the pulse current in the demagnetising direction.

However, it is more usual to refer to windings on magnetic cores as 'magnetising windings' even though they can function as primary windings or secondary windings, the former serving the magnetisation function with input power and the latter serving a demagnetising function with return of power.

According to another feature of the invention, the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide a reversal of magnetic flux direction in the stator poles as the stator and rotor poles separate from an in-register position, whereby to draw on power supplied from the electric current source to provide additional forward drive torque.

According to a further feature of the invention, the electric current source connected to a stator magnetising winding of a first stator pole comprises, at least partially, the electrical pulses induced in the stator magnetising winding of a different second stator pole, the stator pole set configuration in relation to the rotor pole set configuration being such that the first stator pole is coming into register with a rotor pole as the second stator pole separates from its in-register position with a rotor pole.

This means that the magnetising windings of two stator poles are connected so that both serve a 'demagnetising' function, one in resisting the magnetic action of the mutual attraction in pulling poles into register, an action which develops a current pulse output and one in absorbing this current pulse, again by resisting the magnetic inter-pole action to demagnetise the stator pole as its associated rotor pole separates.

In order to facilitate the function governed by this circuit connection between stator magnetising windings, a phase difference is needed and this is introduced by designing the machine to have a different number of poles in a set of stator poles from the number of rotor poles in each rotor section. Together with the dual rotor section feature, this has the additional merit of assuring a smoother torque action and reducing magnetic flux fluctuations and leakage effects which contribute substantially to machine efficiency.

Thus, according to another feature of the invention, the stator configuration provides pole pieces which are common to both rotor sections in the sense that when stator and rotor poles are in-register the stator pole pieces constitute bridging members for magnetic flux closure in a magnetic circuit including that of the rotor magnetisation means disposed between the two rotor sections.

Preferably, the number of poles in a set of stator poles and the number of rotor poles in each section do not share a common integer factor, the number of rotor poles in one rotor section is the same as that in the other rotor section and the number of poles in a stator set and the number of poles in a rotor section differs by one, with the pole faces being of sufficient angular width to assure that the magnetic flux produced by the rotor magnetisation means can find a circular magnetic flux closure route through the bridging path of a stator pole and through corresponding rotor poles for any angular position of the rotor.

It is also preferable from a design viewpoint for the stator pole faces of this invention to have an angular width that is no greater than half the angular width of a rotor pole and for the rotor sections to comprise circular steel laminations in which the rotor poles are formed as large teeth at the perimeter with the rotor magnetisation means comprising a magnetic core structure the end faces of which abut two assemblies of such laminations forming the two rotor sections.

According to a further feature of the invention, the rotor magnetisation means comprises at least one permanent magnet located with its polarisation axis parallel with the rotor axis. The motor-generator may include an apertured metal disc that is of a non-magnetisable substance mounted on a rotor shaft and positioned intermediate the two rotor sections, each aperture providing location for a permanent magnet, whereby the centrifugal forces acting on the permanent magnet as the rotor rotates are absorbed by the stresses set up in the

disc. Also, the rotor may be mounted on a shaft that is of a non-magnetisable substance, whereby to minimise magnetic leakage from the rotor magnetising means through that shaft.

According to another aspect of the invention, an electrodynamic motor-generator machine comprises a stator configured to provide a set of stator poles, a corresponding set of magnetising windings mounted on the stator pole set, a rotor having two sections each of which has a set of salient pole pieces, the rotor sections being axially spaced along the axis of rotation of the rotor, rotor magnetisation means incorporated in the rotor structure and arranged to polarise the rotor poles, whereby the pole faces of one rotor section all have a north polarity and the pole faces of the other rotor section all have a south polarity and electric circuit connections between an electric current source and the stator magnetising windings arranged to regulate the operation of the machine by admitting current pulses for a duration determined according to the angular position of the rotor, which pulses have a direction tending to oppose the polarisation induced in the stator by the rotor polarisation as stator and rotor poles separate from an in-register position, whereby the action of the rotor magnetisation means provides a reluctance motor drive force to bring stator and rotor poles into register and the action of the stator magnetisation windings opposes the counterpart reluctance braking effect as the poles separate.

According to a feature of this latter aspect of the invention, the electric current source connected to a stator magnetising winding of a first stator pole comprises, at least partially, the electrical pulses induced in the stator magnetising winding of a different second stator pole, the stator pole set configuration in relation to the rotor pole set configuration being such that the first stator pole is coming into register with a rotor pole as the second stator pole separates from its in-register position with a rotor pole.

BRIEF DESCRIPTION OF THE DRAWINGS

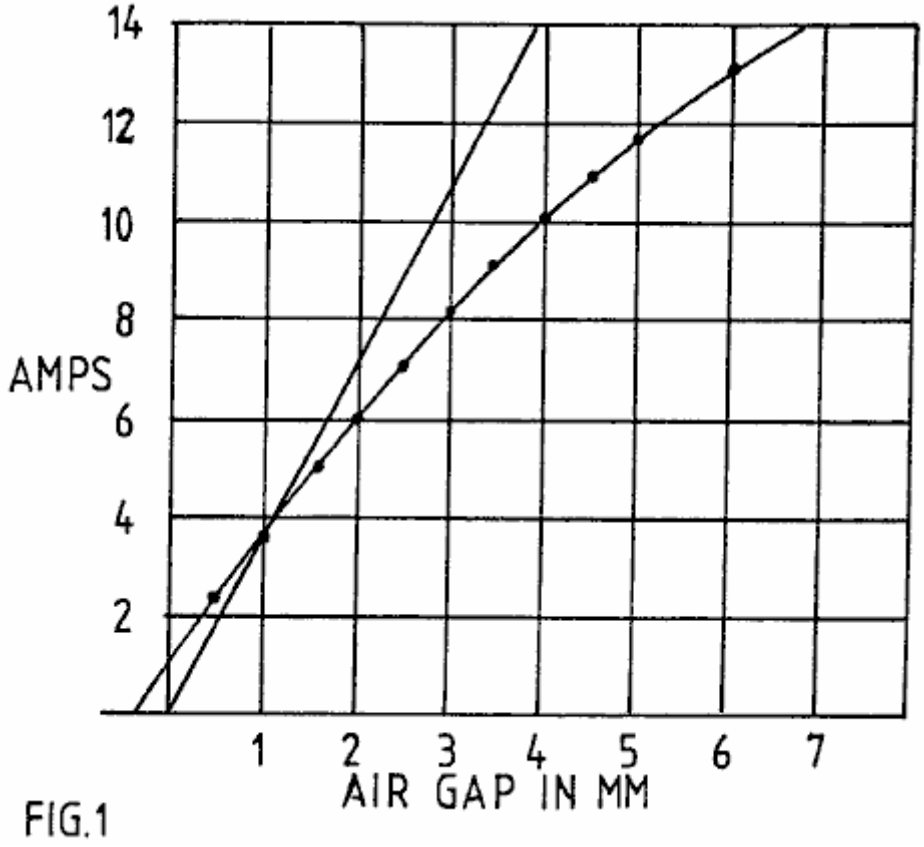

FIG.1

Fig.1 presents magnetic core test data showing how the volt-amp reactance power required to set up a constant magnetic flux action in an air gap, as assured by constant AC voltage excitation of a magnetising winding, falls short of the associated power of the potential implicit in the force action across that air gap.

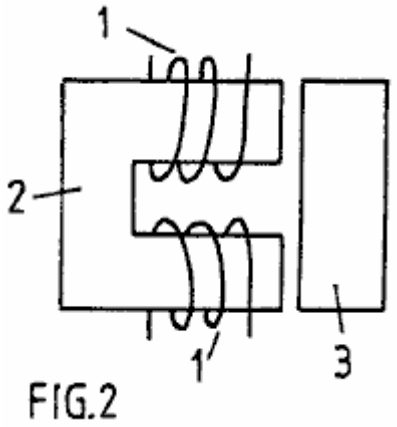

FIG.2

Fig.2 depicts the test structure to which Fig. 1 data applies.

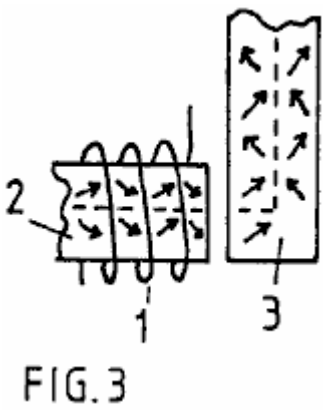

FIG.3

Fig.3 depicts the magnetisation action at work in causing magnetic flux to traverse an air-gap and turn a corner in a circuit through a magnetic core.

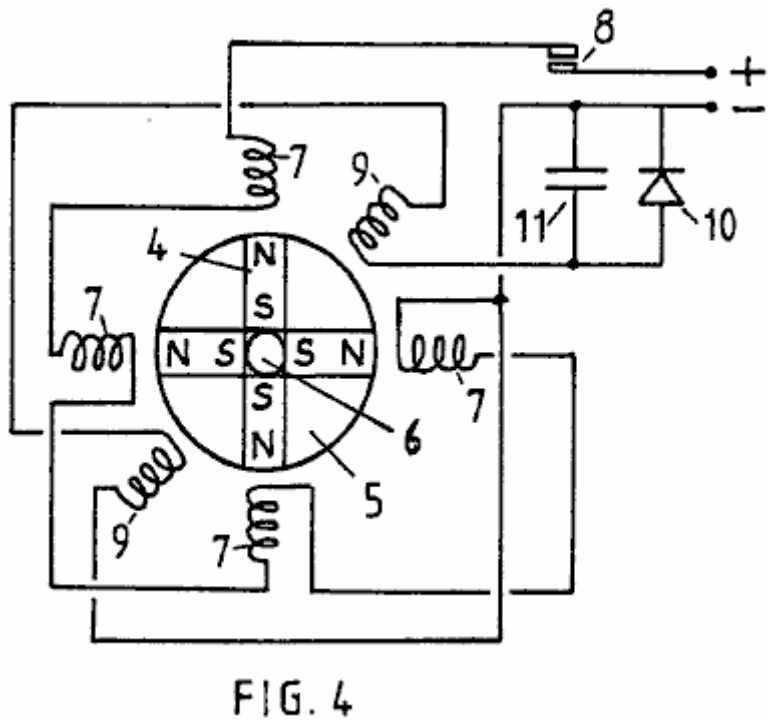

FIG. 4

Fig.4 shows the configuration of a test device used to prove the operating principles of the invention described.

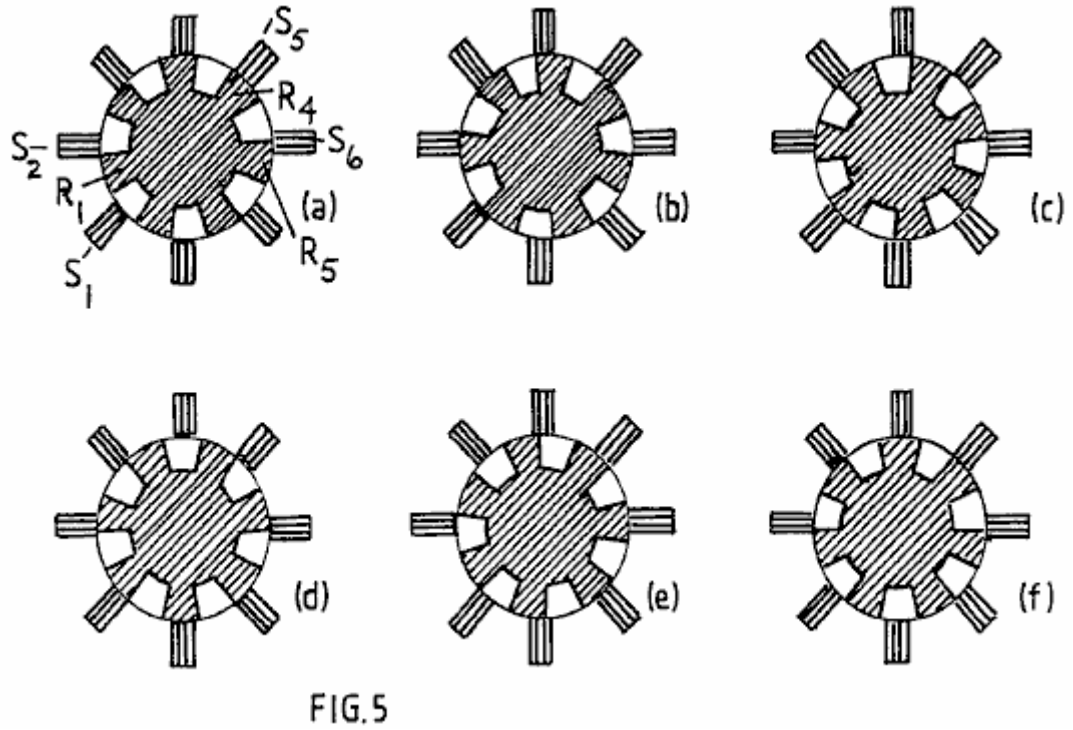

FIG.5

Fig.5 in its several illustrations depicts the progressive rotor pole to stator pole relationship as a rotor turns through a range of angular positions in a preferred embodiment of a machine according to the invention.

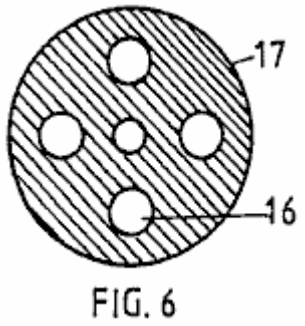

FIG. 6

Fig.6 shows the form of a disc member which provides location for four permanent magnets in the machine described.

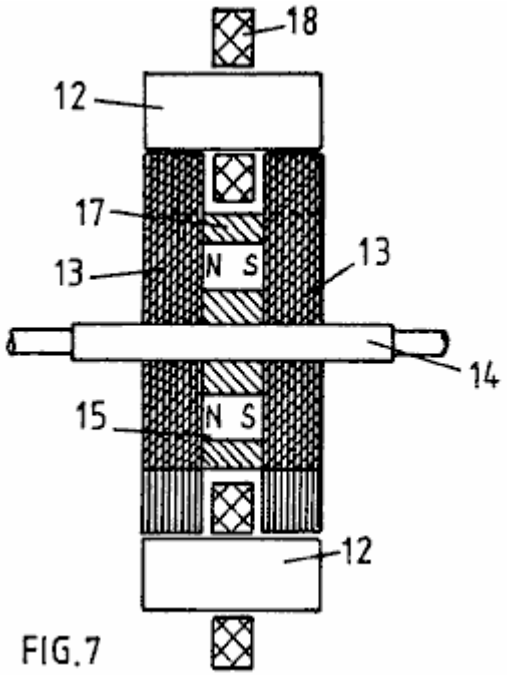

FIG.7

Fig.7 shows a cross-section of the magnetic circuit structure of a machine embodying the invention.

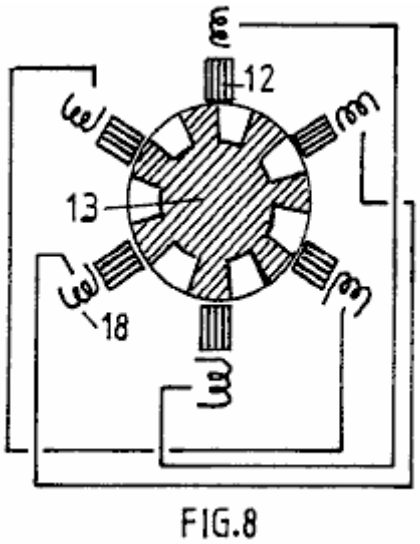

FIG.8

Fig.8 shows a six stator pole configuration with a seven pole rotor and depicts a schematic series connected linking of the magnetising windings of diametrically opposite stator poles.

DETAILED DESCRIPTION OF THE INVENTION

The fact that one can extract energy from the source which powers the intrinsic ferromagnetic state is not explicitly evident from existing textbooks, but it is implicit and, indeed, does become explicit once pointed out, in one textbook authored by E. B. Moullin. His book 'The Principles of Electromagnetism' published by Clarendon Press, Oxford (3rd Edition, 1955) describes on pages 168-174 an experiment concerned with the effect of air gaps between poles in a magnetic circuit. The data obtained are reproduced in **Fig.1**, where Professor Moullin shows a curve representing AC current input for different air gaps, given that the voltage supplied is constant. In the same figure, Moullin presents the theoretical current that would need to be applied to sustain the same voltage, and so the related pole forces across the air gap, assuming (a) no flux leakage and (b) that there is complete equality between inductive energy input and the mechanical energy potential for the magnetisation that is established in the air gap in a quarter-cycle period at the AC power excitation frequency.

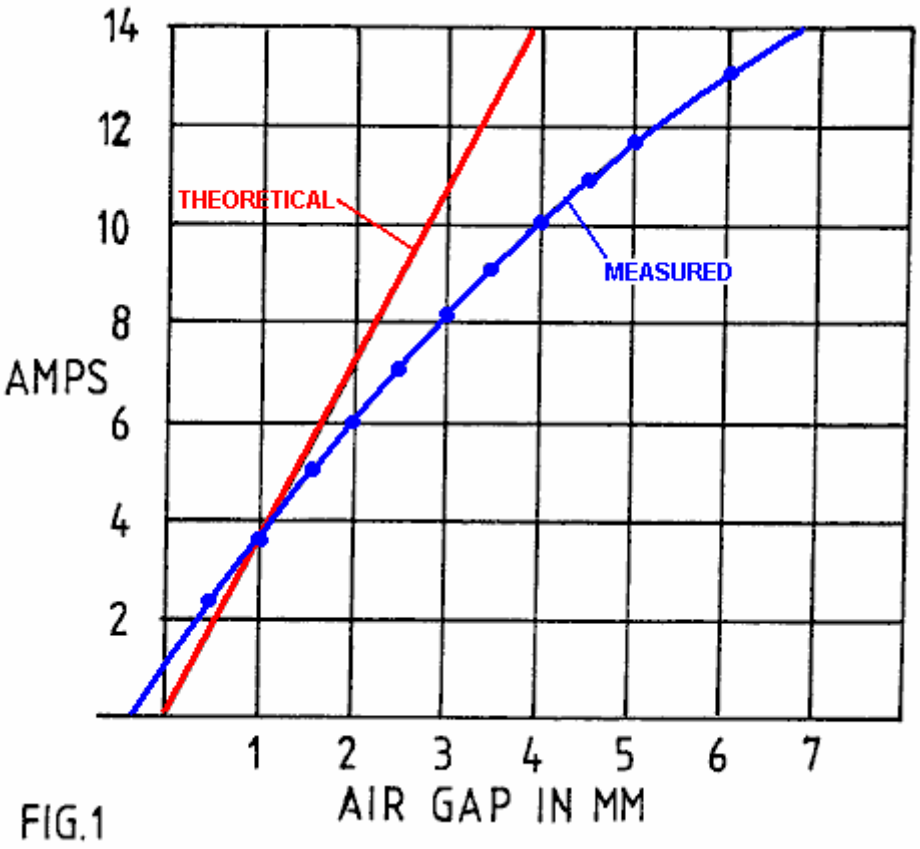

FIG.1

The data show that, even though the level of magnetic polarisation is well below the saturation value, being confined to a range that is regarded as the linear permeability range in transformer design, there is a clear drop-off of current, and so the volt-amp reactive power input needed, as current increases, compared with that predicted by the mechanical potential built up in the air gaps. Unless leakage flux is excessive, here was clear evidence of anomalous energy activity.

Moullin discusses the leakage flux inferred by this experiment but points out that there is considerable mystery in why the effect of a small gap, which should certainly not result in much flux leakage in the gap region, nevertheless has an enormous effect in causing what has to be substantial leakage in the light of the energy discrepancy. Moullin did not contemplate that energy had been fed in from the zero-point field system and so he left the issue with the statement that it was virtually impossible to predict leakage flux by calculation.

He was, of course, aware of magnetic domain structure and his argument was that the leakage flux problem was connected with what he termed a 'yawing' action of the flux as it passes around the magnetic circuit. Normally, provided the level of polarisation is below the knee of the B-H curve, which occurs at about 70% of saturation in iron cores of general crystal composition, it requires very little magnetising field to change the magnetic flux density. This is assuming that every effort is made to avoid air gaps. The action involves domain wall movements so that the magnetic states of adjacent domains switch to different crystal axes of easy magnetisation and this involves very little energy change.

However, if there is an air gap ahead in the flux circuit and the magnetising winding is not sitting on that air gap, the iron core itself has to be the seat of a progressive field source linking the winding and the gap. It can only serve in that sense by virtue of the lines of flux in the domains being forced to rotate somewhat from the preferred easy axes of magnetisation, with the help of the boundary surfaces around the whole core. This action means that, forcibly, and consequential upon the existence of the air gap, the flux must be carried through the core by

that 'yawing' action. It means that substantial energy is needed to force the establishment of those fields within the iron core. More important, however, from the point of view of this invention, it means that the intrinsic magnetic polarisation effects in adjacent magnetic domains in the iron cease to be mutually parallel or orthogonal so as to stay directed along axes of easy magnetisation. Then, in effect, the magnetising action is not just that of the magnetising winding wrapped around the core but becomes also that of adjacent ferromagnetic polarisation as the latter act in concert as vacuum-energy powered solenoids and are deflected into one another to develop the additional forward magnetomotive forces.

The consequences of this are that the intrinsic ferromagnetic power source with its thermodynamic ordering action contributes to doing work in building up forces across the air gap. The task, in technological terms, is then to harness that energy as the gap is closed, as by poles coming together in a reluctance motor, and avoid returning that energy as the poles separate, this being possible if the controlling source of primary magnetisation is well removed from the pole gap and the demagnetisation occurs when the poles are at the closest position.

This energy situation is evident in the Moullin data, because the constant AC voltage implies a constant flux amplitude across the air gap if there is no flux leakage in the gap region. A constant flux amplitude implies a constant force between the poles and so the gap width in relation to this force is a measure of the mechanical energy potential of the air gap. The reactive volt-amp power assessment over the quarter-cycle period representing the polarisation demand can then be compared with the mechanical energy so made available. As already stated, this is how Moullin deduced the theoretical current curve. In fact, as his data show, he needed less current than the mechanical energy suggested and so he had in his experiment evidence of the vacuum energy source that passed unnoticed and is only now revealing itself in machines that can serve our energy needs.

In the research leading to this patent application the Moullin experiment has been repeated to verify a condition where a single magnetising winding serves three air gaps. The Moullin test configuration is shown in **Fig.2**, but in repeating the experiment in the research leading to this invention, a search coil was mounted on the bridging member and this was used to compare the ratio of the voltage applied to the magnetising winding and that induced in the search coil.

The same fall-off feature in current demand was observed, and there was clear evidence of substantial excess energy in the air gap. This was in addition to the inductive energy that necessarily had to be locked into the magnetic core to sustain the 'yawing' action of the magnetic flux already mentioned.

It is therefore emphasised that, in priming the flux 'yawing' action, energy is stored inductively in the magnetic core, even though this has been deemed to be the energy of flux leakage outside the core. The air gap energy is also induction energy. Both energies are returned to the source winding when the system is demagnetised, given a fixed air gap.

If, however, the air gap closes after or during magnetisation, much of that inductive energy goes into the mechanical work output. Note then that the energy released as mechanical work is not just that stored in the air gap but is that stored in sustaining the 'yaw'. Here, then is reason to expect an even stronger contribution to the dynamic machine performance, one that was not embraced by the calculation of the steady-state situation.

Given the above explanation of the energy source, the structural features which are the subject of this invention will now be described.

The 'yawing' action is depicted in **Fig.3**, which depicts how magnetic flux navigates a right-angled bend in a magnetic core upon passage through an air gap. By over-simplification it is assumed that the core has a crystal structure that has a preferred axis of magnetisation along the broken line path. With no air gap, the current needed by a magnetising winding has only to provide enough magnetomotive force to overcome the effects of non-magnetic inclusions and impurities in the core substance and very high magnetic permeabilities can apply. However, as soon as the air gap develops, this core substance has to find a way of setting up magnetomotive force in regions extending away from the locality of the magnetising winding. It cannot do this unless its effect is so powerful that the magnetic flux throughout the magnetic circuit through the core substance is everywhere deflected from alignment with a preferred easy axis of magnetisation. Hence the flux vectors depicted by the arrows move out of alignment with the broken line shown.

There is a 'knock-on' effect progressing all the way around the core from the seat of the magnetising winding and, as already stated, this harnesses the intrinsic ferromagnetic power that, in a system with no air gap, could only be affected by magnetisation above the knee of the B-H curve. Magnetic flux rotation occurs above that knee, whereas in an ideal core the magnetism develops with very high permeability over a range up to that knee, because it needs very little power to displace a magnetic domain wall sideways and promote a 900 or a1800 flux reversal. Indeed, one can have a magnetic permeability of 10,000 below the knee and 100 above the knee, the latter reducing progressively until the substance saturates magnetically.

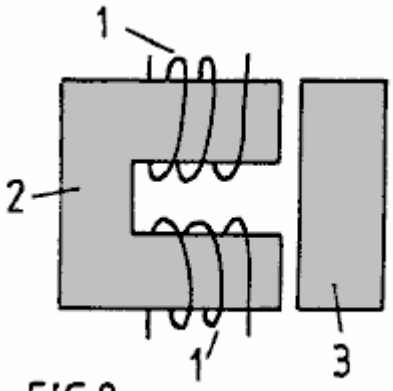

FIG.2

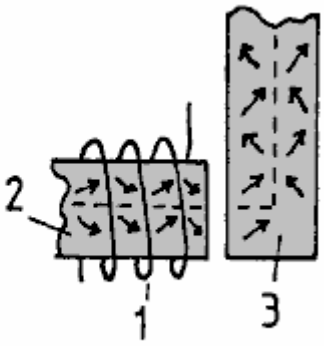

FIG.3

In the situation depicted in **Fig.2** and **Fig.3** the field strength developed by the magnetising windings **1** on magnetic core **2** has to be higher, the greater the air gap, in order to achieve the same amount of magnetisation as measured by the voltage induced in a winding (not shown) on the bridging member **3**. However, by virtue of that air gap there is potential for harnessing energy supplied to that air gap by the intrinsic zero-point field that accounts for the magnetic permeability being over unity and here one can contemplate very substantial excess energy potential, given incorporation in a machine design which departs from convention.

One of the applicants has built an operative test machine which is configured as depicted schematically in **Fig.4**. The machine has been proved to deliver substantially more mechanical power output than is supplied as electrical input, as much as a ratio of 7:1 in one version, and it can act regeneratively to produce electrical power.

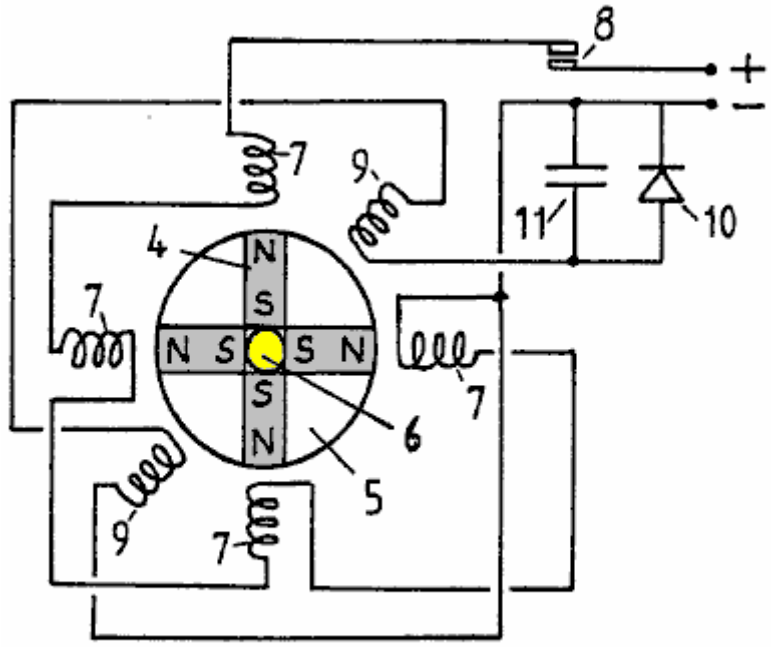

FIG. 4

What is shown in **Fig.4** is a simple model designed to demonstrate the principle of operation. It comprises a rotor in which four permanent magnets **4** are arrayed to form four poles. The magnets are bonded into four sectors of a non-magnetic disc **5** using a high density polyurethane foam filler and the composite disc is then assembled on a brass spindle **6** between a split flange coupling. Not shown in the figure is the structure holding the spindle vertically in bearings or the star wheel commutator assembly attached to the upper shaft of the spindle.

Note that the magnets present north poles at the perimeter of the rotor disc and that the south poles are held together by being firmly set in the bonding material. A series of four stator poles were formed using magnetic cores from standard electromagnetic relays are were positioned around the rotor disc as shown. The magnetising windings **7** on these cores are shown to be connected in series and powered through commutator contacts **8** by a DC power supply. Two further stator cores formed by similar electromagnetic relay components are depicted by their windings **9** in the intermediate angle positions shown and these are connected in series and connected to a rectifier **10** bridged by a capacitor **11**.

The rotor spindle **6** is coupled with a mechanical drive (not shown) which harnesses the torque developed by the motor thus formed and serves as a means for measuring output mechanical power delivered by the machine.

In operation, assuming that the rotor poles are held initially off-register with the corresponding stator poles and the hold is then released, the strong magnetic field action of the permanent magnets will turn the rotor to bring the stator and rotor poles into register. A permanent magnet has a strong attraction for soft iron and so this initial impulse of rotation is powered by the potential energy of the magnets.

Now, with the rotor acting as a flywheel and having inertia it will have a tendency to over-shoot the in-register pole position and that will involve a reverse attraction with the result that the rotor will oscillate until damping action brings it to rest. However, if the contacts of the commutating switch are closed as the poles come

The commutating switch **8** needs only to be closed for a limited period of angular travel following the top dead centre in-register position of the stator and rotor poles. The power supplied through that switch by those pulses will cause the rotor to continue rotating and high speeds will be achieved as the machine develops its full motor function.

Tests on such a machine have shown that more mechanical power can be delivered than is supplied electrically by the source powering the action through the commutating switch. The reason for this is that, whereas the energy in the air gap between rotor and stator poles which is tapped mechanically as the poles come into register is provided by the intrinsic power of the ferromagnet, a demagnetising winding on the part of the core system coupled across that air gap needs very little power to eliminate the mechanical force acting across that air gap. Imagine such a winding on the bridging member shown in **Fig.2**. The action of current in that winding, which sits astride the 'yawing' flux in that bridging member well removed from the source action of the magnetising windings **1**, is placed to be extremely effective in resisting the magnetising influence communicated from a distance. Hence very little power is needed to overcome the magnetic coupling transmitted across the air gap.

Although the mutual inductance between two spaced-apart magnetising windings has a reciprocal action, regardless of which winding is primary and which is secondary, the action in the particular machine situation being described involves the 'solenoidal' contribution represented by the 'yawing' ferromagnetic flux action. The latter is not reciprocal inasmuch as the flux ‘yaw' depends on the geometry of the system. A magnetising winding directing flux directly across an air gap has a different influence on the action in the ferromagnetic core from one directing flux lateral to the air gap and there is no reciprocity in this action.

In any event, the facts of experiment do reveal that, owing to a significant discrepancy in such mutual interaction, more mechanical power is fed into the rotor than is supplied as input from the electrical source.

This has been further demonstrated by using the two stator windings **9** to respond in a generator sense to the passage of the rotor poles. An electrical pulse is induced in each winding by the passage of a rotor pole and this is powered by the inertia of the rotor disc **5**. By connecting the power so generated, to charge the capacitor **11,** the DC power supply can be augmented to enhance the efficiency even further.

Indeed, the machine is able to demonstrate the excess power delivery from the ferromagnetic system by virtue of electrical power generation charging a battery at a greater rate than a supply battery is discharged.

This invention is concerned with a practical embodiment of the motor-generator principles just described and aims, in its preferred aspect, to provide a robust and reliable machine in which the tooth stresses in the rotor poles, which are fluctuating stresses communicating high reluctance drive torque, are not absorbed by a ceramic permanent magnet liable to rupture owing to its brittle composition.

Another object is to provide a structure which can be dismantled and reassembled easily to replace the permanent magnets, but an even more important object is that of minimising the stray leakage flux oscillations from the powerful permanent magnets. Their rotation in the device depicted in **Fig.4** would cause excessive eddy-current induction in nearby metal, including that of the machine itself, and such effects are minimised if the flux changes are confined to paths through steel laminations and if the source flux from the magnets has a symmetry or near symmetry about the axis of rotation.

Thus, the ideal design with this in mind is one where the permanent magnet is a hollow cylinder located on a non-magnetic rotor shaft, but, though that structure is within the scope of this invention, the machine described will utilise several separate permanent magnets approximating, in function, such a cylindrical configuration.

Referring to **Fig.4**, it will further be noted that the magnetic flux emerging from the north poles will have to find its way along leakage paths through air to re-enter the south poles. For periods in each cycle of machine operation

the flux will be attracted through the stator cores, but the passage through air is essential and so the power of the magnets is not used to full advantage and there are those unwanted eddy-current effects.

To overcome this problem the invention provides for two separate rotor sections and the stator poles become bridging members, which with optimum design, allow the flux from the magnets to find a route around a magnetic circuit with minimal leakage through air as the flux is directed through one or other pairs of air gaps where the torque action is developed.

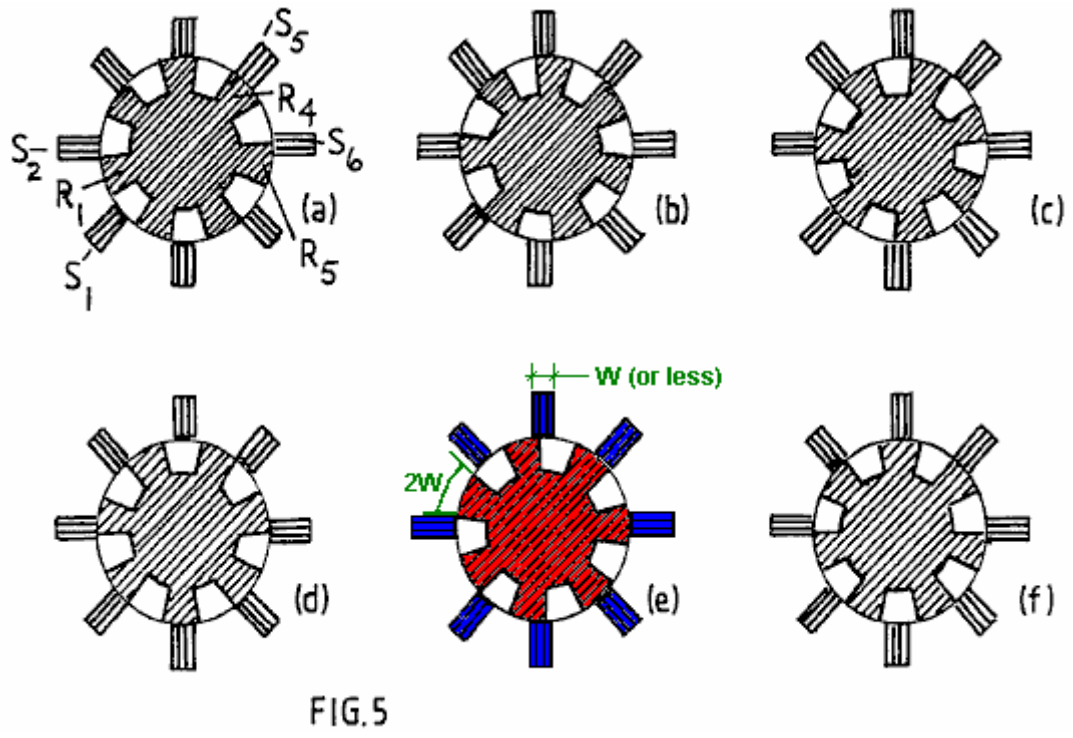

FIG.5

Reference is now made to **Fig.5** and the sequence of rotor positions shown. Note that the stator pole width can be significantly smaller that that of the rotor poles. Indeed, for operation using the principles of this invention, it is advantageous for the stator to have a much smaller pole width so as to concentrate the effective pole region. A stator pole width of half that of the rotor is appropriate but it may be even smaller and this has the secondary advantage of requiring smaller magnetising windings and so saving on the loss associated with the current circuit.

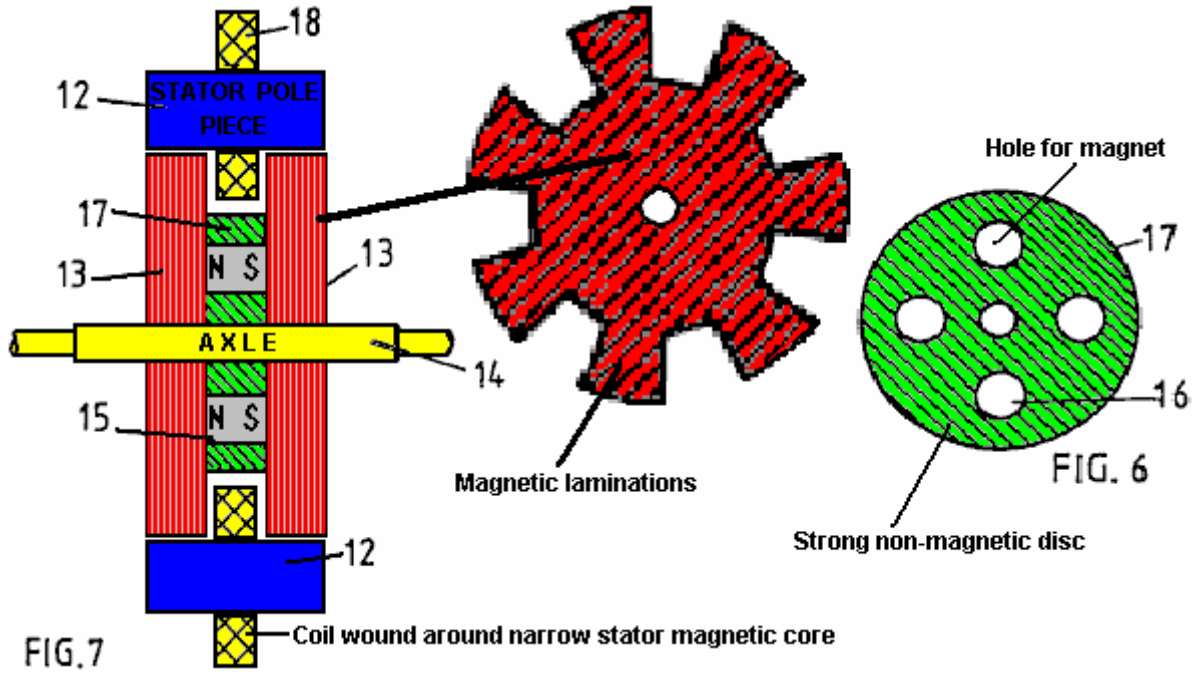

FIG.7

FIG. 6

The stator has eight pole pieces formed as bridging members **12**, more clearly represented in **Fig.7**, which shows a sectional side view through two rotor sections **13** axially spaced on a rotor shaft **14**. There are four permanent magnets **15** positioned between these rotor sections and located in apertures **16** in a disc **17** of a non-magnetic

substance of high tensile strength, the latter being shown in **Fig.6**. The rotor sections are formed from disc laminations of electrical steel which has seven large teeth, the salient poles. Magnetising windings **18** mounted on the bridging members **12** constitute the system governing the action of the motor-generator being described.

The control circuitry is not described as design of such circuitry involves ordinary skill possessed by those involved in the electrical engineering art.

It suffices, therefore, to describe the merits of the structural design configuration of the core elements of the machine. These concern principally the magnetic action and, as can be imagined from **Fig.7**, the magnetic flux from the magnets enters the rotor laminations by traversing the planar faces of the laminations and being deflected into the plane of the laminations to pass through one or other of the stator pole bridging members, returning by a similar route through the other rotor.

By using eight stator poles and seven rotor poles, the latter having a pole width equal to half the pole pitch in an angular sense, it will be seen from **Fig.5**, that there is always a flux passage across the small air gap between stator and rotor poles. However, as one pole combination is in-register the diametrically-opposed pole combinations are out-of register.

As described by reference to **Fig.4** the operation of the machine involves allowing the magnet to pull stator and rotor poles into register and then, as they separate, pulsing the winding on the relevant stator member to demagnetise that member. In the **Fig.4** system, all the stator magnetising windings were pulsed together, which is not an optimum way in which to drive a multi-pole machine.

In the machine having the pole structure with one less rotor pole than stator poles (or an equivalent design in which there is one less stator pole than rotor poles) this pulsing action can be distributed in its demand on the power supply, and though this makes the commutation switch circuit more expensive the resulting benefit outweighs that cost. However, there is a feature of this invention by which that problem can be alleviated if not eliminated.

Suppose that the rotor has the position shown in **Fig.5(a)** with the rotor pole denoted **R1** midway between stator poles **S1** and **S2** and imagine that this is attracted towards the in-register position with stator pole **S2**. Upon reaching that in-register position, as shown in **Fig.5(c)**, suppose that the magnetising winding of stator pole **S2** is excited by a current pulse which is sustained until the rotor reaches the **Fig.5(e)** position.

The combination of these two actions will have imparted a forward drive impulse powered by the permanent magnet in the rotor structure and the current pulse which suppresses braking action will have drawn a smaller amount of energy from the electrical power source which supplies it. This is the same process as was described by reference to **Fig.4**.

However, now consider the events occurring in the rotor action diametrically opposite that just described. In the **Fig.5(a)** position rotor pole **R4** has come fully into register with stator pole **S5** and so stator pole **S5** is ready to be demagnetised. However, the magnetic coupling between the rotor and stator poles is then at its strongest. Note, however, that in that **Fig.5(a)** position **R5** is beginning its separation from stator poles and the magnetising winding of stator pole **S6** must then begin draw power to initiate demagnetisation. During that following period of pole separation the power from the magnet is pulling **R1** and **S2** together with much more action than is needed to generate that current pulse needed to demagnetise **S6**. It follows, therefore, that, based on the research findings of the regenerative excitation in the test system of **Fig.4**, the series connection of the magnetising windings on stators **S2** and **S6** will, without needing any commutative switching, provide the regenerative power needed for machine operation.

The complementary action of the two magnetising windings during the pole closure and pole separation allows the construction of a machine which, given that the zero-point vacuum energy powering the ferromagnet is feeding input power, will run on that source of energy and thereby cool the sustaining field system.

There are various design options in implementing what has just been proposed. Much depends upon the intended use of the machine. If it is intended to deliver mechanical power output the regenerative electrical power action can all be used to power the demagnetisation with any surplus contributing to a stronger drive torque by reversing the polarity of the stator poles during pole separation.

If the object is to generate electricity by operating in generator mode then one could design a machine having additional windings on the stator for delivering electrical power output. However, it seems preferable to regard the machine as a motor and maximise its efficiency in that capacity whilst using a mechanical coupling to an alternator of conventional design for the electrical power generation function.

In the latter case it would still seem preferable to use the self-excitation feature already described to reduce commutation switching problems.

The question of providing for machine start-up can be addressed by using a separate starter motor powered from an external supply or by providing for current pulsing limited to, say, two stator poles. Thus, for example, with the eight stator pole configuration, the cross-connected magnetising windings could be limited to three stator pairs, with two stator magnetising windings left free for connection to a pulsed external supply source.

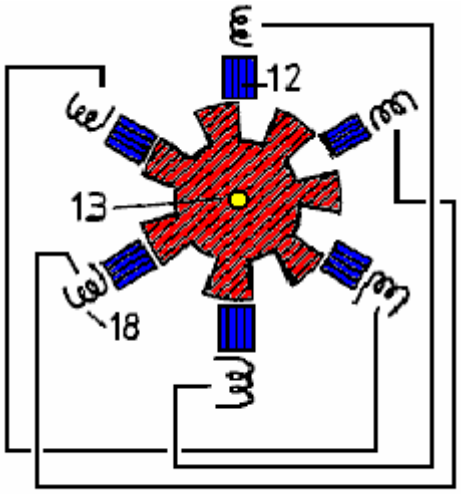

FIG.8

If the latter feature were not required, then the stator magnetising windings would all be connected in pairs on a truly diametrically opposite basis. Thus **Fig.8** shows a rotor-stator configuration having six stator poles interacting with seven rotor poles and stator magnetising windings linked together in pairs.

The invention, therefore, offers a wide range of implementation possibilities, which, in the light of this disclosure will become obvious to persons skilled in the electrical engineering art, all based, however, on the essential but simple principle that a rotor has a set of poles of common polarity which are attracted into register with a set of stator poles that are suppressed or reversed in polarity magnetically during pole separation. The invention, however, also offers the important feature of minimising commutation and providing further for a magnetic flux closure that minimises the leakage flux and fluctuations of leakage flux and so contributes to efficiency and high torque performance as well as durability and reliability of a machine incorporating the invention.

It is noted that although a machine has been described which uses two rotor sections it is possible to build a composite version of the machine having several rotor sections. In the eventuality that the invention finds use in very large motor-generator machines the problem of providing very large magnets can be overcome by a design in which numerous small magnets are assembled. The structural concept described by reference to **Fig.6** in providing locating apertures to house the magnets makes this proposal highly feasible. Furthermore, it is possible to replace the magnets by a steel cylinder and provide a solenoid as part of the stator structure and located between the rotor sections. This would set up an axial magnetic field magnetising the steel cylinder and so polarising the rotor. However, the power supplied to that solenoid would detract from the power generated and so such a machine would not be as effective as the use of permanent magnets such as are now available.

Nevertheless, should one see significant progress in the development of warm superconductor materials, it may become feasible to harness the self-generating motor-generator features of the invention, with its self-cooling properties, by operating the device in an enclosure at low temperatures and replacing the magnets by a superconductive stator supported solenoid.

CLAIMS

1. An electrodynamic motor-generator machine comprising a stator configured to provide a set of stator poles, a corresponding set of magnetising windings mounted on the stator pole set, a rotor having two sections each of which has a set of salient pole pieces, the rotor sections being axially spaced along the axis of rotation of the rotor, rotor magnetisation means disposed between the two rotor sections arranged to produce a unidirectional magnetic field which magnetically polarises the rotor poles, whereby the pole faces of one rotor section all have a north polarity and the pole faces of the other rotor section all have a south polarity and electric circuit connections between an electric current source and the stator magnetising windings arranged to regulate the operation of the machine by admitting current pulses for a duration determined according to the angular position of the rotor, which pulses have a direction tending to oppose the polarisation induced in the stator by

the rotor polarisation as stator and rotor poles separate from an in-register position, whereby the action of the rotor magnetisation means provides a reluctance motor drive force to bring stator and rotor poles into register and the action of the stator magnetisation windings opposes the counterpart reluctance braking effect as the poles separate.

2. A motor-generator according to claim 1, wherein the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide demagnetisation of the stator poles as the stator and rotor poles separate from an in-register position.

3. A motor-generator according to claim 1, wherein the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide a reversal of magnetic flux direction in the stator poles as the stator and rotor poles separate from an in-register position, whereby to draw on power supplied from the electric current source to provide additional forward drive torque.

4. A motor-generator according to claim 1, wherein the electric current source connected to a stator magnetising winding of a first stator pole comprises, at least partially, the electrical pulses induced in the stator magnetising winding of a different second stator pole, the stator pole set configuration in relation to the rotor pole set configuration being such that the first stator pole is coming into register with a rotor pole as the second stator pole separates from its in-register position with a rotor pole.

5. A motor-generator according to claim 1, wherein the number of poles in a set of stator poles is different from the number of rotor poles in each rotor section.

6. A motor-generator according to claim 1, wherein the stator configuration provides pole pieces which are common to both rotor sections in the sense that when stator and rotor poles are in-register the stator pole pieces constitute bridging members for magnetic flux closure in a magnetic circuit including that of the rotor magnetisation means disposed between the two rotor sections.

7. A motor-generator according to claim 6, wherein the number of poles in a set of stator poles and the number of rotor poles in each section do not share a common integer factor and the number of rotor poles in one rotor section is the same as that in the other rotor section.

8. A motor-generator according to claim 7, wherein the number of poles in a stator set and the number of poles in a rotor section differs by one and the pole faces are of sufficient angular width to assure that the magnetic flux produced by the rotor magnetisation means can find a circuital magnetic flux closure route through the bridging path of a stator pole and through corresponding rotor poles for any angular position of the rotor.

9. A motor-generator according to claim 8, wherein each rotor section comprises seven poles.

10. A motor-generator according to claim 7, wherein there are N rotor poles in each rotor section and each has an angular width that is 180/N degree of angle.

11. A motor-generator according to claim 7, wherein the stator pole faces have an angular width that is no greater than half the angular width of a rotor pole.

12. A motor-generator according to claim 1, wherein the rotor sections comprise circular steel laminations in which the rotor poles are formed as large teeth at the perimeter, and the rotor magnetisation means comprise a magnetic core structure the end faces of which abut two assemblies of such laminations forming the two rotor sections.

13. A motor-generator according to claim 1 in which the rotor magnetisation means comprises at least one permanent magnet located with its polarisation axis parallel with the rotor axis.

14. A motor-generator according to claim 13, wherein an apertured metal disc that is of a non-magnetisable substance is mounted on a rotor shaft and positioned intermediate the two rotor sections and each aperture provides location for a permanent magnet, whereby the centrifugal forces acting on the permanent magnet as the rotor rotates are absorbed by the stresses set up in the disc.

15. A motor-generator according to claim 1, having a rotor mounted on a shaft that is of a non-magnetisable substance, whereby to minimise magnetic leakage from the rotor magnetising means.

16. An electrodynamic motor-generator machine comprising a stator configured to provide a set of stator poles, a corresponding set of magnetising windings mounted on the stator pole set, a rotor having two sections each of which has a set of salient pole pieces, the rotor sections being axially spaced along the axis of rotation of the

rotor, rotor magnetisation means incorporated in the rotor structure and arranged to polarise the rotor poles, whereby the pole faces of one rotor section all have a north polarity and the pole faces of the other rotor section all have a south polarity and electric circuit connections between an electric current source and the stator magnetising windings arranged to regulate the operation of the machine by admitting current pulses for a duration determined according to the angular position of the rotor, which pulses have a direction tending to oppose the polarisation induced in the stator by the rotor polarisation as stator and rotor poles separate from an in-register position, whereby the action of the rotor magnetisation means provides a reluctance motor drive force to bring stator and rotor poles into register and the action of the stator magnetisation windings opposes the counterpart reluctance braking effect as the poles separate.

17. A motor-generator according to claim 16, wherein the electric current source connected to a stator magnetising winding of a first stator pole comprises, at least partially, the electrical pulses induced in the stator magnetising winding of a different second stator pole, the stator pole set configuration in relation to the rotor pole set configuration being such that the first stator pole is coming into register with a rotor pole as the second stator pole separates from its in-register position with a rotor pole.

Amendments to the claims have been filed as follows 1. An electrodynamic motor-generator machine comprising a stator configured to provide a set of stator poles, a corresponding set of magnetising windings mounted on the stator pole set, a rotor having two sections each of which has a set of salient pole pieces, the rotor sections being axially spaced along the axis of rotation of the rotor, rotor magnetisation means disposed between the two rotor sections arranged to produce a unidirectional magnetic field which magnetically polarises the rotor poles, whereby the pole faces of one rotor section all have a north polarity and the pole faces of the other rotor section all have a south polarity and electric circuit connections between an electric current source and the stator magnetising windings arranged to regulate the operation of the machine by admitting current pulses for a duration determined according to the angular position of the rotor, which pulses have a direction tending to oppose the polarisation induced in the stator by the rotor polarisation as stator and rotor poles separate from an in-register position, whereby the action of the rotor magnetisation means provides a reluctance motor drive force to bring stator and rotor poles into register and the action of the stator magnetisation windings opposes the counterpart reluctance braking effect as the poles separate, the machine being characterised in that the stator comprises separate ferromagnetic bridging members mounted parallel with the rotor axis, the ends of which constitute stator poles and the core sections of which provide closure paths operative when the stator and rotor poles are in register to confine magnetic flux developed by the rotor magnetisation means to a stator flux path of restricted cross-section disposed anti-parallel with the unidirectional magnetic field polarisation axis of the rotor magnetising means 2. A motor-generator according to claim 1, wherein the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide demagnetisation of the stator poles as the stator and rotor poles separate from an in-register position.

3. A motor-generator according to claim 1, wherein the circuit connecting the electric current source and the stator magnetising windings is designed to deliver current pulses which are of sufficient strength and duration to provide a reversal of magnetic flux direction in the stator poles as the stator and rotor poles separate from an in-register position, whereby to draw on power supplied from the electric current source to provide additional forward drive torque.

4. A motor-generator according to claim 1, wherein the electric current source connected to a stator magnetising winding of a first stator pole comprises, at least partially, the electrical pulses induced in the stator magnetising winding of a different second stator pole, the stator pole set configuration in relation to the rotor pole set configuration being such that the first stator pole is coming into register with a rotor pole as the second stator pole separates from its in-register position with a rotor pole.

5. A motor-generator according to claim 1, wherein the number of poles in a set of stator poles is different from the number of rotor poles in each rotor section.

6. A motor-generator according to claim 1, wherein the stator configuration provides pole pieces which are common to both rotor sections in the sense that when stator and rotor poles are in-register the stator pole pieces constitute bridging members for magnetic flux closure in a magnetic circuit including that of the rotor magnetisation means disposed between the two rotor sections.

7. A motor-generator according to claim 6, wherein the number of poles in a set of stator poles and the number of rotor poles in each section do not share a common integer factor and the number of rotor poles in one rotor section is the same as that in the other rotor section.

SELF-SUSTAINING ELECTRIC POWER GENERATOR UTILISING ELECTRONS OF LOW INERTIAL MASS TO MAGNIFY INDUCTIVE ENERGY

This patent application shows a very neat, self-powered electrical generator with a theoretical output of anything up to a COP of 59 when using cadmium selenide. The discussion of the theoretical aspects of the design includes a large amount of historical information and it covers the origin of the "law" of Conservation of Energy which, in spite of being incorrect, has been for decades, a major obstacle to the scientific development of free-energy devices.

Filed: 6th March 2006
Assignee: Levitronics, Inc.
Provisional application No. 60/697,729 filed on 8th July 2005

ABSTRACT

Electrical oscillations in a metallic "sending coil" radiate inductive photons toward one or more "energy-magnifying coils" comprised of a photoconductor or doped semiconductor coating a metallic conductor, or comprised of a superconductor. Electrons of low inertial mass in the energy-magnifying coil(s) receive from the sending coil, a transverse force having no in-line backforce, which exempts this force from the energy-conservation rule. The low-mass electrons in the energy-magnifying coil(s) receive increased acceleration proportional to normal electron mass divided by the lesser mass. Secondarily radiated inductive-photon energy is magnified proportionally to the electrons' greater acceleration, squared, e.g., the inductive-energy-magnification factor of CdSe photoelectrons with 0.13 x normal electron mass is 59 times. Magnified inductive-photon energy from the energy-magnifying coil(s) induces oscillating electric energy in one or more metallic "output coil(s)". The electric energy output exceeds the energy input if more of the magnified photon induction energy is directed toward the output coil(s) than is directed as a counter force to the sending coil. After an external energy source initiates the oscillations, feedback from the generated surplus energy makes the device a self-sustaining generator of electric power for useful purposes.

CROSS REFERENCE TO RELATED APPLICATION

This application corresponds to, and claims the benefit under 35 U.S.C. 119(e), of U.S. provisional application No. 60/697,729, filed on 8th July 2005, incorporated herein by reference in its entirety.

FIELD

This disclosure introduces a technical field in which practical electrical energy is created in accordance with the overlooked exception to the energy-conservation rule that Herman von Helmholtz described in his 1847 doctrine on energy conservation: "If . . . bodies possess forces which depend upon time and velocity, or which act in directions other than lines which unite each pair of material points, . . . then combinations of such bodies are possible in which force may be either lost or gained as infinitum". A transverse inductive force qualifies for Helmholtz's ad infinitum rule, but this force is not sufficient of itself to cause a greater energy output than input when applied to electrons of normal mass due to their unique charge-to-mass ratio. However, the increased acceleration of conduction electrons of less-then-normal inertial mass, as occurs in photoconductors, doped semiconductors, and superconductors, is proportional to the normal electron mass divided by the low electron mass, and the magnification of harnessable inductive energy is proportional to the square of the greater relative acceleration.

BACKGROUND

Magnetic force also satisfies Helmholtz's exemption to the energy-conservation rule because magnetic force is transverse to the force that causes it, and magnetic force is determined by the "relative velocity" (i.e. perpendicular to the connecting line) between electric charges. Magnification of magnetic force and energy was demonstrated by E. Leimer (1915) in the coil of a speaker phone and in the coil of a galvanometer when he irradiated a radio antenna-wire with radium. A 10 milligram, linear radium source produced a measured 2.6 fold increase in electrical current in the antenna wire in comparing inaudible radio reception without radium to audible reception with radium. This represented a $(2.6)^2$ = 7 times increase in electrical energy flowing through the

respective wire coils. The possibility of this enhanced reception being attributed to a person's body holding the unit of radium to the wire was eliminated by Leimer's additional observation that whenever the orientation of the small radium unit was changed to approximately 30 degrees relative to the wire, the energy enhancement ceased.

Applicant has deduced that Leimer's energy magnification was most likely due to low-mass electrons that were liberated and made conductive in the antenna by alpha radiation, which allowed these special electrons to be given a greater than normal acceleration by the received radio broadcast photons. Applicant has further deduced that such low-mass electrons must have originated in a thin-film coating of cupric oxide (CuO) on the antenna wire. CuO is a dull black polycrystalline semiconducting compound that develops in situ on copper and bronze wire in the course of annealing the wire in the presence of air. Such CuO coatings have been observed by Applicant on historical laboratory wire at the Science Museum at oxford University, U.K. and on copper house wire of that era in the U.S., indicating that CuO coatings were commonplace. In later years, annealing has taken place under conditions that prevent most oxidation. This is followed by acid treatment to remove any remaining oxides, leaving shiny wire.

The same year that the English translation of Leimer's paper appeared in *Scientific American*, 16-year old Alfred M. Hubbard of Seattle, Washington, reportedly invented a fuelless generator, which he later admitted, employed radium. Applicant interprets this as implying that Leimer's energy-magnification was utilised by Hubbard with feedback to make it self-sustaining. Three years later, Hubbard publicly demonstrated a relatively advanced fuelless generator that illuminated a 20-watt incandescent bulb (Anon. 1919a). A reputable physics professor from Seattle College, who was intimately familiar with Hubbard's device (but not at liberty to disclose its construction details), vouched for the integrity of the fuelless generator and declared that it was not a storage device, but he did not know why it worked (Anon. 1919b). Because Hubbard initially had no financial means of his own, it is likely that the professor had provided Hubbard with the use of the expensive radium initially and thereby witnessed the inventing process in his own laboratory.

Newspaper photos (Anon. 1920a) of a more impressive demonstration of Hubbard's fuelless generator, show a device described as 14 inches (36 cm) long and 11 inches (28 cm) in diameter, connected by four heavy electrical cables to a 35 horsepower (26 kW) electric motor. The motor reportedly propelled an 18-foot open launch around a like at a speed of 8 to 10 knots (Anon. 1920b). The event was witnessed by a cautious news reporter who claims to have checked thoroughly for any wires that might have been connected to hidden batteries, by lifting the device and motor from the boat. Radioactive-decay energy can be eliminated as the main power source because about 10^8 times more radium than the entire world's supply would have been needed to equal Hubbard's reported electric energy output of 330 amperes and 124 volts.

Lester J. Hendershott of Pittsburgh, Pa., reportedly demonstrated a fuelless generator in 1928 that was claimed by Hubbard to be a copy of his own device (1928h). The president of Stout Air services, William B. Stout, who also designed the Ford Trimotor aeroplane, reported (1928b): "The demonstration was very impressive. It was actually uncanny.... The small model appeared to operate exactly as Hendershot explained it did". Also reportedly attesting to the operability of Hendershott's fuelless generator were Colonel Charles A. Lindbergh and Major Thomas Lanphier of the U.S. Air Corps (1928a, et seq.), and Lanphier's troops reportedly assembled a working model of his device.

To the Applicant's best knowledge, the only depiction that was made public of the interior components of any of these reported generators consists of a sketchy drawing (Bermann 1928h) of Hubbard's apparatus similar in size to the device shown in his 1919 demonstration. It depicts a complex set of parallel coils measuring 6 inches (15 cm) in length and 4.5 inches (11.4 cm) in overall diameter. Four leads of insulated wire, with the insulation peeled back, are shown coming out of the end of the device. What those four wires were connected to internally was not shown. Hubbard's description of the internal arrangement of coils in the device generally matches the drawing (Anon. 1920a): "It is made up of a group of eight electromagnets, each with primary and secondary windings of copper wire, which are arranged around a large steel core. The core likewise has a single winding. About the entire group of cells is a secondary winding". Nothing was reported or depicted about how components functioned with each other, or how much radium was used and where the radium was positioned. The only connectors visible on the drawing were between the outer windings of the eight electromagnet coils. These connectors show that the direction of the windings alternated between clockwise and counterclockwise on adjacent coils, so that the polarity of each electromagnet would have been opposite to that of it's adjacent neighbours.

If the Hubbard and Hendershot devices actually operated as reported, they apparently never attained acceptance or commercial success. Assuming the devices actually worked, their lack of success may have been largely financially or supply based, or both, compounded with scepticism from believers in the energy-conservation doctrine. How much radium was employed by Hubbard in his larger generator can only be guessed at, but assuming a typical laboratory radium needle containing 10 milligrams of radium was used, that amount would have cost $900 in 1920, dropping to $500 in 1929. That much radium in a fuelless generator would have cost as much as an inexpensive automobile in the 1920s. Possibly much more radium was used than 10 milligrams.

In 1922, when the Radium Company of America of Pittsburgh, Pa., reportedly discontinued its work with Hubbard on his invention (1928h), the entire world's supply of radium was only about 250 grams. With the extreme

assumption that only 1 milligram of radium was needed per generator, less than 10% of a single year's production of autos in the US in the mid-1920s could have been supplied with such generators. Apparently Hendershott had tried to revive the technology by showing that the fuelless generator could extend the range of air flight indefinitely, but his technology never attracted a sponsor from any private, public or philanthropic entity.

U.S. Pat. No. 4,835,433 to Brown, superficially resembles the drawing of Hubbard's device. Brown's device appears to have the same number and essentially the same general arrangement of wire coils as Hubbard's generator, as nearly as can be understood from the newspaper articles depicting that device. Apparently, no information concerning either the Hubbard or Hendershot devices was considered during the prosecution of the '433 patent. Brown discusses the conversion of energy of radioactive decay products, principally alpha emissions, to electrical energy by amplifying electrical oscillations in a high-Q L-C circuit irradiated by radioactive materials. "During the absorption process, each alpha particle will collide with one or more atoms in the conductor, knocking electrons from their orbits and imparting some kinetic energy to the electrons in the conductor, thereby increasing its conductivity". (Col. 3, Line 68 to Col. 4, line 5). No claim was made by Brown, that the device employed a semiconductor or photoconductor that could have provided low-mass electrons for energy magnification.

Brown claimed an output of 23 amps at 400 volts, which is vastly greater than all the decay energy represented by his reported radioactive content of 1 milligram of radium that was surrounded by weakly radioactive uranium rods and thorium powder. Powered thorium is highly pyrophoric, so it is typically sealed in a nitrogen atmosphere to prevent spontaneous combustion. In his device, Brown reportedly confined the thorium in cardboard without any mention of sealing out air. This condition would have invited a meltdown that could have been interpreted as massive out-of-control electrical production.

To the best of the Applicant's knowledge, no person other than the Applicant has ever indicated that the presence of cupric oxide on their wires could have provided energy magnification. If Hubbard's device actually did work, certain characteristics of its design are unexplainable by the Applicant, namely the use of four rather than two large electrical cables to connect his device to an electrical motor, and the use of alternating polarity instead of single-direction polarity in the orientation of the multiple coils surrounding a central coil. Applicant therefore believes that the specification herein sets forth original configurations of electrical-energy generators that have no known precedent.

SUMMARY

To address the needs for electrical generators which are capable of self-generating substantial amounts of electrical power in various environments, and which are portable as well as stationary, apparatus and methods are provided for magnifying an electrical input, and (with feedback) for generating usable electrical power indefinitely without fuel or other external energy source, except for starting. The apparatus utilises electrons of low effective mass, which receive greater acceleration than normal electrons in an amount that is inversely proportional to the effective mass. Applicant has determined that effective mass is the same as the electron's true inertial mass. The photon energy that is radiated when an electron is accelerated is proportional to the square of the acceleration, so the increase in radiated photon energy from an accelerated low-mass electron over the energy from a normal electron is equal to the inverse square of the effective mass, e.g. the calculated energy magnification provided by photoconducting electrons in cadmium selenide, with an electron effective mass of 0.13, is 59 times. The use of a transverse force, that lacks a direct back-force, to accelerate low-mass electrons in an oscillating manner, circumvents any equal-and-opposite force that would invoke the application of the energy-conservation law of kinetics and thermodynamics.

The various embodiments of the apparatus, which are configured either to continuously magnify an input of oscillating electric energy, or to serve as a self-sustaining electric generator, employ three principal components:

At least one sending coil

At least one energy-magnification coil, comprising a material that produces , in a "condition" low-mass electrons, and

At least one output coil.

It is desirable that the apparatus also includes a means for establishing the condition with respect to the energy-magnifying coil(s). Except where otherwise indicated in the remainder of this text, where the number of coils of a particular type is referred to in the singular, it will be understood that a plurality of coils of the respective type can alternatively be utilised.

Electrical oscillation in the sending coil, which is comprised of a metallic conductor, causes radiation of inductive photons from the sending coil. The energy-magnifying coil is situated in a position relative to the sending coil so as to receive inductive photons from the sending coil. The inductive photons radiating from electrical oscillations in the sending coil, convey a transverse force to the low-mass electrons in the energy-magnification coil with no

back-force on the sending coil. The greater-than-normal accelerations which are produced in the low-mass electrons of the energy-magnifying coil, produce greater irradiation energy of inductive photons than normal.

The output coil is positioned so as to receive the magnified inductive-photon energy from the energy-magnifying coil. The inductive-photon energy received by the output coil, which is comprised of a metallic conductor, is converted into an oscillating electrical current of normal electrons. In order for the electrical output to exceed the electrical input, the output coil is situated in such a manner that it receives more of the magnified inductive-photon energy than that which is directed back against the sending coil to act as a back-force. This “energy leverage” causes the electrical energy output to exceed the electrical energy input.

By way of example, the energy-magnifying coil can comprise a superconducting material, wherein the “condition” is a temperature (e.g. a cryogenic temperature) at which the superconducting material exhibits superconducting behaviour characterised by production of low-mass electrons.

By way of another example, the energy-magnifying coil can comprise a photoconductive material, wherein the “condition” is a situation in which the photoconductive material is illuminated by a wavelength of photon radiation sufficient to cause the photoconductive material of the energy-magnifying coil to produce conduction electrons having low effective mass. In this latter example, the means for establishing the condition can comprise a photoconductor exciter (e.g. one or more LEDs) situated and configured to illuminate the photoconductive material of the energy-magnifying coil with the wavelength of photon radiation.

By way of yet another example, the “condition” is the presence of a particular dopant in a semiconductor that provides a low-mass electron as a charge carrier. Also, by way of example, the energy-magnifying coil can comprise a semiconductive element or compound that has been doped with a particular element or compound that makes it conductive of low-mass electrons without illumination by photon radiation other than by ambient photons.

Various apparatus embodiments comprise different respective numbers and arrangements of the principal components. The various embodiments additionally can comprise one or more of circuitry, energisers, shielding and other components to fulfill the object of providing a self-sustaining source of electrical power for useful purposes.

Also provided, are methods for generating an electrical current. In an embodiment of such a method, a first coil is energised with an electrical oscillation sufficient to cause the first coil to radiate inductive photons. At least some of the radiated inductive photons from the first coil are received by a second coil, called “the energy-magnifying coil”, comprising a material that produces low-mass electrons. The received inductive photons impart respective transverse forces to the low-mass electrons that cause the low-mass electrons to experience accelerations in the material which are greater than accelerations that otherwise would be experienced by normal free electrons experiencing the transverse forces.

Conduction of the accelerated low-mass electrons in the second coil, causes the second coil to produce a magnified inductive force. The magnified inductive force is received by a third coil which causes the third coil to produce an oscillating electrical output of normal conduction electrons which has greater energy than the initial oscillation. A portion of the oscillating electrical output is directed as feed-back from the third coil to the sending coil, so as to provide the electrical oscillation to the sending coil. This portion of the oscillating electrical current directed to the sending coil, desirably is sufficient to cause self-sustaining generation of inductive photons by the first coil without the need for any external energy source. The surplus oscillating electrical output from the third coil can be directed to a work loop.

The method can further comprise the step of starting the energisation of the first coil to commence generation of the oscillating electrical output. This “starting” step can comprise momentarily exposing the first coil to an external oscillating inductive force or for example, to an external magnetic force which initiates an electrical pulse.

The foregoing and additional features and advantages of the invention will be more readily apparent from the following detailed description, which proceeds with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

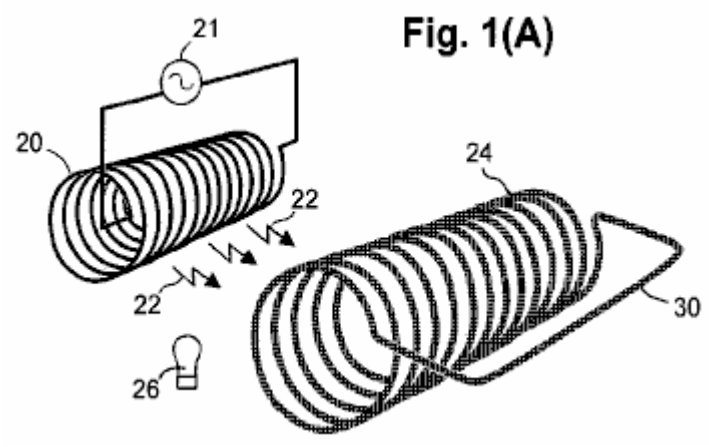

Fig.1A is a perspective view schematically depicting a sending coil in relationship to an energy-magnifying coil such that inductive photons from the sending coil, propagate to the energy-magnifying coil.

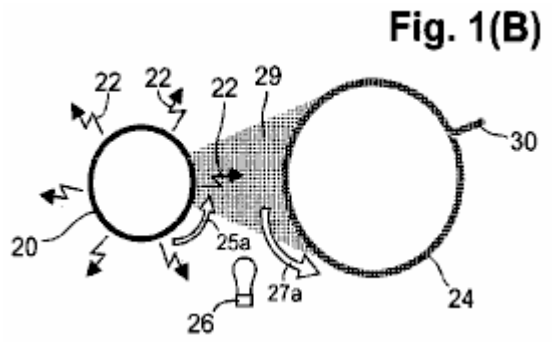

Fig.1B is a schematic end-view of the sending coil and energy-magnifying coil of **Fig.1A**, further depicting radiation of inductive photons from the sending coil and the respective directions of electron flow in the coils.

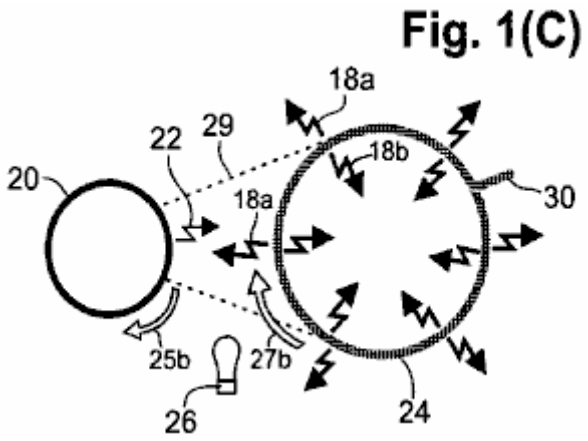

Fig.1C is a schematic end-view of the sending coil and energy-magnifying coil of **Fig.1A**, further depicting the production of inwardly-radiating and outwardly-radiating magnified inductive photons from the energy-magnifying coil.

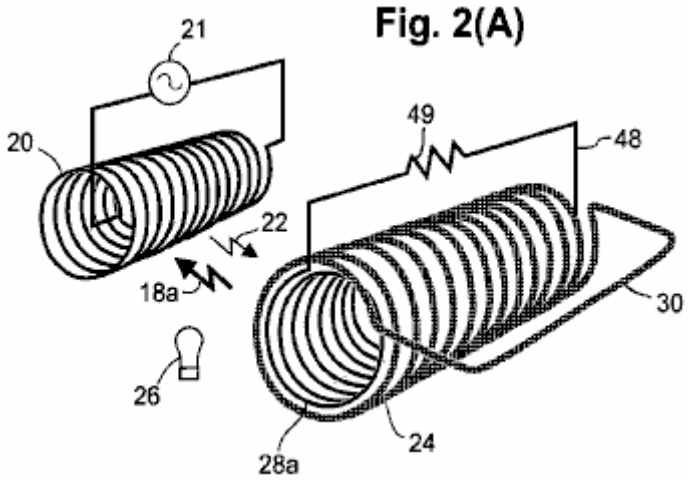

Fig.2A is a perspective view schematically showing an internal output coil, coaxially nested inside the energy-magnifying coil to allow efficient induction of the internal output coil by the energy-magnifying coil, wherein the induction current established in the internal output coil is used to power a load connected across the internal output coil.

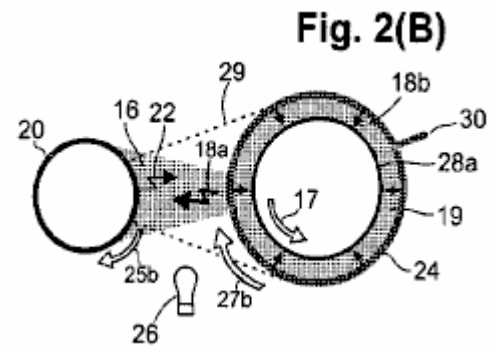

Fig.2B is a schematic end-view of the coils shown in **Fig.2A**, further depicting the greater amount of magnified inductive-photon radiation that is received by the external output coil in comparison to the lesser amount that is directed toward the sending coil to act as a back-force.

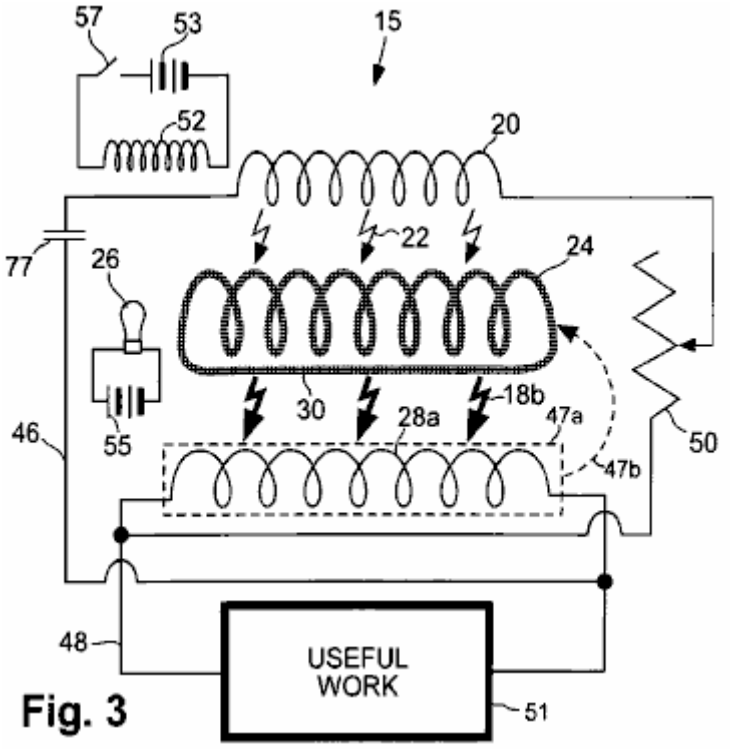

Fig.3 is an electrical schematic diagram of a representative embodiment of a generating apparatus.

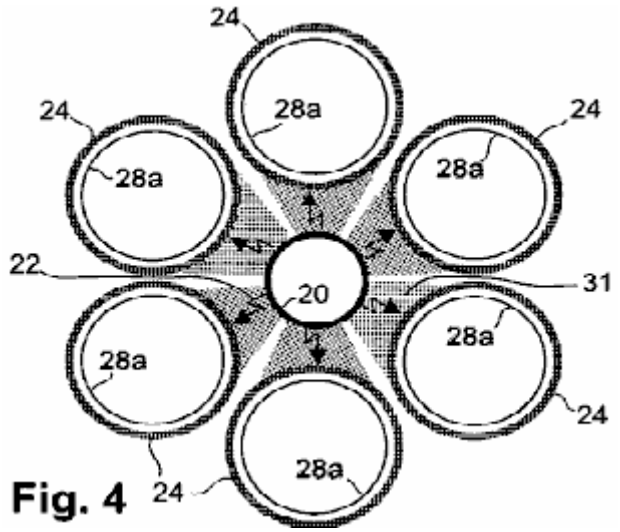

Fig. 4

Fig.4 is a schematic end-view of a representative embodiment, comprising a centrally disposed sending coil surrounded by six energy-magnifying coils, each having and axis which is substantially parallel to the axis of the sending coil. A respective internal output coil is coaxially nested inside each energy-magnifying coil, and the energy-magnifying coils are arranged so as to capture substantially all the inductive photons radiating from the sending coil.

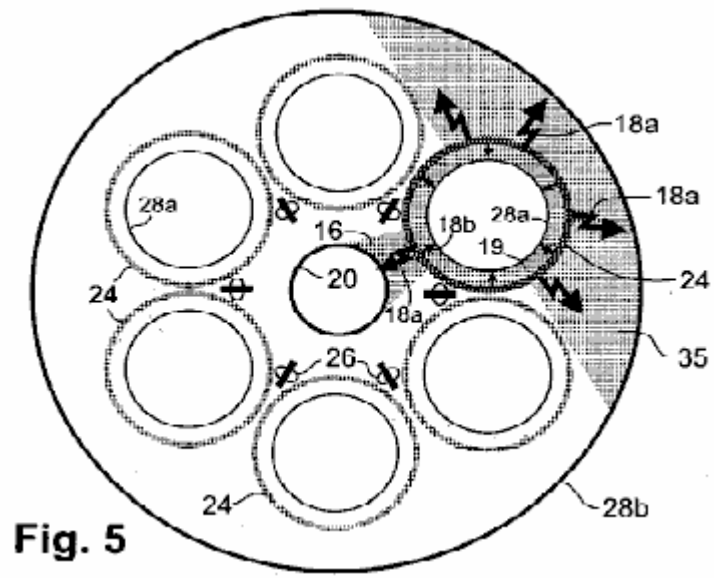

Fig. 5

Fig.5 is a schematic end-view of the embodiment of **Fig.4**, further including an external output coil situated coaxially with the sending coil and configured to surround all six energy-magnifying coils so as to capture outwardly-radiating inductive photons from the energy-magnifying coils. Also depicted is the greater amount of magnified inductive-photon radiation that is received by the internal output coils and the external output coil in comparison to the lesser amount of inductive-photon radiation that is directed towards the sending coil to act as a back-force. Also shown are the arrays of LEDs used for exciting the energy-magnifying coils to become photoconductive.

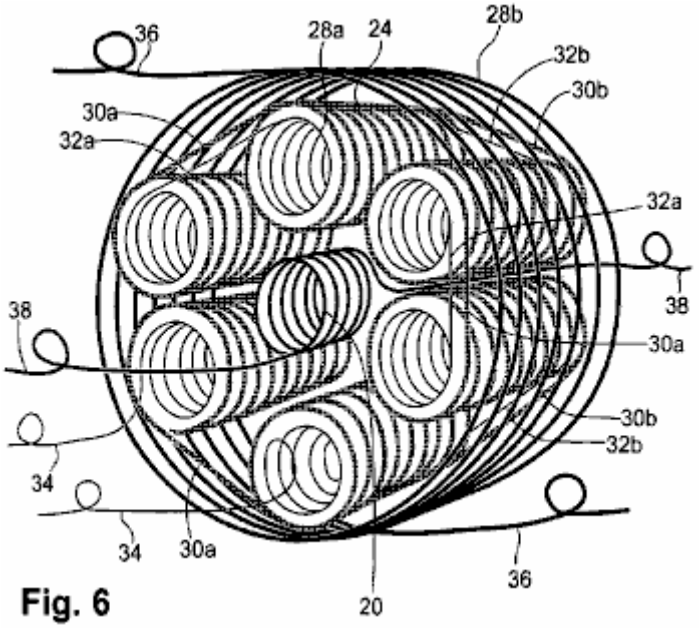

Fig. 6

Fig.6 is a perspective view of the embodiment of **Fig.4** and **Fig.5** but further depicting respective inter-coil connections for the energy-magnifying and internal output coils, as well as respective leads for the sending coil, internal output coils and external output coil.

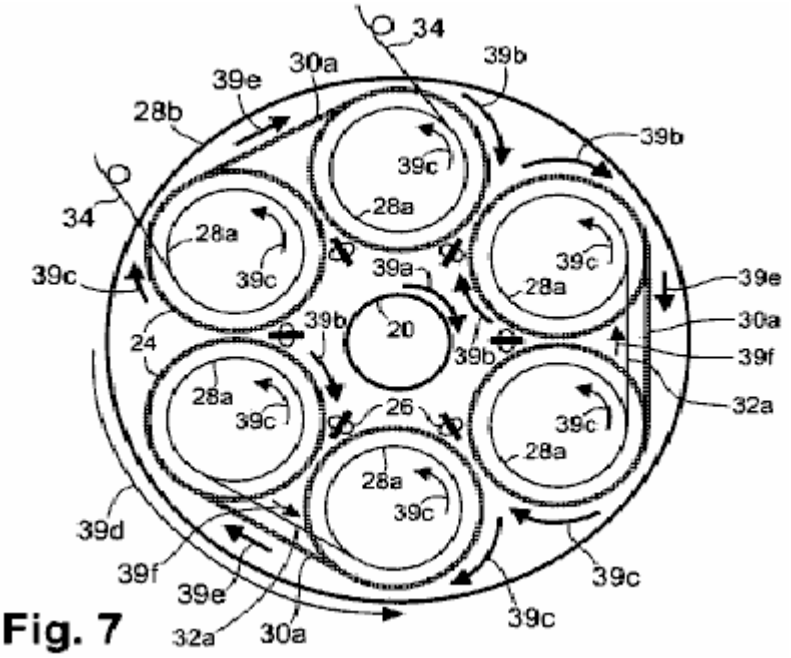

Fig. 7

Fig.7 is a head-end view schematically depicting exemplary current-flow directions in the sending coil, energy-magnifying coils, internal output coils, and external output coils, as well as in the various inter-coil connections of the embodiment of **Fig.4**.

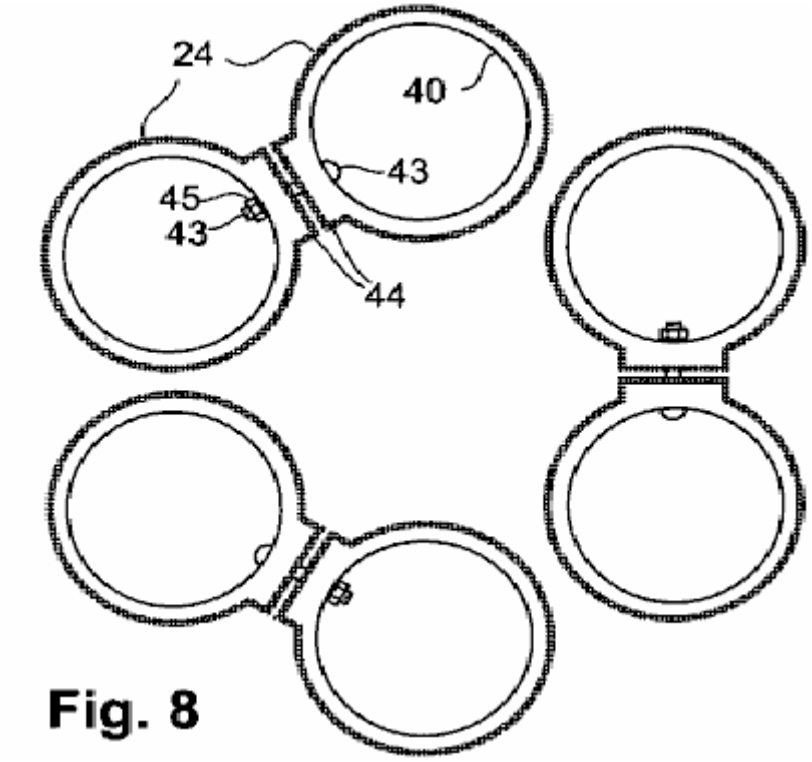

Fig. 8

Fig.8 is a schematic end-view showing an embodiment of the manner in which inter-coil connections can be made between adjacent energy-magnifying coils.

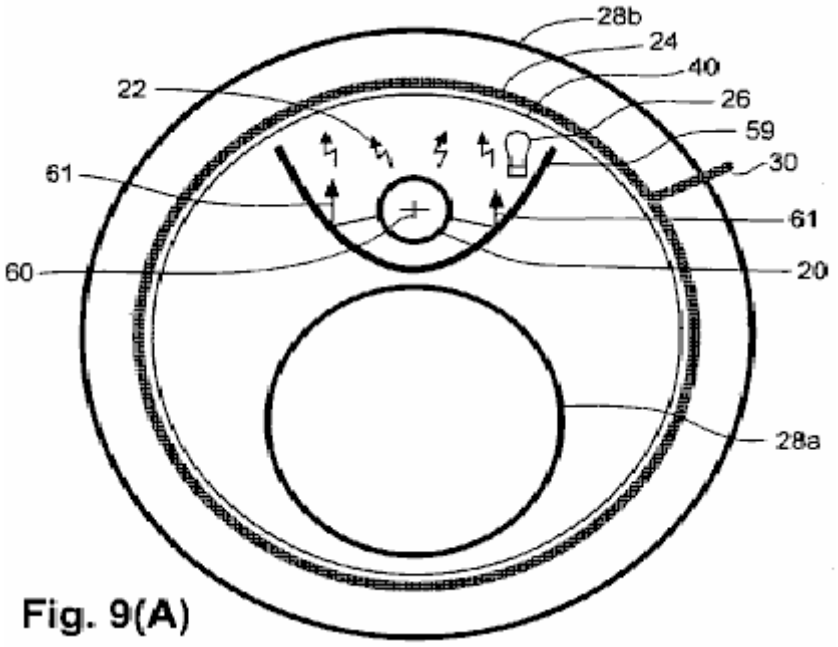

Fig. 9(A)

Fig.9A is a schematic end-view depicting the coil configuration of an embodiment in which a sending coil and an internal output coil are nested inside an energy-magnifying coil, which in turn is nested inside an exterior output coil. A metallic separator, having a substantially parabolic shape, and being situated between the sending coil and the internal output coil, reflects some of the otherwise unused inductive-photon radiation to maximise the effective radiation received by the energy-magnifying coil. Also, the metallic shield prevents the internal output coil from receiving radiation sent from the sending coil.

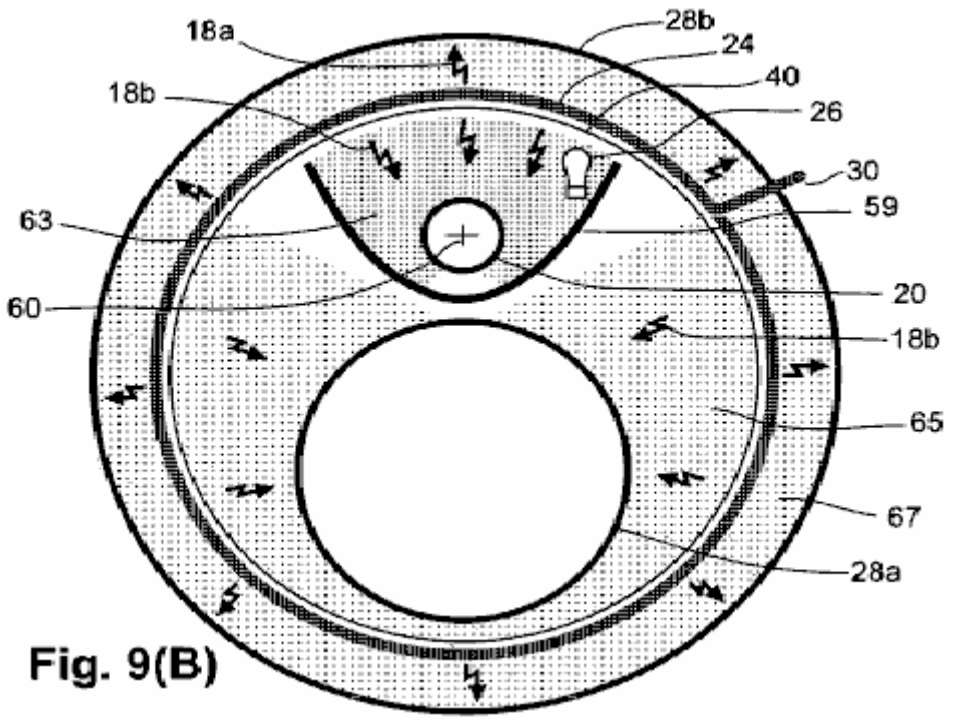

Fig. 9(B)

Fig.9B is a schematic end-view of the coil configuration of **Fig.9A**, further depicting the metallic separator acting as a shield to restrict the back-force radiation reaching the sending coil while allowing the internal output coil to receive a substantial portion of the magnified radiation from the energy-magnifying coil. Also depicted is the greater amount of magnified inductive-photon radiation that is received by the internal output coil and the external output coil in comparison to the lesser amount that is received by the sending coil to act as a back-force.

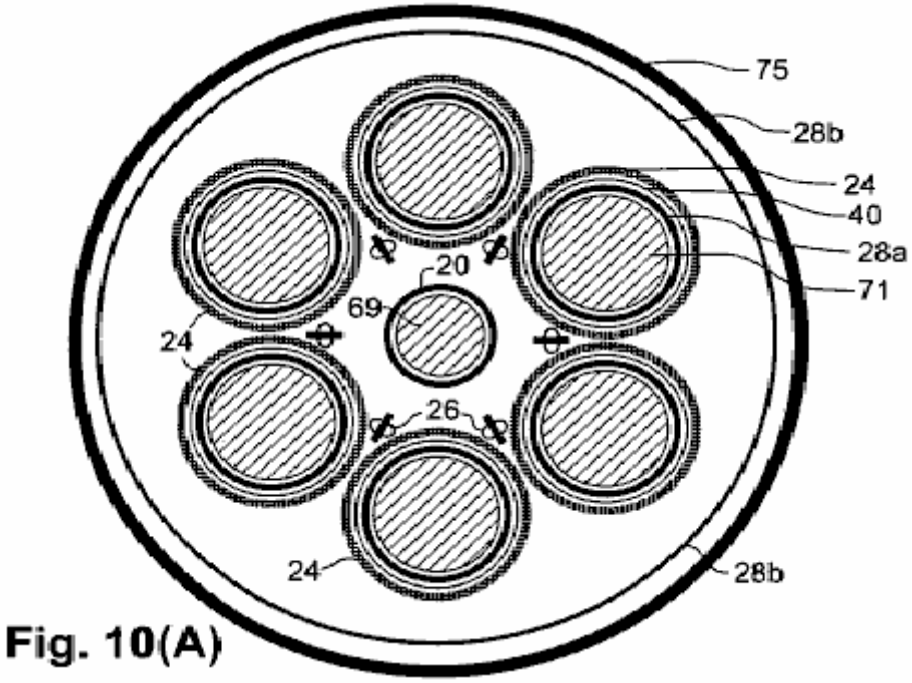

Fig. 10(A)

Fig10A is a schematic end-view depicting the coil configuration of yet another embodiment that is similar in some respects to the embodiment of **Fig.4**, but also including respective ferromagnetic cores inside the sending coil and internal output coils. Also depicted is a metallic shield surrounding the entire apparatus.

Fig. 10(B)

Fig.10B is a schematic end-view of a sending coil of yet another embodiment in which a ferromagnetic sleeve is disposed coaxially around the sending coil.

DETAILED DESCRIPTION

General Technical Considerations

An understanding of how “infinite energy” mistakenly came to be rejected by the scientific community, clarifies the basis of this invention. The electrodynamic function described in the embodiments described below, conforms to Helmholtz’s alternate energy rule, which states that a force which is not in line with it’s causative force “may be lost or gained ad infinitum”. This rule was included in “Uber die Erhaltung der Kraft” (“On the Conservation of Force”) that Hermann Helmholtz delivered to the Physical Society of Berlin in 1847. But, Helmholtz mistakenly believed that “all actions in nature are reducible to forces of attraction and repulsion, the intensity of the forces depending solely upon the distances between the points involved .... so it is impossible to obtain an unlimited amount of force capable of doing work as the result of any combination whatsoever of natural objects”.

Helmholtz refused to accept the idea that magnetic energy qualifies for ad infinitum status despite the fact that Ampere’s (1820) magnetic force on parallel straight conductors is obviously transverse to the direction of the electric currents rather than being in line with the currents. He omitted mention that the magnetic force in Ampere’s (1825) important invention, the solenoidal electromagnet, is caused by currents in the loops of his coils, which are transverse to the direction of magnetic force. Also, he failed to mention that Ampere considered the magnetic force of a permanent magnet to be caused by minute transverse circular currents, which are now recognised as electrons that spin and orbit transversely.

Helmholtz, who was educated as a military medical doctor without any formal study of physics, relied instead on an obsolete metaphysical explanation of magnetic force: “Magnetic attraction may be deduced completely from the assumption of two fluids which attract or repel in the inverse ratio of the square of their distance....It is known that the external effects of a magnet can always be represented by a certain distribution of the magnetic fluids on its surface”. Without departing from this belief in magnetic fluids, Helmholtz cited Wilhelm Weber’s (1846) similarly wrong interpretation that magnetic and inductive forces are directed in the same line as that between the moving electric charges which cause the forces.

Weber had thought that he could unify Coulombic, magnetic, and inductive forces in a single, simple equation, but Weber’s flawed magnetic-force term leads to the absurd conclusion that a steady current in a straight wire induces a steady electric current in a parallel wire. Also, a changing current does not induce an electromotive force in line with the current, as Weber’s equation showed. The induced force is offset instead, which becomes more apparent the further that two nested, coaxial coils are separated. What appears to be a directly opposing back-force is actually a reciprocal inductive force.

Helmholtz’s assertion that the total sum of the energy in the universe is a fixed amount that is immutable in quantity from eternity to eternity appealed to his young friends. But, the elder scientists of the Physical Society of Berlin declared his paper to be “fantastical speculation” and a “hazardous leap into very speculative metaphysics”, so it was rejected for publication in Annalen der Physik. Rather than accept this rejection constructively, Helmholtz found a printer willing to help him self-publish his work. Helmholtz headed the publication with a statement that his paper had been read before the Society, but he disingenuously withheld mention of its outright rejection. Unwary readers have since received the wrong impression that his universal energy-conservation rule had received the Society’s endorsement rather than its censure.

Helmholtz (1862, 1863) publicised his concept thus: “We have been led up to a universal natural law, which ... expresses a perfectly general and particularly characteristic property of all natural forces, and which ... is to be placed by the side of the laws of the unalterability of mass and the unalterability of the chemical elements”. Helmholtz (1881) declared that any force that did not conserve energy would be “in contradiction to Newton’s axiom, which established the equality of action and reaction for all natural forces” (sic). With this deceitful misrepresentation of Newton’s strictly mechanical principle, Helmholtz had craftily succeeded in commuting the profound respect for Newton’s laws to his unscientific doctrine. Subsequently, the Grand Cross was conferred on Helmholtz by the kings of Sweden and Italy and the President of the French Republic, and he was welcomed by the German Emperor into nobility with the title of “von” added to his name. These prestigious awards made his doctrine virtually unassailable in the scientific community.

Ampere’s principle of transverse magnetic attraction and repulsion between electric currents had been made into an equation for the magnetic force between moving electric charges by Carl Fredrick Gauss (written in 1835, published posthumously in 1865). The critical part of the Gauss equation shows, and modern physics texts agree, that magnetic force is transverse to the force that imparts a relative velocity (i.e. perpendicular to a connecting line) between charges. Lacking a direct back-force, a transverse magnetic force can produce a greater force than the force that causes it.

The only physicist to recognise in print, the profound significance of the work of Gauss, was James Clerk Maxwell (1873), who stated "(If Gauss's formula is correct), energy might be generated indefinitely in a finite system by physical means". Prepossessed with Helmholtz's "law", Maxwell chose not to believe Gauss's transverse magnetic-force equation and accepted Wilhelm Weber's (1846) erroneous in-line formula instead. Maxwell even admitted knowing of Gauss's (1845) rebuke of Weber for his mistaken direction of magnetic force as "a complete overthrow of Ampere's fundamental formula and the adoption of essential a different one".

In 1893, the critical part of Ampere's formula for magnetic force, which Weber and Maxwell rejected, and which Helmholtz had replaced with his contrary metaphysical explanation, was proposed for the basis for the international measure of electric current, the Ampere (or amp), to be defined in terms of the transverse magnetic force which the current produces. But Helmholtz's doctrine had become so impervious to facts that anyone who challenged this "law" faced defamation and ridicule.

The first recognition of unlimited energy came from Sir Joseph Larmor who reported in 1897, "A single ion e, describing an elliptic orbit under an attraction to a fixed centre ... must rapidly lose its energy by radiation ... but in the cases of steady motion, it is just this amount that is needed to maintain the permanency of motion in the aether". Apparently to mollify critics of his heretical concept, Larmor offered a half-hearted recantation in 1900: "The energy of orbital groups ... would be through time, sensibly dissipated by radiation, so that such groups could not be permanent".

In 1911, Rutherford found that an atom resembles a small solar system with negative ions moving like planets around a small, positively charged nucleus. These endlessly orbiting electrons were a source of the perpetual radiation that had aptly been described by Larmor, and these orbiting electrons were also Planck's (1911) "harmonic oscillators" which he used to explain Zero-point Energy (ZPE). ZPE was shown by the fact that helium remains liquid under atmospheric pressure at absolute zero, so that helium must be pressurised to become solid at that temperature. Planck believed that harmonic oscillators derived "dark energy" from the aether to sustain their oscillations, thereby admitting that an infinite source of energy exists. However, he assigned an occult origin to this infinite energy, rather than a conventional source that had not met with Helmholtz's approval.

Niels Bohr (1924) was bothered by the notion that radiation from an orbiting electron would quickly drain its energy so that the electron should spiral into the nucleus. Whittaker (1951) states, "Bohr and associates abandoned the principle ... that an atom which is emitting or absorbing radiation must be losing or gaining energy. In its place, they introduced the notion or virtual radiation, which was propagated in ... waves but which does not transmit energy or momentum". Subsequently, the entire scientific community dismissed Larmor radiation as a source of real energy because it failed to conform to Helmholtz's universally accepted doctrine.

Helmholtz's constraining idea that the vast amount of light and heat radiating from the many billions of stars in the universe can only come from previously stored energy, has led scientists to concur that fusion of pre-existing hydrogen to helium, supplies nearly all the energy that causes light and heat to radiate from the sun and other starts. If so, then the entire universe will become completely dark after the present hydrogen supply in stars is consumed in about 20 billion years. William A. Fowler (1965) believed that essentially all the hydrogen in the universe "emerged from the first few minutes of the early high-temperature, high-density stage of the expanding Universe, the so-called 'big bang' ..." Moreover, the background energy of the universe was thought by some to be "relic" radiation from the "Big Bang".

To accept the Big Bang idea that all the stars in the universe originated at the same time, it was necessary to disregard the fact that most stars are much younger or much older than the supposed age of the one-time event, which indicates that their energy must have come from a recurring source. The Big Bang is entirely dependent on the idea that the whole universe is expanding, which stemmed from the interpretation that Hubble's red-shift with distance from the light source, represents a Doppler shift of receding stars and galaxies. This expanding-universe interpretation was shattered by William G. Tifft (1976, 1977), who found that observed red-shifts are not spread randomly and smoothly over a range of values, as would be expected from the Doppler shifts of a vast number of receding stars and galaxies. Instead, the observed red-shifts all fall on evenly spaced, quantised values.

Moreover, Shpenkov and Kreidik (2002) determined that the radiation temperature corresponding to the fundamental period of the orbital electron motion in the hydrogen atom of 2.7289^0K matches the measured temperature of cosmic background radiation of 2.725^0K plus or minus 0.002^0K. This represents perpetual zero-level Larmor radiation from interstellar hydrogen atoms dispersed in the universe. So, Helmholtz's idea that "the energy in the universe is a fixed amount immutable in quantity from eternity to eternity" does not stand up to known facts.

The large aggregate quantity of heat-photons which is generated continually by Larmor radiation can account for the illumination of stars and for the enormous heat and pressure in active galactic centres. Based on the fact that photons exhibit momentum, photons must posses mass, because, as Newton explained, momentum is mass times velocity, which in this case is "c". Consequently, the creation of photons by induction or by Larmor radiation, also creates new mass. The conditions that Fowler was seeking for hydrogen nucleosynthesis, are apparently being supplied indefinitely in active galaxies and possibly in the sun and other stars above a certain size. This invention utilises a similar unlimited energy source.

Another principle that is important to this specification, is that the transfer of energy by electrical induction was found by the Applicant to work in the same manner as the transfer of energy by broadcast and reception of oscillating radio signals. A transverse force is communicated in both cases, the force declines similarly with distance, and the effects of shielding and reflection are identical. Since radio signals are communicated by photons, Applicant considers that inductive force is also communicated by photons. The radiation of newly formed inductive photons results when an accelerated charge experiences a change in direction of acceleration. Inductive radiation occurs when the acceleration of electric charges is reversed, as in Rontgen's bremsstrahlung, in Hertz's linear oscillator (plus all other radio-broadcasting antennas), and in coils which carry an alternating current.

In a similar case, when electric charges move in a curving motion due to a continually changing centripetal acceleration, inductive photons are radiated steadily. This includes the radiation from electrons orbiting atomic nuclei (Larmor radiation) and from conduction electrons flowing in a wire coil, whether the current is steady or not. Circularly produced inductive photons induce a circular motion (diamagnetism) in mobile electrons located near the axis of the electron's circular movement.

In both the reverse-acceleration and centripetal-acceleration cases, inductive photons convey a force to mobile electrons that is transverse to the photon's propagation path. As Lapp and Andrews (1954) reported, "Low-energy photons produce photoelectrons at right angles to their path ...". This same right-angle force without a direct back-force, applies as well, to all conduction electrons which are accelerated by low-energy photons. Hence, inductive energy qualifies for exemption from the energy-conservation law by Helmholtz's same ad infinitum principle which exempts magnetic energy.

The transverse force that inductively produced photons delivered to mobile electrons, is opposite in direction to the simultaneous movement of the primary charge which produces the radiation. This is shown by Faraday's induced current opposite to the inducing current and by the diamagnetically-induced circular motion which, in a rotational sense, is opposite to the circular electron motion in the coil producing it. An oscillating flow of electrons within a loop of a wire coil, induces a force on the conduction electrons which is in the opposite direction in adjacent loops of the same wire. This results in self-induction.

Important to this specification is the realisation that the energy transmitted by photons is kinetic rather than electromagnetic. Inductively radiated photons of low energy, light rays and X-rays cannot be deflected by and electric or magnetic field due to the photons' neutral charge. Neither do neutral photons carry an electric or magnetic field with them. Photon radiation is produced by a change in the acceleration of an electric charge, so only in special cases does it have an electrokinetic origin which involves a magnetic force. To honour these facts, Applicant uses the term "electrokinetic spectrum" in place of "electromagnetic spectrum".

Another principle which is important to this specification is the realisation that, although the charge on the electron has a constant value under all conditions, the mass of an electron is not a fixed, unchanging amount. All free electrons, as in cathode rays, have exactly the same amount of mass at sub-relativistic velocities. This is called "normal" mass and is denoted by m_e. Free electrons have a unique charge to mass ratio that makes the magnetic force resulting from a sub-relativistic velocity imparted to such an electron, exactly equal to the energy input with "normal" electrons.

Also, when a normal electron is given a sub-relativistic acceleration, the inductive force it produces is equal to the force it receives. The mass of highly conductive electrons of metals is apparently very close to normal, but any very slight inductive-energy gains would be masked by inefficiencies. The ubiquity of free electrons and the conduction electrons of metals has led to the view that electron mass is a never-varying figure that would allow the energy conservation law to apply to magnetic energy and inductive energy.

Accurate determinations of electron mass in solid materials have been made possible by cyclotron resonance, which is also called diamagnetic resonance. The diamagnetic force produced by the steady flow of electrons in a wire coil, induces the mobile electrons of a semiconductor to move in a circular orbit of indefinite radius but at a definite angular frequency. This frequency is only related to the inductive force and the mass of the electron. At the same time, a repulsive magnetic force is developed by the relative velocity between the electron flow in the coil and the conduction electrons, causing the mobile electrons of the semiconductor to move in a helical path away from the coil rather than in planar circles. Only two measurements are needed to determine the mass of such an electron: the cyclotron frequency which resonates with the frequency of the electron's circular motion, and the strength of the inductive force, which is determined by the current and dimensions of the coil. Since the co-produced magnetic field is related to the same parameters, its measurement serves as a surrogate for inductive force.

Because the measured mass of conduction electrons in semiconductors is less than normal, a complicated explanation has been adopted to defend the constancy of electron mass in order to support Helmholtz's energy doctrine. An extra force is supposedly received from the vibrational lattice-wave energy of the crystal (in what would have to be an act of self-refrigeration) to make normal-mass electrons move faster than expected around a circular path, thereby giving the appearance that the electron has less mass than normal. In this explanation, the electron is considered to be a smeared-out wave rather than a particle, which is contradicted by the billiard-ball-

like recoil of an electron when it is bumped by a quantum of radiation, as described by Arthur Crompton and Samuel Allison (1935).

The fallacy that borrowed energy can provide a boost in velocity to an electron, is more apparent in the case of linear motion. The effective-mass theory considers that the greater linear velocity is caused by a boost given to normal-mass electrons by a "longitudinal wave" imparted by an externally applied force in the same direction as the electron motion. Since this longitudinal wave is also considered to have a source in crystal-lattice vibrations, the effective-mass theory relies on a reversal of entropy in violation of the second Law of Thermodynamics.

No reasonable contribution of direct directional energy can be invoked from any source to impart abnormally great velocity to the conduction electrons in semiconductors. So, the operation of apparatus embodiments described herein, relies on electrons having particle properties and on electrons having less-then-normal inertial mass without invoking any special forces. This is supported by Brennan's (1999) statement that "the complicated problem of an electron moving within a crystal under the interaction of a periodic but complicated potential, can be reduced to that of a simple free particle, but with a modified mass". The term "effective" is herein considered redundant in referring to truly inertial mass, but "effective mass" still has relevance in referring to the net movement of orbital vacancies or "holes" in the opposite direction of low-mass electrons.

By F = ma, a low-mass electron receives greater acceleration and greater velocity from a given force than an electron of normal mass. The velocity and kinetic energy imparted to an electrically charged body by a force, are determined by the electric charge without regard to the body's mass. Having a smaller amount of mass, allows a body to attain a greater velocity with any given force. Hence, the magnetic force produced by the charge at this higher velocity will be greater than it would normally be for that same amount of force. This allows low-mass electrons to produce a magnetic force that is greater than the applied force.

Also, the amount of inductive radiation energy from accelerated electrons is related to an electron's charge without regard to its mass. The energy of inductive radiation increases with the square of the electron's acceleration according to Larmor's (1900) equation, while the acceleration is inversely proportional to the lesser electron mass relative to normal electron mass. Therefore, the greater-than-normal acceleration of low-mass electrons, allows the re-radiation of magnified inductive-photon energy at a magnification factor which is proportional to the inverse square of the electron's mass, e.g., the inductive-energy magnification factor of cadmium selenide photoelectrons with 0.13 of the normal electron mass is $(0.13)^2$ which is 59 times.

Electrons appear to acquire or shed mass from photons in order to fit the constraints of particular orbits around nuclei, because each orbit dictates a very specific electron mass. In metals, where the conduction electrons seem to move as would a gas, one might think that they would assume the normal mass of free electrons. But the largest mean free path of electrons in the most conductive metals is reportedly about 100 atomic spacings between collisions (Pops, 1997), so the conduction electrons apparently fall back into orbit from time to time and thereby regain their metal-specific mass values.

As conduction electrons pass from one metal type to another, they either lose or gain heat-photons to adjust their mass to different orbital constraints. In a circuit comprising two different metallic conductors placed in series contact with each other, the flow of conduction electrons in one direction will cause the emission of heat-photons at the junction, while an electron flow in the reverse direction causes cooling as the result of ambient heat-photons being absorbed by the conduction electrons at the junction (Peltier cooling effect). When a metal is joined with a semiconductor whose conductive electrons have much lower mass than in metals, much greater heating or cooling occurs at their junction.

John Bardeen (1941) reported that the (effective) mass of superconducting electrons in low-temperature superconductors is only 10^{-4} as great as the mass of normal electrons. This is demonstrated when superconducting electrons are accelerated to a much higher circular velocity than normal in diamagnetically induced eddy currents, which results in enormous magnetic forces which are capable of levitating heavy magnetic objects. Electrons with 10^{-4} times normal mass are apparently devoid, (or nearly devoid) of included photon mass, so normal electrons are deduced to posses about 10^4 times more included photon mass than the bare electron's own mass.

The means by which photon mass may be incorporated within, or ejected from electrons, can be deduced from known information. Based on the Thompson scattering cross-section, the classical radius of a normal electron is 2×10^{-15} cm. If the electron has uniform charge throughout a sphere of that radius, the peripheral velocity would greatly exceed the velocity of light in order to provide the observed magnetic moment. Dehmelt (1989) determined that the radius of the spinning charge which creates an electron's magnetism, is approximately 10^{-20} cm. This apparent incongruity can be explained if the electron is considered to be a hollow shell (which is commensurate with the bare electron's tiny mass in comparison to the very large radius) and if the negative charge of the shell is not the source of the magnetic moment.

It has long been known that a photon can be split into an negative ion (electron) and a positive ion (positron), each having the same amount of charge but of opposite sign. Electrons and positrons can recombine into electrically neutral photons, so it is apparent that photons are composed of a positive and a negative ion. Two

ions spinning around each other could produce the photon's wave nature. The only size of photon ion that can exist as a separate entity has a charge of exactly plus one or minus one, whereas the ions can have a very much larger or very much smaller charge and mass when combined in photons, as long as the two ions are equal in charge and mass. Combined in a photon, the two ions are apparently attracted together so strongly that their individual volumes are very much smaller than as separate entities.

When a dipole photon enters an electron shell, its negative-ion portion is expected to be forced towards the shell's centre by Coulombic repulsion, while the photon's positive ion would be attracted by the negative charge of the shell equally in all directions. The negative photon ions would likely merge into a single body at the electron's centre, while the positive-ion portion would orbit around the centralised negative ion to retain the photon's angular momentum. The high peripheral velocity of this orbiting photon mass would enable portions of photon material to spin off and exit the electron shell at the same velocity at which they entered the electron, i.e., the speed of light. The orbiting of the positive photon charge at Dehmelt's small radius, most likely accounts for the magnetic moment that is observed in electrons of normal mass.

Liberated low-mass conduction electrons within intrinsic semiconductors (which are also photoconductors by their nature) and within doped semiconductors, are mostly protected against acquiring mass from ambient-heat photons by the heat-insulative properties of the semiconductors. In contrast, low-mass electrons injected into heat-conducting metals, rapidly acquire mass from ambient-heat photons by the existence of cryogenic conditions, but they are vulnerable to internal heat-photons created by excessive induction.

Conduction electrons of metals, typically move as a group at drift velocities of less than one millimetre per second, although the velocity of the electrical effects approaches the velocity of light. (Photons are probably involved in the movement of electrical energy in metallic conductors.) In contrast, conductive low-mass electrons can move individually at great velocities in superconductors and semiconductors. Brennan (1999, p. 631) reports the drift velocity of a particular electron moving in a semiconductor, to be one micrometer in about 10 picoseconds, which is equivalent to 100 kilometers per second.

The concentration of the conduction electrons in metals is the same as the number of atoms, whereas in semiconductors, the mobile low-mass electrons which are free to move, can vary greatly with the amount of certain photon radiation received. Since the magnitude of an electric current is a summation of the number of electrons involved, times their respective drift velocities, the current developed by a small ensemble of photoconducting electrons moving at high speed, can exceed the current of a much greater number of conduction electrons moving at a very low speed in a metal.

A general feature of intrinsic semiconductors is that they become photoconductive in proportion to the amount of bombardment by some particular electron-liberating frequency (or band of frequencies) of photon energy, up to some limit. The amount of bombardment by the particular wavelength (or, equivalently, the frequency), increases along with all other photon wavelengths as the ambient temperature rises, that is, as the area under Planck's black-body radiation curve increases. Consequently, the conductivity of semiconductors continues to increase with temperature, while the conductivity drops to almost zero at low temperature unless superconductivity occurs.

A single high-energy alpha particle can liberate a great number of low-mass electrons in a thin-film semiconductor, as Leimer's (1915) energy-magnifying experiment appears to show. Leimer's alpha radiation was situated near the distant end of a suspended antenna wire of unreported length, when he experienced the maximum magnetic energy increase in the coil of the ammeter in the receiver. The low-mass electrons had to have travelled the entire length of the suspended antenna and the connecting line to his receiving apparatus without encountering any trapping holes. Assuming these electrons traversed a distance of 1 to 10 metres in less than one half-cycle of the radio frequency, (that is, less than 4 microseconds at 128 kHz) at which time the direction of the low-mass electron would have been reversed, this would be equivalent to velocities of 25 to 250 km/sec.

A great number of superconducting electrons can be set in motion by inductive photon radiation. In contrast, inductive photon radiation can pass mostly through photoconductors that have low concentrations of mobile, low-mass electrons. Applicant's interpretation of Leimer's experiment is that the liberated low-mass electrons of the semiconductor coating of the antenna wire, were not directly accelerated by the inductive photons of the radio signal, but rather were accelerated to high velocities by an oscillating electric field created in the metallic wire by the radio photons.

A review of an experiment performed by File and Mills (1963), shows that the very low mass of superconducting electrons is responsible for causing supercurrents to differ from normal electric currents. A superconducting solenoidal coil (comprising a Nb-25% Zr alloy wire below 4.3^0 K.) with the terminals spot-welded together to make a continuous conductor, was employed. Extremely slow declines of induced supercurrents were observed, which can be attributed to an enormous increase in the coil's self-induction. Because a supercurrent approaches its maximum charge asymptotically when discharging, a convenient measure of the coil's charging or discharging rate is the "time-constant". The time-constant has the same value for both charging and discharging, and it is defined as (a) the time needed for charging the coil to 63% of the maximum amount of current inducible in the coil by a given diamagnetic force, or (b) the time needed to discharge 63% of the coil's induced current.

In normal conductors, the inductive time-constant is calculated by the inductance of the coil, divided by the resistance of the coil. By use of an empirical equation, the inductance of the coil in its non-superconducting state is calculated to be 0,34 Henry, based on a double-layered solenoid of 384 turns that measured 4 inches (10 cm) diameter and 10 inches (25 cm) long. The resistance of the 0.020 inch (0.51 mm) diameter wire at a temperature of 5^0 K. (just above T_c) is estimated by using data for Zr alone, to be 4×10^2 ohms. (Resistivity data were not available for Nb or the subject alloy). Under non-superconducting conditions, the time-constant for charging and discharging this coil is thereby calculated to be approximately 8×10^{-5} sec.

The time it took to charge up a supercurrent in the coil in the experiment was not reported. But, based on the reported 50 re-energisings and magnetic determinations performed in 200 hours, the measured charging time in the superconducting state is computed to be no more than 4 hours on average.

Using Bardeen's (1941) formula of m is approximately equal to m_e times 10^{-4} for the order of magnitude of the low T_c superconducting electron's mass, and using Larmor's equation (1900) which relates inductive radiation power to the square of the acceleration of the charge, the inductance of the coil is expected to increase by $(10^4)^2 = 10^8$ times in the superconducting state. Thus, the calculated increase in the time-constant of charging up the supercurrent is $8 \times 10^{-5} \times 10^8$ which equals 8×10^3 seconds, or 2.2 hours, which is the same order of magnitude as the maximum actual charging time. The self-induction increased by that amount because the low-mass electrons are accelerated 10^4 times faster.

In the case of discharging, the time constant of the supercurrent was projected by File and Mills from measured declines observed over periods of 21 and 37 days. The projections of the two 63% declines agreed closely at 4×10^{12} seconds ($= 1.3 \times 10^5$ years). Therefore, the time-constant of supercurrent discharge, based on projecting actual measurements, had increased by 5×10^{16} times over the time-constant for electrons of normal mass.

The driving force during charging, had been the applied inductive force, whereas the driving force during discharging was the supercurrent that had been magnified 10^8 times. Therefore, during the discharging of the supercurrent, the time-constant is increased again by 10^8 times, so the calculated total increase in the time-constant of discharge is $10^8 \times 10^8 = 10^{16}$ times greater than the normal time-constant. This calculated value of the non-superconducting time-constant, based solely on the increase of inductive radiation due to extremely low electron mass, compares favourably in magnitude with the actually observed value of 5×10^{16} times the normal time-constant.

The superconducting coil required no more than four hours to charge up the supercurrent, yet during subsequent discharge, the superconducting coil was projected to radiate inductive photon energy from the centripetal acceleration of the superconducting electrons for 130,000 years before declining by 63%. If this experiment could take place where no energy would needed to sustain critical cryogenic conditions, as in outer space, the lengthy discharge of this energised coil would clearly demonstrate the creation of energy in the form of newly-created photons inductively radiating from the superconducting low-mass electrons that circulate around the coil's loops. Applicant interprets this as showing that low-mass electrons are capable of inductive-energy-magnification based solely on their mass relative to that of normal electrons.

In the embodiments described below, the magnified inductive energy of low-mass electrons is utilised in coils for electric-energy generation by employing a flow of inductively accelerated photons that alternates in direction. This, in turn, drives low-mass electrons in an oscillating manner, so this forced reversal involves only a single stage of inductive-energy magnification, rather than the two stages (charging and naturally discharging) in the foregoing experiment.

Mode of Operation

Inductive photons radiating from an oscillating electric current in a sending conductor (e.g. from a radio-wave broadcasting antenna) convey a force, on conduction electrons in a receiving conductor, that is transverse to the incidence direction of the incident inductive photons on the receiving conductor. As a result, no back-force is transferred directly back to the sending conductor. Applicant has discovered that the action of this transverse force on low-mass electrons in a receiving conductor is analogous to the action of Gauss's transverse magnetic force on free electrons in a conductor, which is not subject to the kinetics law of conservation of energy. If the receiving conductor has low-mass conduction electrons, then this transverse force would impart greater acceleration to the low-mass electrons than that it would impart to normal free electrons. The resulting greater drift velocities of low-mass electrons than normal free electrons in the receiving conductor, would yield an increased magnitude of inductive force produced by the low-mass electrons in the receiving conductor and hence produce a magnification of the irradiation energy of inductive photons.

The direction of the transverse force imparted by the radiated inductive photons on conduction electrons in the receiving conductor is opposite to the direction of the corresponding electron flow in the sending conductor. This

relationship is similar to the inductive force on electrons in the secondary coil of a transformer, which also is opposite to the direction of flow of electrons in the primary coil.

Various embodiments of Applicant's electrical generator employ inductive photons radiated from electrical oscillations in a "sending coil". Inductive photons are radiated from the sending coil toward and inductive-photon receiving coil, termed an "energy-magnifying coil", which comprises a photoconductive or superconductive material, or other suitable material as described below. The energy-magnifying coil is placed in a condition favourable for the production of low-mass electrons that participate in electrical conduction in the energy-magnifying coil. For example, if the energy-magnifying coil is made of photoconductive material, the coil is provided with a photoconduction exciter. Alternatively, if the energy-magnifying coil is made of a superconductive material, the coil is placed in an environment at a temperature (T) no greater than the critical temperature (T_C); i.e., $T < T_C$. In the former example, the photoconduction exciter can be a source of illumination which provides an appropriate wavelength of excitive electrokinetic radiation. If the energy-magnifying coil is comprised of a doped semiconductor, the condition that provides mobile low-mass electrons already exists.

In the energy-magnifying coil, the greater-than-normal acceleration of the low-mass electrons produces greater-than-normal inductive forces in the form of greater-than-normal radiation of inductive photons from the coil. The resulting increased inductive-photon energy from the photoconductor or superconductor is converted into useful electrical energy in an output coil inductively coupled to the energy-magnifying coil. The output coil can be made of insulated metallic wire. An exemplary output coil is situated coaxially with, and nested within, the energy-magnification coil. A coil of this type is termed herein, an "internal output coil".

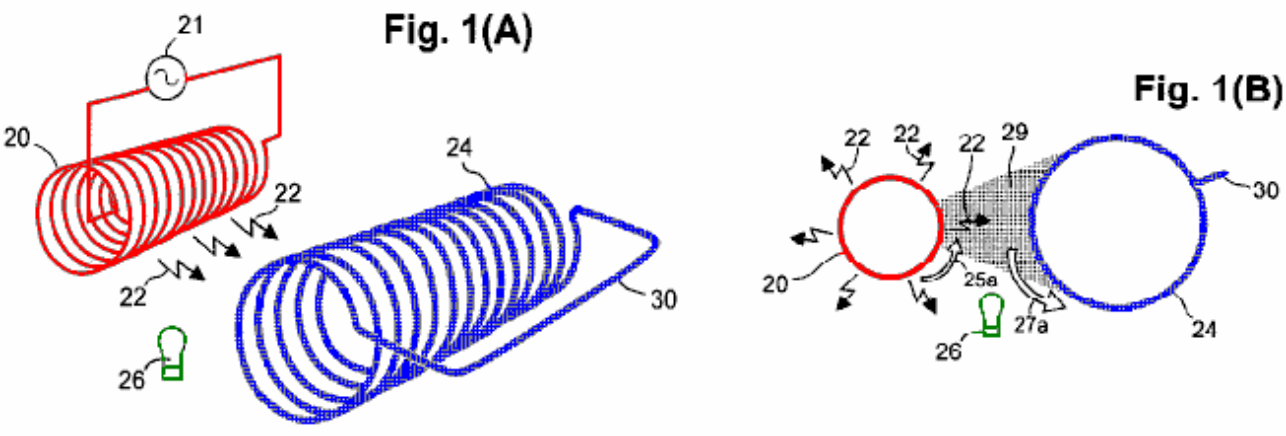
The ability of the subject apparatus to produce more energy output than energy input, is based on the output coil receiving more of the magnified energy from the energy-magnifying coil than is returned as a back-force from the output coil to the energy-magnifying coil. This principle is termed herein "energy leverage".

The oscillations in the energy-magnifying coil are initiated by an external energy-input source that provides an initiating impulse of electron flow in the sending coil. For example, the external energy-input source can be an adjacent independent electromagnet or an adjacent permanent magnet moved rapidly relative to the sending coil. The initiating impulse starts an oscillation in the sending coil that stimulates radiation of inductive photons from the sending coil to the energy-magnifying coil. Energy from the external energy-input source is magnified by the apparatus so long as the energy-magnifying coil does not act as an independent oscillator at a different frequency. Independent oscillation is desirably avoided by connecting the ends or terminals of the energy-magnifying coil to each other in such a way that it results in one continuous coil, or a continuous multiple-coil system or systems, connected together in such a way that continuity exists for the conduction of low-mass electrons throughout the entire coil system. The energy-magnifying coil inductively creates more energy in the output coil than the energy of the initial impulse. The resulting magnified output of electrical energy produced by the apparatus is available for useful purposes in a work loop.

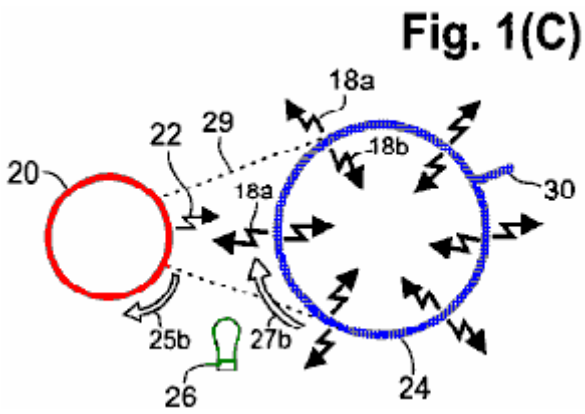
After initiation, the apparatus is made self-sustaining using a feed-back loop arranged in parallel with the work loop that includes the sending coil, and with a capacitor located in the feed-back loop to make it an L-C circuit, i.e., after start-up of the apparatus using the external energy-input source, the apparatus becomes self-resonating, which allows the external energy-input source to be decoupled from the apparatus without causing the apparatus to cease production of electrical energy.

During normal self-sustained operation, a portion of the output electrical energy is returned to the sending coil by the feed-back loop, thereby overcoming the need to use the external energy-input source for sustaining the oscillations in the sending coil. In other words, after startup, the external energy which was used by the sending coil to excite the photoconductive material or the superconducting material in the energy-magnifying coil is replaced by a portion of the output energy produced by the apparatus itself. The remainder of the output electrical energy is available in the work loop for useful purposes.

Initiating the generation of electrical energy by the apparatus, takes advantage of the fact that the inductive back-force sent from the output coil to the energy-magnifying coil (and hence ultimately, back to the sending coil), arrives at the sending coil one cycle behind the corresponding pulse that initiated the flow of electrons. This one-cycle lag of the back-force, as well as a corresponding one-cycle lag in the feed-back, enables small starting pulses produced in the sending coil to produce progressively greater electrical outputs each successive cycle. Consequently, assuming that the electrical load is not excessive during start-up, only a relatively few initiating cycles from the external energy-input source typically are needed for achieving production by the apparatus of an amount of output power sufficient to drive the load as well as providing sufficient energy feed-back to the sending coil in a sustained manner.



A half-cycle of the one-cycle lag occurs between an initial acceleration of electrons in the sending coil and a corresponding initial oscillation in the energy-magnifying coil. This half-cycle lag occurs because induction photons are not radiated from the initial acceleration of electrons in the sending coil, but rather are radiated when the electrons are reverse-accelerated. (Kramers, 1923, and Compton and Allison, 1935, p.106). As the newly formed photons are being radiated by the respective deceleration of electrons in the sending coil, even more new photons are simultaneously being formed by the new direction (i.e. reverse direction) of acceleration under



oscillating conditions. Thus, the radiation of photons from electrons alternatingly accelerated in the opposite direction from the conveyed force, continues each half-cycle after the initial half-cycle.

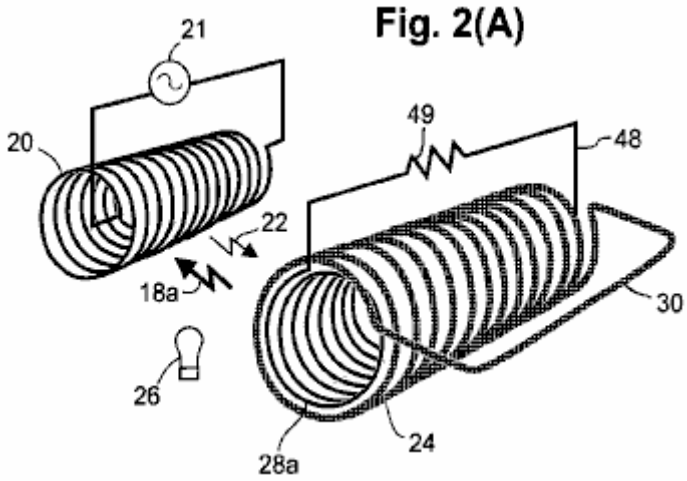
Applicant also discovered that a half-cycle lag also occurs between the initial flow of electrons in the primary coil of a certain type of transformer, which is simply comprised of coils nested coaxially rather than being inductively coupled by an iron core, and the resulting electron flow induced in the secondary coil. When applied to this apparatus, these finding indicate that a second half-cycle lag occurs between the acceleration of low-mass electrons in the energy-magnifying coil and the corresponding electron flow induced in the output coil. The feed-back from the output coil boosts the electron flow in the sending coil one whole cycle after the initial pulse.

As discussed above, the energy-magnifying coil comprises either a photoconductor, a doped semiconductor or a superconductor as a source of, and as a conductor of, low-mass electrons. The general configuration of the coil is similar in either case. The coil including a photoconductor or doped semiconductor, has an operational advantage at normal temperatures, and the coil including a superconductor has an operational advantage at sub-critical temperatures ($T < T_c$), such as in outer space.

Representative Embodiments

Reference is now made to **Fig.1A** to **Fig.1C** and **Fig.2A** and **Fig.2B** which depict a sending coil **20** connected to a source of alternating current **21**. The sending coil is shown having a desirable cylindrical profile, desirably with a circular cross-section as the most efficient configuration. In **Fig.1A** and **Fig.1B**, electrical oscillations from the source **21** are conducted to the sending coil **20** where they cause inductive photons **22** to radiate from the sending coil. The radiated photons **22** convey transverse forces in the same manner that a radio-broadcasting antenna transmits oscillating energy. The sending coil **20** can be a single layer or multiple layers of insulated metal wire (e.g. insulated copper wire). One layer is sufficient, but an additional layer or layers may increase operational efficiency. If necessary, or desired, the turns of wire can be formed on a cylindrical substrate made of a suitable dielectric.

The inductive photons **22** radiating from the sending coil **20**, propagate to an energy-magnifying coil **24** that desirably has a cylindrical profile extending parallel to the sending coil. In the embodiment shown in **Fig.1A** and **Fig.1B**, the energy-magnifying coil **24** does not terminate at the ends, but rather, it is constructed with a connector **30** to form a continuous conductor. The energy-magnifying coil **24** desirably is a helical coil made of a material comprising a photoconductive or superconductive material, or other suitable material. If necessary or desired, the energy-magnifying coil can be formed on a substrate which, if used, desirably is transmissive to the inductive-photon radiation produced by the coil.



In an energy-magnifying coil **24** made of a superconducting material, a large population of conductive low-mass electrons is produced in the coil by lowering the temperature of the coil to a point below the critical temperature for that material. By way of an example, sub-critical temperatures are readily available in outer space or are produced under cryogenic conditions.

In an energy-magnifying coil **24** made of a photoconductor material, a large population of conductive low-mass electrons is produced in the coil by illuminating the coil with photons of an appropriate wavelength, such as photons produced by a photoconduction exciter **26**. The photoconductor exciter **26** desirably is situated and configured so as to illuminate substantially at least the same side of the energy-magnifying coil **24** that receives inductive photons **22** radiating directly from the sending coil **20**. Alternatively, the photoconduction exciter **26** can be situated and configured so as to illuminate all sides of the energy-magnifying coil **24**. In the depicted embodiment, the photoconduction exciter **26** can be at least one incandescent lamp (as shown) energised by conventional circuitry (not shown). Alternatively, the photoconduction exciter **26** can be at least one gas-discharge lamp or one or more Light Emitting Diodes. The wavelength produced by the photoconduction exciter **26** can be, for example, in the infrared (IR), visible, ultraviolet (UV), or X-ray range as required by the particular photoconductor material in the energy-magnifying coil **24**. Another possible form of the photoconduction exciter **26**, is a source of photons in the gigahertz or the terahertz portion of the electrokinetic spectrum. Other photoconduction exciters are configured, as required, to produce a suitable wavelength from the radio-wave portion of the electrokinetic spectrum. The illumination can be either direct from the photoconduction exciter **26** to the energy-magnifying coil **24** or conveyed from a remotely located photoconduction exciter to the energy-magnifying coil via optical fibres, light pipes, or the like.

Fig.1B and **Fig.1C** are respective orthogonal end views of the sending coil **20** and energy-magnifying coil **24** shown in **Fig.1A**. The radiation of inductive photons **22** from the sending coil **20**, is indicated schematically in **Fig.1A**, **Fig.1B** and **Fig.1C** by small, jagged arrows. The forces delivered by the photons **22** to the conductive low-mass electrons in the energy-magnifying coil **24**, alternate in directions which are opposite to the respective directions of simultaneous electron flow in the sending coil **20**. Whenever the particular oscillation phase of electron flow in the sending coil **20** is in the direction of the curved arrow **25a** adjacent to the sending coil **20** in **Fig.1B**, the resulting transverse photon force causes a flow of low-mass electrons in the energy-magnifying coil **24**, depicted by the curved arrow **27a** adjacent to the energy-magnifying coil **24**.

The shaded sector **29**, shown in **Fig.1B**, denotes the proportion of inductive-photon radiation **22** from the sending coil **20**, actually received by the single energy-magnifying coil **24** shown, compared to the entire 360-degree radiation of inductive photons **22** from the sending coil **20**. Aside from a small amount of inductive-photon radiation lost from the ends of the sending coil **20**, the relative amount of the total energy of inductive-photon radiation received by the energy-magnifying coil **24** is determined by the angle subtended by the energy-magnifying coil **24**, relative to the entire 360 degrees of inductive-photon radiation from the sending coil **20**.

In **Fig.1C**, the low-mass conduction electrons of the energy-magnifying coil **24** are accelerated to a higher drift velocity than normal free electrons in the energy-magnifying coil **24** would be. As noted above, the sending coil **20** is energised by alternating electron flow, which causes a periodic reversal of direction of electron flow in the sending coil **20** (compare the direction of the arrow **25b** in **Fig.1C** with the direction of the arrow **25a** in **Fig.1B**). Each reversal of direction of electron flow in the sending coil **20**, causes a corresponding reversal in the direction of acceleration of the low-mass electrons in the energy-magnifying coil **24** (compare the direction of the arrow **27b** in **Fig.1C** with the direction of arrow **27a** in **Fig.1B**). Each such reversal in direction of acceleration causes a corresponding radiation of inductive photons (jagged arrows **18a**, **18b**) radially outwards and radially inwards, respectively, from the energy-magnifying coil **24**. Note that the arrows **18a** and **18b** are larger than the arrows denoting the inductive photons (arrows **22**) from the sending coil **20**. This symbolically denotes energy magnification. Note also that, of the magnified inductive-photon energy radiating from the energy-magnifying coil **24**, substantially half is directed inwards (arrows **18b**), and substantially the other half is radiated outwards (arrows **18a**).

Turning now to **Fig.2A**, the sending coil **20**, and the energy-magnifying coil **24**, are shown. The energy-magnifying coil **24** in **Fig.2A** includes an internal output coil **28a**, that desirably is situated co-axially inside and is of the same length as the energy-magnifying coil **24**. A work loop **48** can be connected to the ends of the internal output coil **28a**, thereby forming an electrical circuit in which a load **49** is indicated symbolically as a resistor. The internal output coil **28a** and the conductors of the work loop **48**, desirably are made of insulated metallic (e.g. copper) wire.

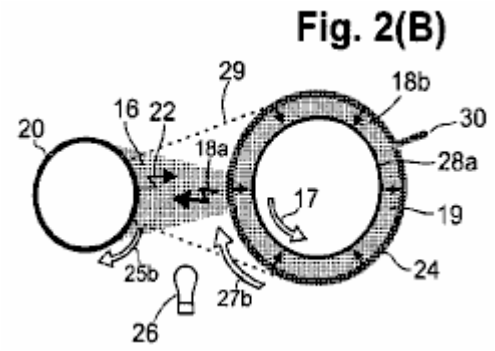


Fig.2B depicts a transverse section of the coils shown in **Fig.2A**. In **Fig.2B**, the magnified inductive-photon energy (shaded area **19**) produced by the energy-magnifying coil **24** and directed radially inwards towards the internal output coil **28a**, induces a corresponding oscillating electron flow in the internal output coil **28a**. Thus, the work loop **48** connected across the internal output coil **28a**, is provided with greater energy than was received by the energy-magnifying coil **24** from the sending coil **20**. The direction of the electron flow (arrow **17**) in the internal output coil **28a**, is opposite to the direction of flow (arrow **27b**) in the energy-magnifying coil **24**, which in turn is opposite to the direction of electron flow **25b** in the sending coil **20**.

In **Fig.2B**, the annular-shaped shaded area 19 between the energy-magnifying coil **24** and the internal output coil **28a**, indicates that substantially all of the internally-directed magnified inductive-photon energy (i.e. approximately half of the total radiation energy) from the energy-magnifying coil **24**, is directed to, and captured by, the internal output coil **28a**. In contrast, the shaded sector **16** extending from the energy-magnifying coil **24** to the sending coil **20**, indicates that a relatively small proportion of the outwardly directed magnified radiation **18a** from the energy-magnifying coil **24** is directed to the sending coil **20** where the radiation provides a corresponding back-force. Aside from the small amount of inductive-photon radiation lost from the ends of the energy-magnifying coil **24**, the relative amount of the magnified inductive-photon radiation (sector **16**) providing the back-force on the sending coil **20**, is a function of the angle subtended by the sector **16**, compared to the 360-degree radiation from the energy-magnifying coil **24**.

The ratio of magnified energy **18b** from the energy-magnifying coil **24** and received by the internal output coil **28a**, to the magnified energy **18a** received as a back-force by the sending coil **20**, denotes the energy “leverage” achieved by the subject apparatus. If this ratio is greater than unity, then the energy output from the internal output coil **28a** exceeds the energy input to the energy-magnifying coil **24**. This energy leverage is key to the self-sustained operation of the apparatus, especially whenever the apparatus is being used to drive a load. In other words, , with a sufficiently large energy-magnification factor achieved by the energy-magnifying coil **24**, the electrical energy available in the work loop **48**, exceeds the input energy that produces the oscillations in the sending coil **20**. The electric power input to the sending coil **20** thereby produces magnified electric power in the internal output coil **28a** that can perform useful work in the work loop **48** while self-powering the continued operation of the apparatus.

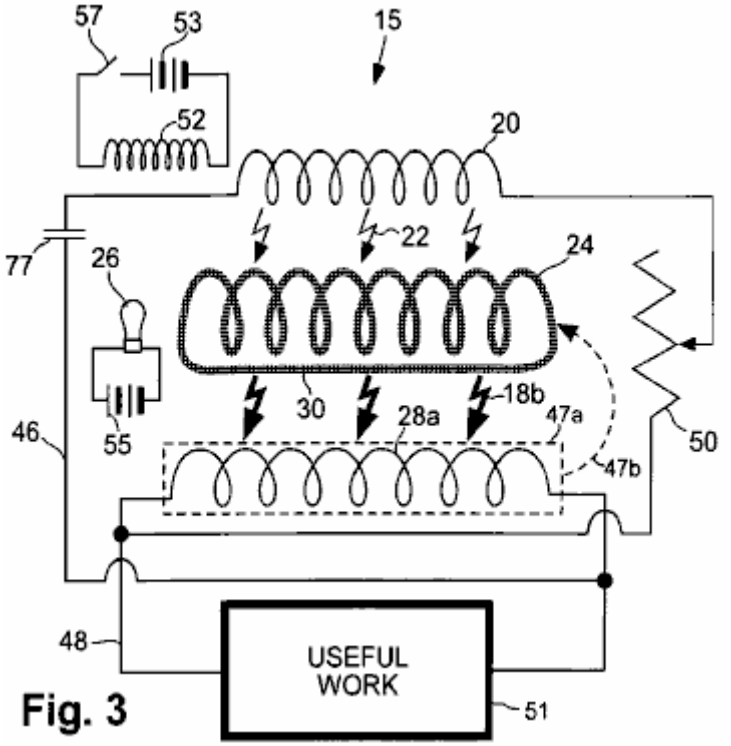

Fig. 3

Reference is now made to **Fig.3**, which schematically depicts aspects of the apparatus **15**, responsible for self-generation of electric power by employing a feed-back loop **46**. The conductors of the feed-back loop **46** can be made of insulated metallic wire. (In **Fig.3**, the dotted lines **47a** and dotted arrow **47b**, indicate that the internal output coil **28a** is actually positioned co-axially inside the energy-magnifying coil **24**, as described above, but is depicted in the figure as being outside the energy-magnifying coil for ease of illustration). The feed-back loop **46**, conducts a portion of the electric power from the internal output coil **28a**, back to the sending coil **20**. The remaining portion of the electric power from the internal output coil **28a** is directed to the work loop **48** where the power is utilised for useful work **51**. The relative proportions of output power delivered to the feed-back loop **46** and to the work loop **48**, can be varied by adjusting a variable resistor **50**.

As noted above, an initial source of electrical energy is used for "starting" the apparatus **15** by initiating an oscillation in the sending coil **20**. After starting, under usual operating conditions, the apparatus **15** is self-resonant and no longer requires the input of energy from the initial source. The particular inductance and distributed capacitance of the sending coil **20**, plus all other capacitances and inductances in the apparatus, provide a certain corresponding frequency of self-resonating oscillation. In the feed-back loop **46** is a capacitor **77** that makes the apparatus an L-C circuit which oscillates at its own frequency. the frequency can be changed by altering the capacitance or inductance of the apparatus, or both. the capacitor **77** can be a variable capacitor by which the frequency can be adjusted.

As shown in **Fig.3**, the initial source of oscillating electrical energy can be an impulse from an external electromagnet **52** powered by its own energy source (e.g. a battery **53** as shown, or other DC or AC source). For example, the electromagnet **52** can be placed near the sending coil **20** or other portion of the feed-back loop **46**, and energised by a momentary discharge delivered from the battery **53** via a switch **57**. The resulting pulse generated in the electromagnet **52**, initiates a corresponding electrical pulse in the sending coil **20** that initiates self-sustaining oscillations in the apparatus **15**. In another embodiment, the electromagnet **52** can be energised briefly by an AC source (not shown). In yet another embodiment, the initial source can be a permanent magnet which is moved rapidly (either mechanically or manually) near the sending coil **20** or other portion of the feed-back circuitry. In any event, the pulse provided by the initial source initiates electrical oscillations in the sending coil **20** that produce corresponding oscillating inductive-photon radiation **22** from the sending coil **20**, as shown schematically in **Fig.3** by thin jagged arrows. The inductive-photon radiation **22** from the sending coil **20** causes, in turn, re-radiation of magnified inductive-photon energy **18b** from low-mass electrons in the energy-magnifying coil **24**, as shown schematically in **Fig.3** by thick jagged arrows. **Fig.3** depicts a photoconductive energy-magnifying coil **24** which is illuminated by an incandescent photoconduction exciter **26** energised by its own power source **55** (e.g., an externally connected battery as shown).

A sufficiently high energy-magnification factor of the apparatus **15** allows the magnified energy from the energy-magnifying coil **24** to induce greater energy in the internal output coil **28a** than the energy of the corresponding initial pulse. A portion of the magnified electrical energy is returned to the sending coil **20** via the feed-back loop **46** to sustain the oscillations.

The remaining surplus energy from the internal output coil **28a** is available for application to useful work via the work loop **48**. In one embodiment, some of this useful work can be used for illuminating the photoconduction exciter **26** (circuitry not shown) in an apparatus configuration in which the energy-magnifying coil **24** comprises a photoconductor. In another embodiment, some of this useful work can be used for maintaining cryogenic ($T < T_c$) conditions for an apparatus configuration in which the energy-magnifying coil **24** comprises a semiconductor.

After starting oscillations in the apparatus **15**, electron flow builds up rapidly, so long as the load **49** does not draw off too much of the output energy during start-up. Upon reaching operating equilibrium, the output of electrical power from the apparatus **15** is a rapidly alternating current (AC). The AC output can be rectified by conventional means to produce direct current (DC), and the output can be regulated as required, using conventional means. Many variations of conventional circuitry are possible, such as, but not limited to, automatic voltage controllers, current controllers, solenoidal switches, transformers, and rectifiers,

Regarding the energy-magnifying coil **24**, an exemplary embodiment can be made from a low - T_c superconductor such as commercially available, flexible, niobium-zirconium wire which can be readily formed into a coil.. Other embodiments, as noted above, of the energy-magnifying coil **24** can be made using a photoconductive material or a high - T_c superconductor. Most high - T_c superconductors (and some photoconductors) have ceramic-like properties and thus require the application of special methods for forming the material into a cylindrical coil having electrical continuity throughout. Some commercially available high - T_c superconductors are available in ribbon or tape form. The energy-magnifying coil **24** can be free-standing or supported on a rigid substrate.

By way of example, an energy-magnifying coil **24** can be made from a ribbon of flexible photoconductive material such as the material discussed in patent US 6,310,281, incorporated herein for reference. Briefly, a layer of stress-compliant metal is placed on a plastic ribbon. Then the photoconductive material is deposited on both sides of the metal-covered ribbon and the edges of the ribbon so that the ribbon is coated all the way around. Such a configuration allows low-mass electrons in the photoconductive material, to receive energy from inductive-photons emitted from the sending coil **20** on one side of the ribbon while re-radiating magnified energy from both sides of the ribbon.

In another example, a flexible photoconductor ribbon is made from flexible organic polymer having photoconductive properties. (High electrical conductivity observed in photoconductive polymers is attributed to the presence of low-mass electrons in the material). The flexible photoconductive ribbon can be wound on a dielectric tubular support, to form the energy-magnifying coil 24.

In yet another example, a thick-film coating of photoconductive cadmium sulphide (CdS) or cadmium selenide (CdSe) is formed on a wire coil by sintering as paste, which comprises a powder of finely ground CdS or CdSe crystals mixed with water and at least a fluidiser such as cadmium chloride, at a temperature of 550^0 C. to 600^0 C. in a controlled atmosphere. During sintering, the boundaries of the small crystals become melted with the heated fluidiser, allowing the crystals to regrow together and solidify when the fluidiser evaporates and the sintered coating is cooled. Alternatively, copper oxides are formed in place on bare copper or bronze wire by heating the wire above about 260^0 C. in an oxygen atmosphere, or by application of chemical oxidants.

In yet another example, a coil of ceramic-like superconductor or photoconductor is made by tape-casting, extruding, slip-casting, cold or hot-pressing, or coating of the material as a thin film arranged helically on a tubular dielectric substrate. The assembly is heat-treated in a controlled atmosphere furnace to increase inter-crystalline contacts. Alternatively, the thin film of superconductor or photoconductor is formed over the entire exterior of the dielectric substrate, followed by removal of selected portions of the superconductor or photoconductor to form the desired helical coil.

[121]In some photoconductors and doped semiconductors, only a small portion of a population of inductive photons irradiated on the material, impact with, and yield acceleration of, low-mass electrons in the material. This is due to a low density of photoconductive low-mass electrons in the material. In such as case, inductive-photon radiation passing through the material can be captured efficiently by normal free conduction electrons in a metallic strip that desirably is in immediate contact with, or embedded in, the material. The acceleration of normal free electrons in the metallic conductor, sets up an electric field that assists in accelerating the low-mass photoelectrons. In this configuration, it is desirable that the photoconductive material be disposed completely over and around the metallic strip so that the photoconductor faces both outwards and inwards, with both sides of the photoconductor or doped semiconductor being in electrical contact with each other.

One factor in the choice of photoconductor material to use in forming the energy-magnifying coil **24** is the potential magnification of energy that can be realised by low-mass electrons of an n-type or p-type photoconductive material. Other important factors are the quantity of low-mass electrons that are available in the photoconductive material for a given amount of illumination and the actual electrical conductance of the material. Standard illumination-sensitivity measurements provide a general overall index of the ability of a photoconductor to serve effectively in magnifying energy.

Cadmium sulphide and cadmium selenide, the most common photoconductive compounds which are available commercially, have calculated magnification factors of 37 and 59, respectively. The peak response wavelength of cadmium sulphide is 515 nanometers (in the green part of the visible spectrum) and of cadmium selenide is 730 nanometers (in the near-infrared part of the spectrum). Cadmium sulphide can be mixed with caesium selenide under certain conditions, so the resulting mixture assumes photoconductive characteristics between those two values. Mixtures can be produced having peak wavelengths which are matched to the wavelengths of commercially available LEDs of many sizes and illumination intensities. Some semiconductors which become photoconductive at a wavelength smaller than the wavelength produced by currently available LEDs can be made conductive of low-mass electrons merely by heating.

Applicant has found that gallium arsenide develops considerably higher conductivity than copper or silver at a temperature of 100^0 C. and that the conductive electrons are low-mass. Also, alpha radiation is capable of liberating many low-mass electrons in some semiconductors. A second electron of comparatively low mass may have been liberated from cupric oxide by alpha radiation along with the outer copper electron in Leimer's (1915) experiments, since the measured energy magnification exceeded the magnification calculated from cyclotron resonance of CuO, which most likely pertains only to the mass of the outer electron.

Dopants can be added to a semiconductor to make it more conductive of low-mass electrons without illumination. Also, the illumination-sensitivity and conductivity of cadmium sulphide are increased by adding small amounts of donor-type dopants such as, but not limited to, sulphides, selenides, tellurides, arsenides, antimonides and phosphides of the Type-IIIa elements: aluminium, gallium, indium and thallium. In this regard, the photoconductors of high-sensitivity photovoltaic cells may comprise as many as five different compounds. The actual mixtures of photoconductive compounds and dopants used in commercially available photovoltaic cells often are trade secrets. But, the sensitivity and conductances of the cells are usually given or are measurable, and these data can be used advantageously in selecting a particular photoconductive compound for use in the apparatus.

Other photoconductive compounds or elements can be employed in energy-magnifying coils. For example, the conduction electrons of silicon have an energy-magnification factor of 15 times. Photoconductors having very high magnification factors include, but are not limited to, gallium arsenide, indium phosphide, gallium antimonide, cadmium-tin arsenide, and cadmium arsenide, which have calculated energy-magnification factors ranging between 200 times and 500 times, and mercury selenide (1100 times), indium arsenide (2000 times), mercury telluride (3400 times) and indium antimonide (5100 times).

The depth of optical transmission largely determines the optimum thickness of photoconductive films for energy-magnifying coils. For example, the highest optical transmission of sintered CdS is reported to be 20 micrometers, but since the average grain size increases (and the average porosity decreases) with an increase in film thickness, the maximum conductivity of a sintered film is at a thickness of 35 micrometers (J. S, Lee et al., 1987).

The metal chosen to be embedded must not react chemically with the photoconductor. For example, aluminium reacts with gallium arsenide (GaAs) in an electrical environment, to change the conductive character of both the GaAs and the aluminium. Gold, platinum, and palladium can serve in many cases because these materials are relatively inert chemically. Gold combines chemically with tellurium, however, so gold is not suitable for embedding in mercury telluride. Cadmium plating over a common metal serves to alleviate the reactivity in cases where cadmium sulphide or cadmium selenide is used as the photoconductor.

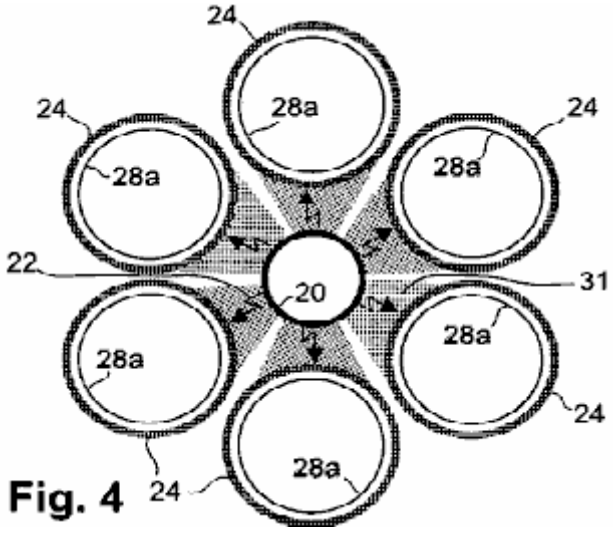

Fig. 4

The discussion above has been, for ease of explanation, in the context of the apparatus including one energy-magnifying coil **24**. However, as discussed, use of a single energy-magnifying coil **24** to capture inductive photons from the sending coil **20**, results in loss (by non-capture) of most of the inductive photons from the

sending coil **20**. This proportion of captured inductive photons can be increased greatly in an embodiment in which multiple energy-magnifying coils **24** substantially completely surround the sending coil **20**, such as shown in **Fig.4**. In this embodiment, the energy-magnifying coils **24** substantially completely surround the sending coil **20**, and (although six energy-magnifying coils **24** are shown) as few as three energy-magnifying coils **24** of adequate diameter, still could substantially completely surround the sending coil **20**. There is no limit, except as possibly related to packaging concerns, to the maximum number of energy-magnifying coils **24** which could be used. The depicted configuration of **Fig.4**, has a desirable number of six energy-magnifying coils **24**. In **Fig.4**, the shaded sectors **31**, considered collectively, illustrate that nearly all 360 degrees of inductive-photon radiation **22** from the sending coil **20**, are received by the energy-magnifying coils **24**. Not shown in **Fig.4** are photoconduction exciters (items **26** in **Fig.3**) used for illuminating respective portions of the energy-magnifying coils **24** in a photoconductive form of the apparatus **15**.

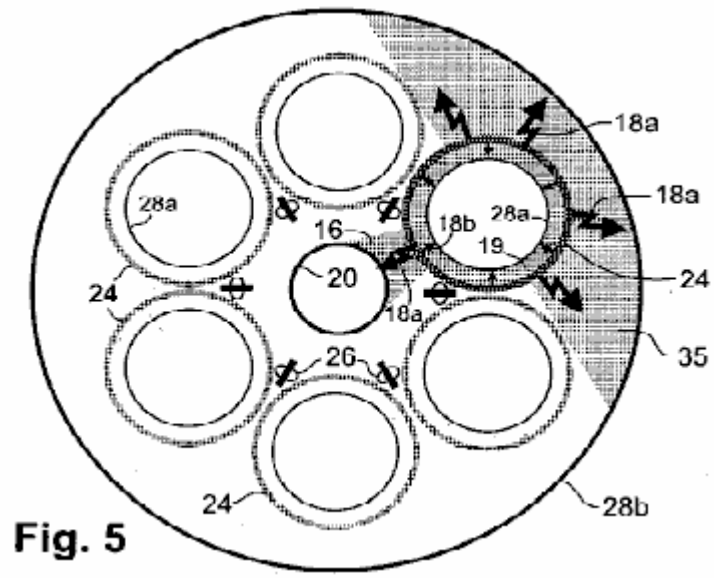

Fig. 5

Fig.4 also depicts respective internal output coils **28a** nested co-axially and co-extensively inside each of the energy-magnifying coils **24**. As discussed earlier, each internal output coil **28a** receives nearly all the inductive-photon radiation propagating radially inwards from the respective energy-magnifying coil **24**. Desirably, the overall energy output of the embodiment of **Fig.4**, can be increased by surrounding the array of energy-magnifying coils **24** with an external output coil **28b**, of which the conductors desirably are made of insulated metallic wire (**Fig.5**). In this embodiment, approximately half of the outwardly propagating magnified inductive-photon radiation (large arrows **18**) from each energy-magnifying coil **24** (one such coil is highlighted in **Fig.5**) is received by the external output coil **28b**. This captured radiation is denoted by the shaded sector **35**. When this externally directed inductive radiation captured from all the energy-magnifying coils **24** is added to all the inwardly directed radiation captured from the energy-magnifying coils **24** by their internal output coils **28a**, **28b**, greatly exceeds the back-force energy directed by the energy-magnifying coils **24** towards the sending coil **20** (the back-force energy from one energy-magnifying coil **24** is shown as the shaded sector **16**). Thus, the resulting energy "leverage" exhibited by the apparatus is increased substantially by including the external output coil **28b**.

The embodiment of **Fig.5** also includes respective arrays (viewed endwise) of light-emitting diodes (LEDs) collectively serving as photoconductor exciters **26** for the energy-magnifying coils **24**. The LED arrays are arranged back-to-back and disposed between adjacent energy-magnifying coils **24**. Each array in **Fig.5** can comprise multiple LEDs or as few as one LED.

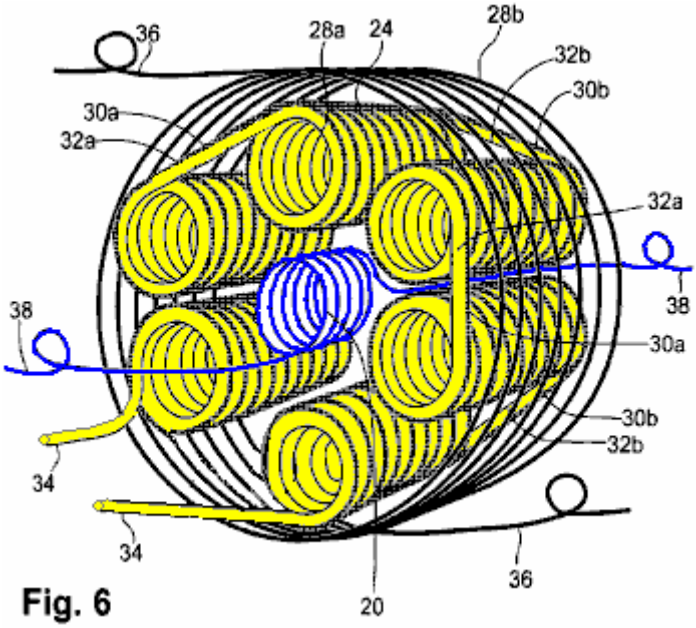

Fig. 6

Fig.6 provides a perspective view of an apparatus **15** having an arrangement of coils similar to the arrangement shown in **Fig.5**. In **Fig.6**, each energy-magnifying coil **24** comprises a helical coil of superconductive or photoconductive material in wire or ribbon (tape-like) form.

Whenever multiple energy-magnifying coils **24** are used, the respective directions of electron flow in them desirably occur in the same circular direction as viewed endwise. Thus, the flow of electrons in all the energy-magnifying coils **24** is clockwise during one phase of an oscillation cycle and counterclockwise during the other phase. The same principle applies to the flow of electrons in the output coils **28a**, **28b**. (But, in such an embodiment, the flow of electrons in the output coils **28a**, **28b**, is in the opposite direction to the electron flow in the energy-magnifying coils **24**). These relationships of electron flow in the coils during a particular phase of an oscillation cycle, are shown in **Fig.7**.

The energy-magnifying coils **24** desirably are connected together in series, using inter-coil connectors **30a**, **30b**, to maintain the same direction of electron flow, which can be clockwise or counterclockwise (as viewed from one end of such a coil). This direction of electron flow in a coil is termed the “handedness” of the coil. If the energy-magnifying coils **24** all have the same handedness, then the ends of adjacent energy-magnifying coils **24** are connected together in a head-to-foot manner progressively in one direction around the group of coils (not shown). (“Head” refers to the forward-facing end, and “foot” refers to the rearward-facing end of the apparatus in relation to the viewer). In this case, the inter-coil connectors **30a**, **30b**, must pass either completely through the apparatus or around the outside of the apparatus for its entire length, which reduces efficiency and can cause undesirable wear if the connectors are subjected to vibrations. A more desirable arrangement is depicted in **Fig.6**, in which short inter-coil connectors **30a**, cross directly head-to-head between one energy-magnifying coil **24** and an adjacent energy-magnifying coil **24**, and short inter-coil connectors **30b** cross over directly foot-to-foot in the next energy-magnifying coils **24**. In this configuration, the handedness of turns of the energy-magnifying coils **24** alternates from right-to-left to left-to-right in adjacent energy-magnifying coils **24**. In the same manner as a right-handed screw advances from head to foot as it is turned clockwise, and a left-handed screw moves in the opposite direction, clockwise electron flow in a right-handed coil advances from head to foot, and clockwise electron flow in a left-handed coil advances from foot to head.

The single-layered internal output coils **28a** in **Fig.6**, present the same situation in which these coils are connected in series. Desirably, the inter-coil connectors **32a** cross over directly from one internal output coil **28a** to the adjacent internal output coil **28a**, head-to-head and the inter-coil connectors **32b** cross over directly foot-to-foot from one internal output coil **28a** to the adjacent internal output coil **28a**. This same handedness convention generally applies to all series-connected internal output coils **28a** connected in this manner. The head-to-head inter-coil connectors **32a** and foot-to-foot inter-coil connectors **32b** for the internal output coils **28a**, need not coincide with the same respective connectors **30a**, **30b** for the energy-magnifying coils **24**.

In another embodiment (not shown), each internal output coil is two-layered, with both leads at either the head or foot. Such a configuration allows for short and direct connections between adjacent internal output coils. Multiple-layered internal output coils may be more efficient, but the extra layers of coiled wire increase the mass of the apparatus, which may be a concern in mobile applications. Multiple wire layers carrying high current may also result in overheating, which may require that some space be left between each internal output coil **28a** and its surrounding energy-magnifying coil **24** to accommodate one or more conduits of a coolant through the

apparatus (at a sacrifice of some efficiency). The coolant can be, for example, forced air (in the case of photoconductors or doped semiconductors) or liquefied cryogenic gas (in the case of superconductors).

Fig.6 also shows two external conductors **34** connected to respective internal output coils **28a**. Electrons flow through the conductors **34** and the internal output coils **28a** in series. In addition, two external conductors **36** are connected to respective ends of the external output coil **28b**, and two external conductors **38** are connected to respective ends of the sending coil **20**.

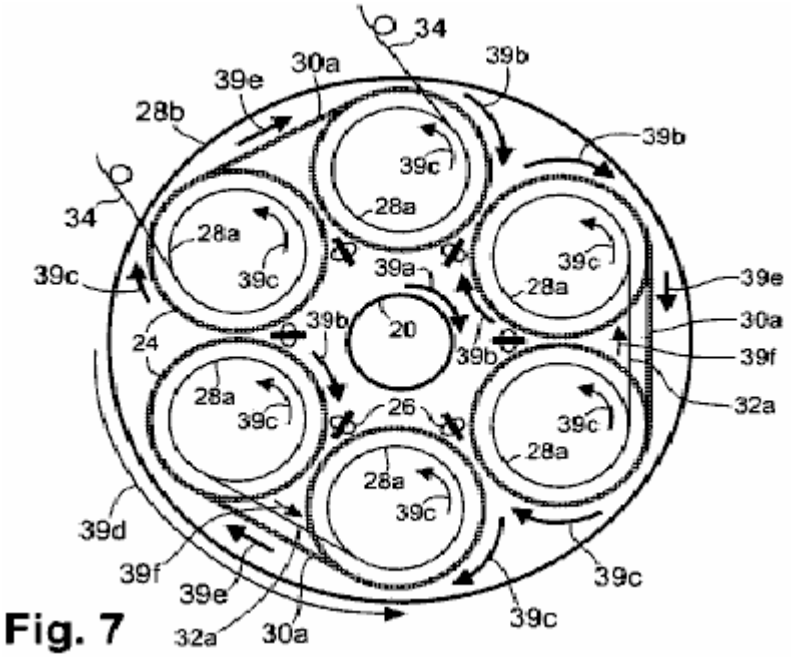

Fig. 7

Fig.7 is a schematic end view of the apparatus of **Fig.6**, showing the relative direction of electron flow in the various coils and in the inter-coil connections described for single-layer coils. At a particular oscillation phase, the clockwise electron flow denoted by the arrow **39a** in the sending coil **20** induces clockwise electron flow **39b** in all the energy-magnifying coils **24**. The magnified radiation from the clockwise electron flow in the energy-magnifying coils **24**, induces counterclockwise electron flow in all the internal output coils **28a**, as indicated by the arrows **39c**. The counterclockwise electron flow, denoted by the arrow **39d**, in the external output coil **28b** is opposite in direction to the electron flow in the energy-magnifying coils **24**.

The electron flow in the inter-coil connectors **30a** extending between adjacent energy-magnifying coils **24** is indicated by the arrows **39e**, and the electron flow in the inter-coil connectors **32a** extending between adjacent internal output coils **28a** is indicated by the arrows **39f**. During the next oscillation phase, all the direction arrows shown in **Fig.7** reverse themselves.

Connecting the internal output coils **28a** together in series is advantages if it is desired to maximise the output voltage from the apparatus **15**. Alternatively, the internal output coils **28a** can be connected together in parallel if it is desired to maximise the output electrical current from the apparatus **15** while minimising the output voltage. In this alternative configuration, all the internal output coils **28a** desirably are wound with the same handedness, with each coil **28a** having two respective leads. The leads at one end (e.g., the foot end) of the coils **28a** are connected to each other, and the leads at the other end (the head end) of the coils **28a** are connected to each other. The resulting parallel-coil system is connected in a conventional manner in other circuitry of the apparatus (not shown).

Further alternatively, the internal output coils **28a** can be connected together so as to provide more than one output circuit (so long as sufficient energy is produced for use as feedback to the sending coil **20** and for use in establishing favourable conditions for producing abundant low-mass electrons). Alternatively, the relative voltage(s) and current(s) of output power can be varied by changing the ratio of the number of turns in the energy-magnifying coils **24** to the number of turns in the internal output coils **28a**. Alternatively again, the energy-magnifying coils **24** can be employed in a separate manner to provide more than one energy-magnifying unit. Each unit can comprise one or more energy-magnifying coils that can serve its respective circuit of internal output coils.

The two conductors **36** connected to the external output coil **28b**, can be connected to the internal output coils **28a** or can be used (without being connected to the internal output coils **28a**) with only the external output coil **28b** to provide an independent output circuit (not shown). The two conductors **38** connected to the sending coil **20**,

are connected in the feed-back loop **46** such that electron flow in the sending coil **20** is in the same circular direction as in the internal output coils **28a**.

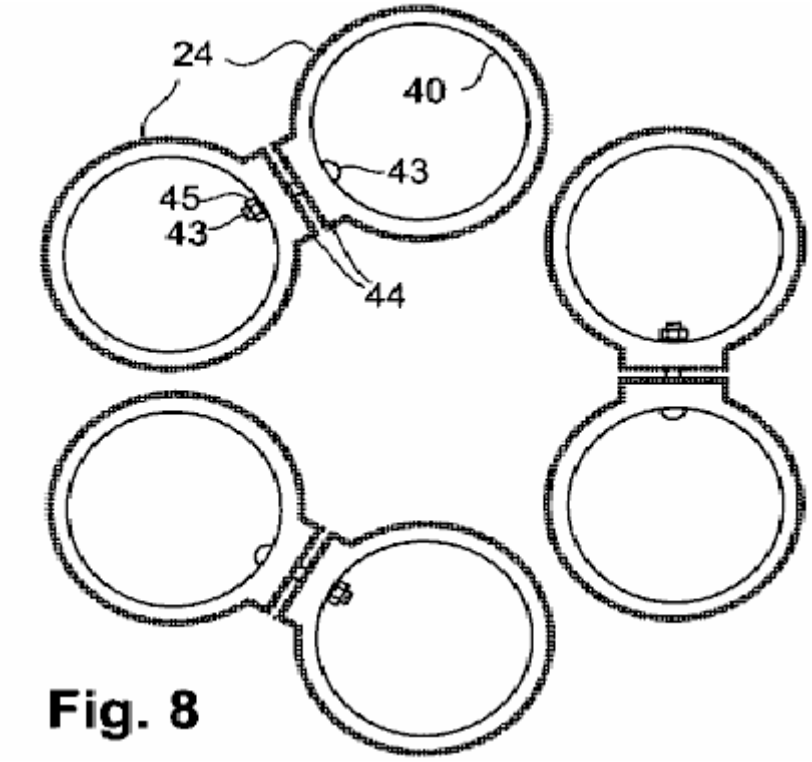

Fig. 8

Fig.8 depicts yet another embodiment of the apparatus **15**, in which each energy magnifying coil **24** comprises a thin film or thick film of a polycrystalline or other suitable photoconductor deposited in a helical manner directly on to a tubular substrate **40** desirably made of ceramic or other suitable dielectric material. on each energy magnifying coil **24**, the polycrystalline photoconductor is formed as a helical band on the outside of the tubular substrate **40**. The helical band of photoconductor can include a thin film of metal embedded within it. In certain cases, inter-coil connections between adjacent energy magnifying coils **24** can be made by extending the deposited photoconductor from the helices to contact areas **44** situated at the ends of the tubular substrates **40** and extending toward contact areas **44** on adjacent tubular substrates **40**. Electrical contact between adjacent energy magnifying coils **24** is made under moderate pressure via the contact areas **44**, which are shown in **Fig.8**. To distinguish the individual contact areas **44**, they are shown in a separated position before being pressed together to make contact. To maintain the integrity of the contact areas **44**, the energy magnifying coils **24** can be held together in mutual proximity by any of various non-metallic fasteners to make continuous electrical contact between all of the photoconductive portions. For example, bolts **43** and nuts **45** made of a plastic such as nylon, or other dielectric material, can be used. Another variation is to maintain contact pressure of one coil to the next by means of spring clips. Thus, in one embodiment, the energy magnifying coils **24** are connected so as to be in endless contact with each other, with no capacitative break between them. The remainder of the apparatus can be constructed in the same manner as the photoconductor or doped-semiconductor embodiment described above, wherein the same attention to the direction of electron flow in respective coils is observed.

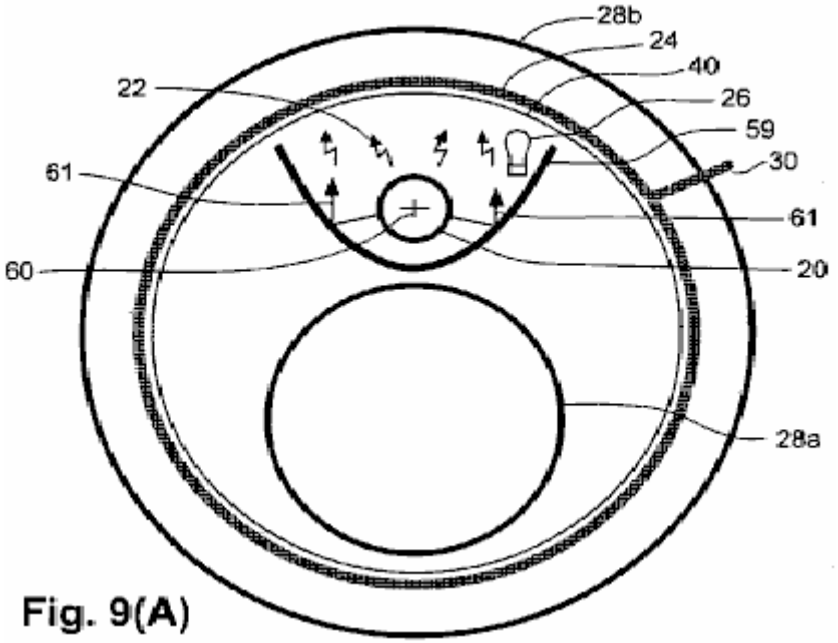

Fig. 9(A)

The coil configuration of yet another embodiment is shown in **Fig.9A** and **Fig.9B**. A tubular substrate **40**, supports a helical, thin film or thick film, dipole-type of energy-magnifying coil **24** that is nested inside and coaxial with a single external output coil **28b**. Nested inside the tubular substrate **40**, and with respective axes parallel to the axis of the tubular substrate **40**, are a sending coil **20** and an internal output coil **28a**. The sending coil **20** and the internal output coil **28a**, are positioned on opposite sides of a reflective metallic separator **59**. The separator **59** is substantially parabolic in cross-section throughout its axial extent, and is positioned so that the longitudinal edges are touching, or nearly touching, the tubular substrate **40**. The separator **59** can be composed of common, non-magnetic metal such as aluminium or magnesium. The sending coil **20** is positioned on the concave side of the separator **59**, with the axis of the sending coil **20** being positioned at the geometric focus **60** of the parabola and disposed parallel to the axis of the energy-magnifying coil **24**. The energy-magnifying coil **24** in this embodiment, comprises a thin film or thick film photoconductor formed helically on the tubular substrate **40**. A photoconduction exciter **26** is positioned inside the separator **59**. (The tubular substrate **40**, is made of a rigid material that is transparent to radiation produced by the photoconduction exciter **26**). All the other forms of the energy-magnifying coil **24** as described herein, including the superconducting form, can be employed in this embodiment.

The separator **59**, serves a double purpose. One purpose is to direct towards the energy-magnifying coil **24** the portion of the inductive-photon radiation **22** which is not otherwise directed towards the separator, as shown by the reflected-photon rays **61** in **Fig.6A**. (Reflection of these radiated photons does not change the directionality of the transverse force which these photons convey). Another purpose of the separator **59** is to serve as a shield to restrict the amount of inward radiation **18b** from the energy-magnifying coil **24** which is returned as a back-force to the sending coil **20**. The restricted back-force radiation is shown by the shaded area **63** in **Fig.9B**.

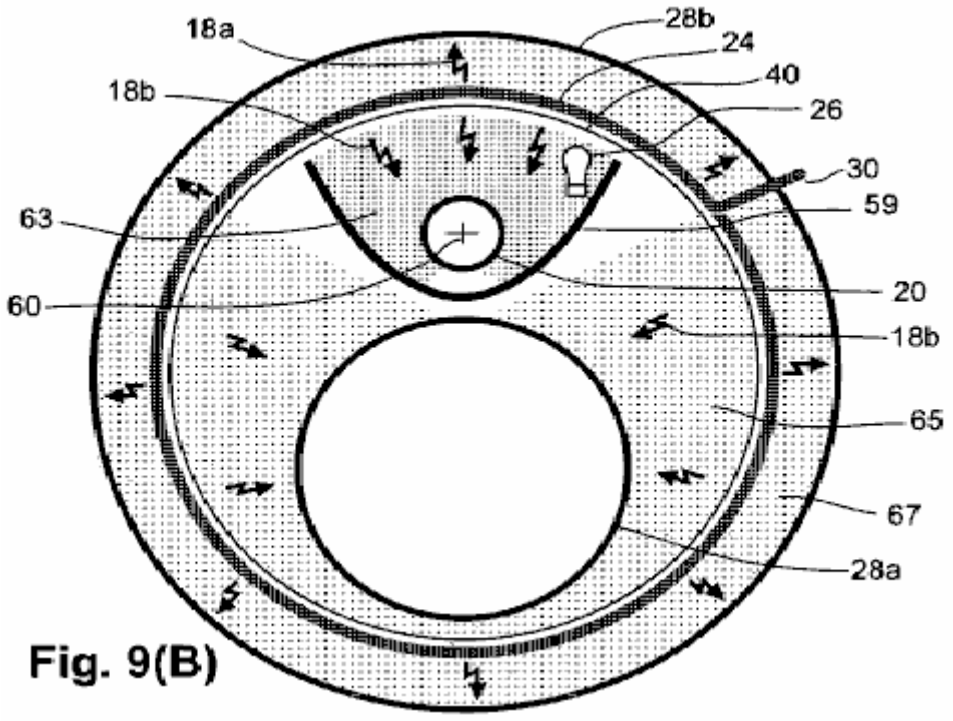

Fig. 9(B)

The portion of the inwardly directed, magnified inductive-photon radiation **18b** which is received by the internal output coil **28a**, is denoted by the shaded area **65**. The proportional amount of outwardly directed magnified radiation **18a** from the energy-magnifying coil **24** which is received by the external output coil **28b**, is shown by the shaded area **67**. The sum of the magnified radiation in the area **65** which reaches the external output coil **28b**, substantially exceeds the magnified radiation in the area **63** (the latter serving as a back-force on the sending coil **20**). This excess of utilised energy over the back-force energy, provides energy leverage. This embodiment also includes a starting mechanism, and initial power source for the photoconduction exciter, a work loop, and a feedback loop (not shown) as provided in the other embodiments described herein.

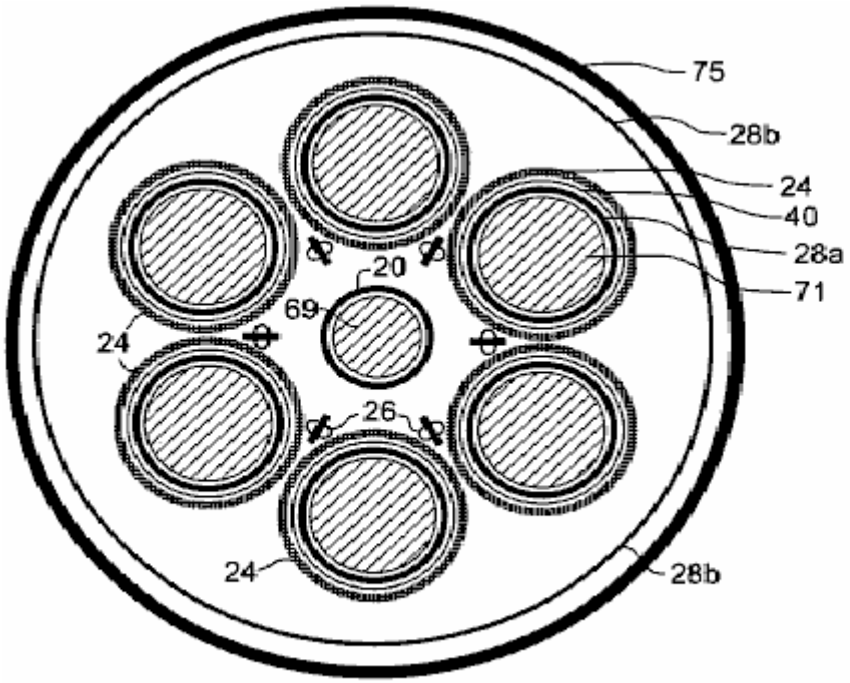

Fig. 10(A)

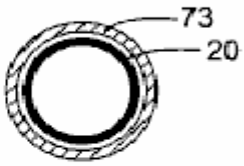

Fig. 10(B)

Certain features can be incorporated with any of the embodiments described herein, to add functional practicality. For example, referring to the schematic representation of a coil configuration shown in end view in **Fig.10A**, a ferromagnetic core **69** can be placed inside the sending coil **20**, and ferromagnetic cores **71** can be placed inside respective internal output coils **28a**. These cores increase the inductance of the apparatus, which lowers the frequency of the electrical oscillations produced by the apparatus. Although increases in inductance can cause

the output voltage and current to be out of phase, the phase difference can be corrected by adding capacitance to the circuitry by conventional means. Also shown, is an external metal shield which completely surrounds the apparatus to block any radiation from the device that could interfere with radios, televisions, telephones, computers and other electronic devices. the shield can be comprised of any of various non-magnetic metals such as aluminium or magnesium.

An alternative means of increasing the inductance of the apparatus is shown in **Fig.10B**, which is a variation of the end view of just the sending coil **20** that is depicted in **Fig.10A**. In **Fig.10B**, a ferromagnetic sleeve **73** is placed coaxially around the sending coil **20**.

The respective dimensional ratios of various components generally remain similar with respect to each other for different apparatus sizes, except for the longitudinal dimension, which generally can be as short or as long as desired, up to some practical limit. The respective gauges of wires used in the sending coil **20** and the output coils **28a** and **28b**, are commensurate with the electric current carried by these wires, and the respective thickness of insulation (if used) on the wires is commensurate with the voltage.

The outside diameter of the internal output coils **28a** desirably is only slightly less than the inside diameter of the respective energy-magnifying coils **24**, as shown in **Fig.6**, **Fig.7** and **Fig.8**, thereby ensuring close proximity of each internal output coil **28a** with its respective energy-magnifying coil **24**. At a sacrifice in efficiency, the outside diameter of the internal output coils **28a** can be made smaller, to allow space for heat from the current-carrying wires to escape or be removed by a coolant such as forced air in the case of a photoconductor type or doped semiconductor type apparatus, or by a cryogenic liquefied gas in the case of a superconductor type apparatus.

Also, desirably, the external output coil **28b** is connected in series with the internal output coils **28a** to maximise the output voltage from the apparatus **15** and to minimise heat produced by electric currents in the apparatus. The output voltage can be stepped down and the output electric current stepped up to normal operating ranges by using a transformer, wherein the primary of the transformer would comprise the load in the work loop **48**.

As discussed above, each energy-magnifying coil **24** can comprise a photoconductor or doped semiconductor formed as a helical pattern on a respective thin-walled tubular substrate provided with extended, raised contact surfaces at each end. The energy-magnifying coils **24** desirably are connected electrically (rather than capacitatively) to each other in series at the raised contact surfaces. The photoconductive coils desirably are coated using clear varnish or enamel to provide electrical insulation and to protect the photoconductors from oxidation and weathering.

Where the low-mass photoconducting electrons in the energy-magnifying coils **24** are present in a concentration which is insufficient for capturing most of the inductive-photon radiation from the sending coil **20**, each energy-magnifying coil desirably includes a thin metallic band. The metal desirably is in intimate contact with the low-mass-electron carrier. the metal can be on the exterior of a doped semiconductor, or it can be embedded in a photoconductor band of the coil to capture the inductive radiation and set up an electric field which, in turn, assists in accelerating the low-mass electrons. In the photoconductive embodiment, the photoconductive material desirably is disposed all around the metallic band so that the low-mass electrons are conducted on the outer side as well as the inner side and edges of the photoconductive band on the portion or portions which are exposed to illumination on the outside. The width of the metal band desirably is sufficient to capture as much of the inductive-photon radiation from the sending coil as is practical, since gaps between turns of the metal band in the energy-magnifying coil permit the sending coil's inductive radiation to pass through to the internal output coil. Since the sending coil's radiation is a half-cycle out of phase with the inductive radiation from the low-mass electrons, all the sending coil radiation which reaches the output coil, reduces the output efficiency of the apparatus.

Appropriate photoconductive materials (e.g. cadmium sulphide, cadmium selenide) for forming the energy-magnifying coils **24** are commercially available. The photoconductive material can be a single material or a mixture of materials, and can be formed by, for example, sputtering. A mixture of cadmium sulphide and cadmium selenide can be adjusted optimally to yield energy-magnifying coils exhibiting maximal energy-magnifying factors at a peak wavelength matching the brightest photoconduction exciters **26** which are available.

With respect to the photoconduction exciters **26**, photo-excitation of the energy-magnifying coils **24** can be provided by one or more LEDs, either surface-emitting or edge-emitting, for example, selected to produce an output wavelength matched to the peak photoconduction wavelength of the energy-magnifying coils **24**. In the embodiment of **Fig.7** and **Fig.10A**, individual LEDs **26** are positioned in linear arrays mounted back-to-back on respective mounting bars. The assembled mounting bars with LEDs are placed in the gaps between adjacent energy-magnifying coils **24** to illuminate at least the sides of the respective energy-magnifying coils **24** which receive inductive-photon radiation from the sending coil **20**. LEDs are advantageous compared to incandescent lamps because LEDs produce more light with less heat and have a much longer operational lifetime than

incandescent lamps. LEDs are also preferred because of their small size which facilitates fitting a large number of them into the relatively small space between adjacent energy-magnifying coils **24**.

Whereas the invention has been described in connection with several representative embodiments, the invention is not limited to those embodiments. On the contrary, the invention is intended to encompass all modifications, alternatives and equivalents as may be included within the spirit and scope of the invention, as defined by the appended claims.

JOHN REARDON

US Patent 6,946,767 **20th September 2005** **Inventor: John Reardon**

ALTERNATING CURRENT GENERATOR

This is a reworded excerpt form this patent which shows a high-efficiency electrical generator of alternating current. It is stated that this generator design is not affected by Lenz's law and the experimental results showed a 13,713% improvement over conventional power output.

ABSTRACT

An alternating current electrical generator creates three different and distinct magnetic fields between would coil elements and rotating magnets, two fields of which are induced fields caused by magnet rotation. A plurality of magnets are positioned such that they extend outwardly from a rotating shaft. The magnets are circumferentially spaced around the shaft such that the north polar end of one magnet follows the south polar end of the next magnet or such that the polar end of one magnet follows a magnet with the same polar end. A plurality of stationary coil elements are positioned in spaced relation to the magnets. The coil elements each have electrical windings and metal cores which extend the lengths of the coil elements. The magnets rotate in spaced relation to the ends of the coil elements in such a way that the magnets' flux lines cut the cores located at the centre of each of the coil elements. This induces alternating electric current that oscillates back and forth along the lengths of the cores. This oscillating current creates an expanding and collapsing set of magnetic flux lines which expand and contract through every inch of the coil element's windings. This expanding and collapsing magnetic field induces an expanding and collapsing magnetic field and an alternating electric field in the coil elements.

BACKGROUND OF THE INVENTION

Alternating current generators are rotating devices which convert mechanical energy into electrical energy. To generate an electromotive force by mechanical motion, there must be movement between an electric coil and a magnetic field in a manner that will cause a change in the flux that passes through the coil. Fundamentally, the induced electromotive force is brought about by a change in the flux passing through the coil.

The use of electromagnets, magnets and magnet components in generators to create the magnetic field and its subsequent effect on electric coils to ultimately generate electric current is well known. Such magnetic generators operate by using the repelling forces created by the effect of changing polarities of both permanent and electromagnets. For instance, there are electrical generating devices which employ electromagnets which are fixed in position and which induce current by being selectively energised, as iron or other magnetic metal discs, bars, or similar elements are rotated at or around the magnets. Other systems employ electromagnet or permanent magnets which are rotated, by various means, in relation to iron cores or coils, inducing an alternating electrical current within the coils.

However, prior alternating current generators which employ rotating magnet systems are inefficient and generally fail to deliver adequate current, in relation to the mechanical effort applied.

SUMMARY OF THE INVENTION

It is thus an object of the present invention to address the limitations and disadvantages of prior alternating electric current generators.

It is an object of the present invention to provide an alternating current generator which generates a substantial amount of electrical current efficiently and effectively.

It is a further object of the present invention to provide an alternating current generator which employs rotating magnets to induce increased alternating electrical current within the iron cores of electrical coils.

It is still another object of the present invention to provide an alternating current generator which can be simply and readily manufactured and be operated with high efficiency.

These and other objects are obtained by the present invention, an alternating current electrical generator which creates three different and distinct magnetic fields between wound coil elements and rotating magnets, two fields of which are induced fields caused by magnet rotation. A plurality of magnets are positioned such that they extend outwardly from a rotating shaft. The magnets are circumferentially spaced around the shaft such that the north polar end of one magnet follows the south polar end of the next magnet or such that the polar end of one magnet follows a magnet with the same polar end. A plurality of stationary coil elements are positioned in spaced relation to the magnets. The coil elements each have electrical windings and metal cores which extend the lengths of the coil elements. The magnets rotate in spaced relation to the ends of the coil elements in such a way that the magnets' flux lines cut the cores located at the centre of each of the coil elements. This induces alternating electric current that oscillates back and forth along the lengths of the cores. This oscillating current creates an expanding and collapsing set of magnetic flux lines which expand and contract through every inch of the coil element's windings. This expanding and collapsing magnetic field induces an expanding and collapsing magnetic field and an alternating electric field in the coil elements.

The novel features which are considered as characteristic of the invention are set forth in particular in the appended claims. The invention itself, however, both as to its design, construction, and use, together with additional features and advantages thereof, are best understood upon review of the following detailed description with reference to the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

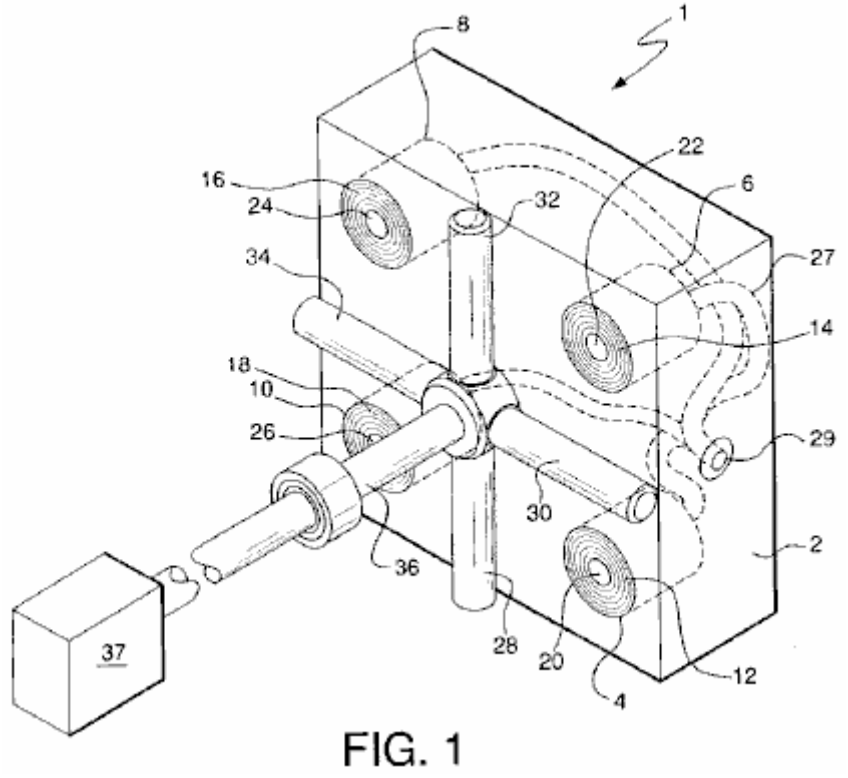

FIG. 1

Fig.1 is an isometric representation of keys components of the present invention.

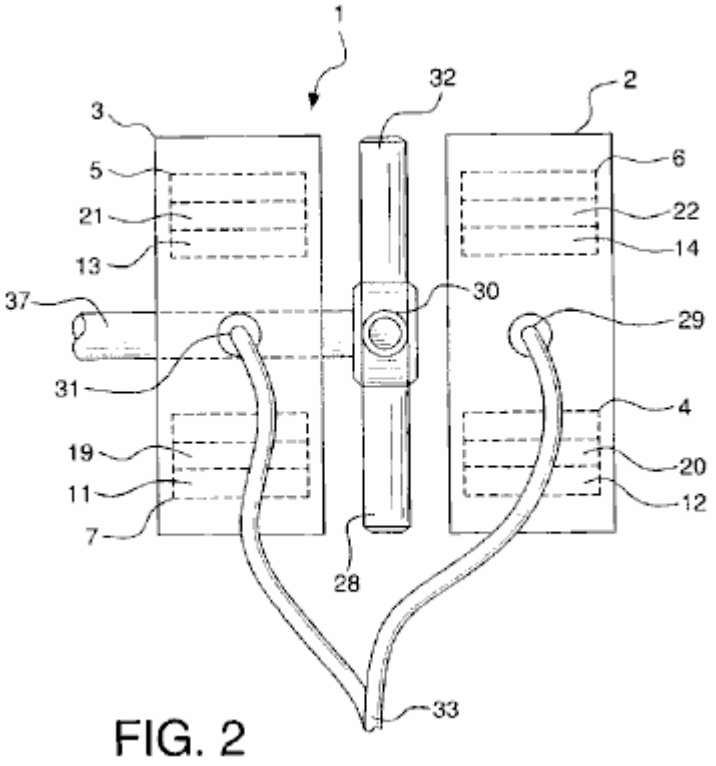

FIG. 2

Fig.2 is a side view representation of the present invention showing the two housed sets of coil elements and their relationship with the magnets.

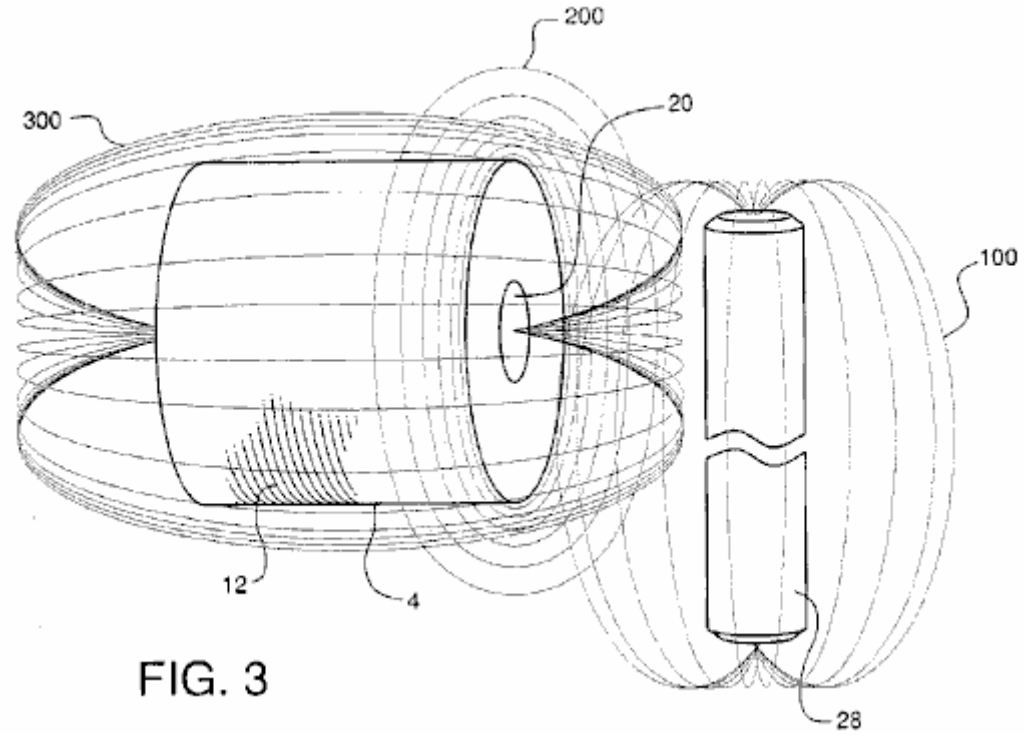

FIG. 3

Fig.3 is an explanatory view, showing the generation of flux lines which forms the basis for the operation of the present invention.

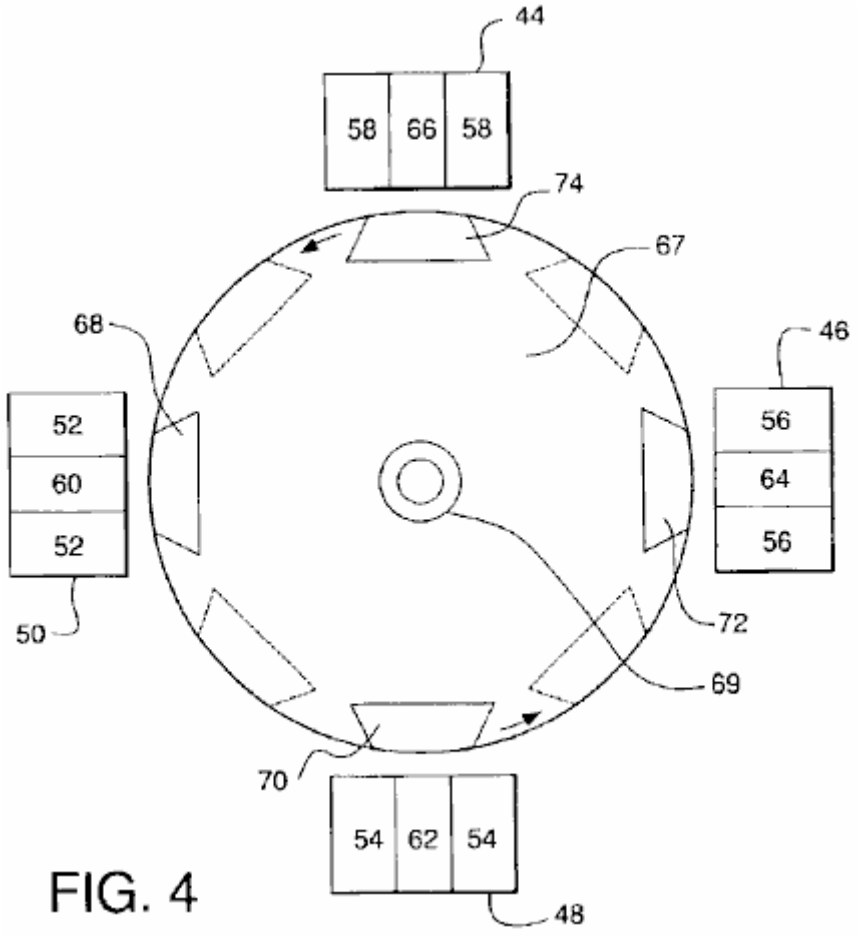

FIG. 4

Fig.4 is an alternate embodiment of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

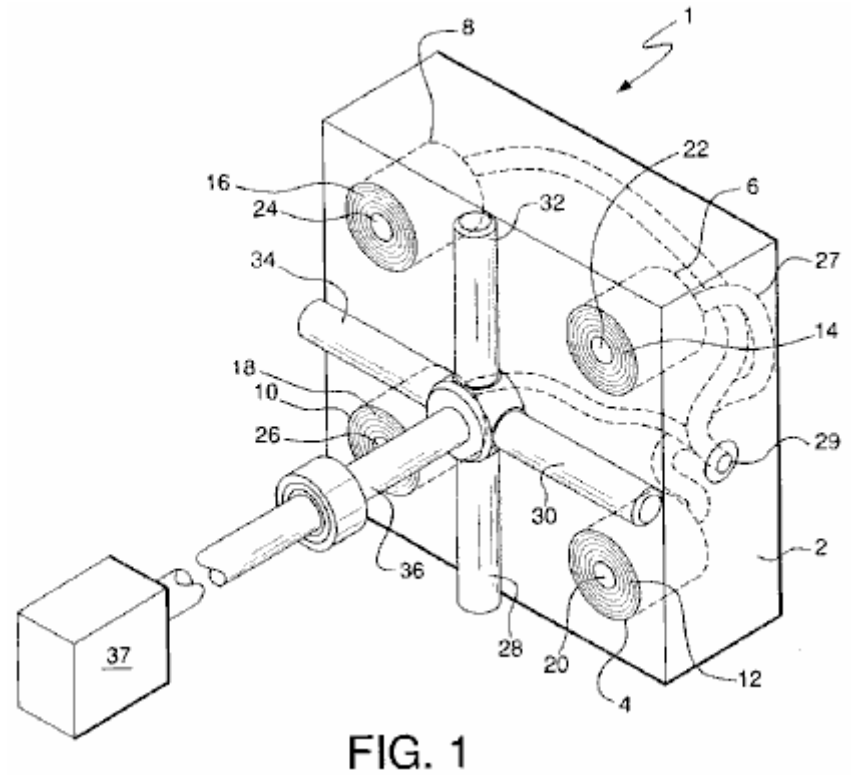

FIG. 1

Fig.1 and **Fig.2** show a clear depiction of the components of alternating current generator 1 of the subject invention. Generator 1 comprises housings **2** and **3**. For simplicity purposes and ease of understanding, only housing 2 is shown in **Fig.1**. It must be understood, however, that generator 1 of the present invention is configured for use with both housings **2** and **3**. Housing **2** contains coil elements **4**, **6**, **8** and **10**. Each coil element comprises multiple windings **12**, **14**, **16**, and **18**, respectively, wound around inner steel or similar metal cores **20**, **22**, **24**, and **26**, respectively. Each steel core extends the full length and directly through each of the coil elements. Coil elements **4**, **6**, **8**, and **10** are mounted within housing **2**, such that the end surfaces of the coil elements and the ends of cores **20**, **22**, **24**, and **26** are positioned flush with the external surface of housing **2**.

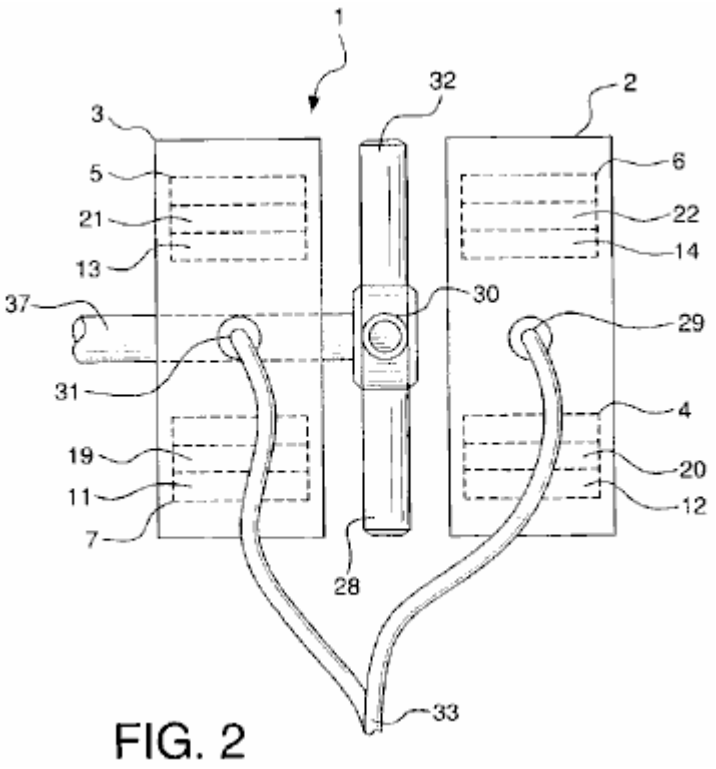

FIG. 2

Housing **3** also contains four coil elements positioned identically as has been described with regard to housing **2**. Two of these coil elements **5** and **7** are shown in **Fig.2**. Coil element **5** has multiple windings **13** and centre core **21** and coil element **7** has multiple windings **11** and centre core **21**.

Magnets **28**, **30**, **32**, and **34** are secured to shaft **36**, which is configured to be rotated by conventional power source **37**, such as a diesel engine, turbine, etc. Magnets **28**, **30**, **31**, and **32** all have ends with outwardly extending polarities. Magnets **28**, **30**, **32**, and **34** are positioned in spaced relation to the ends of exposed cores **20**, **22**, **24** and **26** of coil elements **4**, **6**, **8**, and **10** and in spaced relation to the ends of the four exposed cores in the four coil elements located in housing **3**, cores **19** and **21** being shown in **Fig.2**. All magnets are equidistantly spaced on and around shaft **36**, such that the outwardly extending pole of one magnet circumferentially follows the outwardly extending pole of the next magnet. The north polar end of one magnet may follow the south polar end of the next magnet or the polar end of one magnet may follow a magnet with the same polar end.

While four magnets and four cores are shown, it is contemplated that additional magnets and cores could be employed in the generator. Also, while permanent magnets are shown in the drawings, electromagnets could also be used, as they produce the same magnetic flux.

Alternating electrical current is generated when power source **37** rotates shaft **36**, thus causing rotation of magnets **28**, **30**, **32**, and **34** in spaced, adjacent relation to the ends of cores **20**, **22**, 24, and **26** of coil elements **4**, **6**, **8**, and **10**, and in spaced, adjacent relation to the ends of cores **19** and **21** of coil elements **7** and **5** and the ends of the cores of the other two similarly aligned coil elements in housing **3**. The current which is generated is transmitted through electrical conductive wiring **27**, which merges at connection points **29** in housing **2** and **31** in housing **3**, for the consolidated transmission at connection point **33** of the electricity produced.

As best represented in **Fig.2**, when magnet **28** is rotated in space relation to the end of core **20** of coil element **4**, flux lines **100** of the magnet cut the core at the centre of the coil element. This induces an alternating electrical current that oscillates back and forth along the length of core **20**. This oscillating current creates an expanding and collapsing set of magnetic flux lines **200** which expand and contract through every inch of coil windings **12**. Expanding and collapsing field **200** induces an alternating electric field in coil element **4** which is accompanied by

an expanding and collapsing magnetic field **300**. It is noted, significantly, that none of the magnetic field lines **100**, **200** and **300**, act in a negative fashion or in an opposing action. This allows the subject invention to overcome the limitations of Lenz's law, which states that whenever there is a change in magnetic flux in a circuit, an induced electromotive force is set-up tending to produce a current in a direction which will oppose the flux change.

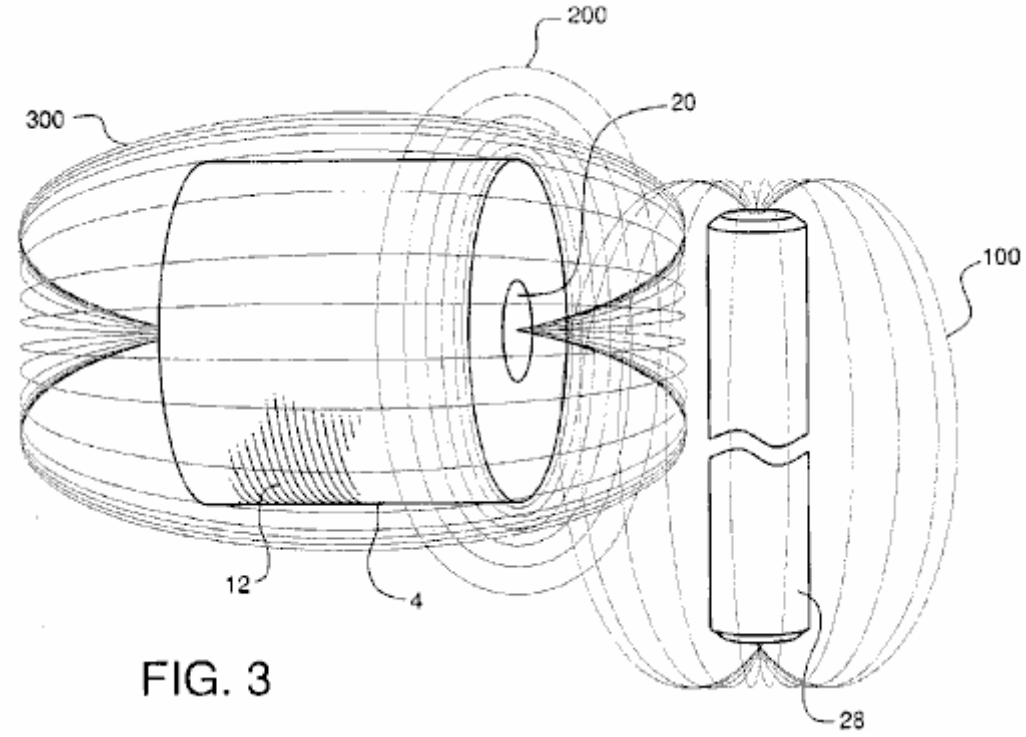

FIG. 3

Fig.3 illustrates an alternate embodiment of the invention to that which is shown in **Fig.1**. As shown in **Fig.3**, coil element **44** with outer windings **58** and inner steel core **66**, coil element **46** with windings **56** and core **64**, coil element **48** with windings **54** and core **62**, and coil element **50** with outer windings **52** and core **60** are positioned adjacent to rotor **67**, which is mounted on shaft **69**. Magnets **68** and **72** are mounted on rotor **67** such that the north poles of the magnets are positioned in spaced relation to coil elements **44**, **46**, **48** and **50**. Magnets **70** and **74** are mounted on rotor **67** such that the south poles of the magnets are also positioned in spaced relation to coil elements **44**, **46**, **48**, and **50**. All magnets are fixedly mounted on rotor **67** such that a north pole of one magnet circumferentially follows a south pole of the next magnet in line. The contemplated gap between the magnets and coil element cones is approximately 0.0001 of an inch, although the scope and use of the invention should not be deemed restricted to this distance.

As in the prior embodiment, rotation of magnets **68**, **70**, **72**, and **74**, by rotation of shaft **69** and hence rotor **67**, causes the flux lines of the magnets to cut cores **60**, **62**, **64**, and **66** of coil elements **44**, **46**, **48**, and **50**, eventually resulting in the output of electrical current as previously described.

It is noted that the larger the diameter of rotor **67**, the more coil elements can be positioned around the rotor. The greater the number of coil elements, the slower rotor **67** needs to rotate; however, there is a power loss in so doing. In addition, while rotor **67** is shown as being circular, it may be as square in shape or formed of as other appropriate multi-sided configurations.

This unique way of generating electricity allows generation of more electrical power, e.g. anywhere in the range of 4 to 137 times more power, than prior, conventional means. It also has the advantage of obtaining unity power with very little effort.

As evidence of such power gains, reference is made to the below outlined experimental outputs from coils and magnets which produced electric power the conventional way compared with the subject invention. The conventional way of generating power, for purpose of the following experimental outputs, as referenced herein, is accomplished by cutting the wires, not the cores, of the coil's windings with the magnet’s flux.

In this regard, proof is also provided that the herein described method of generating electrical power is not affected by Lenz's Law, by reference to the readings obtained by the conventional methods as the rpm and size of the coil increase. With conventional methods, the values do not change linearly, but are less because Lenz's Law restricts the outputs from increasing proportionally to the speed and size of the coil. In comparison, however,

in the method of producing power of the subject invention, there is an increase in the readings of V (voltage), I (current), and P (power) which are actually larger than anticipated.

It is also noted that, just like a transformer, when the number of turns ratio is increased, V increases and I decreases, which is exactly what is seen at the various rpm readings for the different size coils. However, they do not increase or decrease proportionally.

Thus, this presents the ideal model for producing electrical power that corresponds to the general law that states that as the speed increases, the voltage will increase proportionally, through the equation:
V = q (charge) × v (velocity) × B (magnetic field strength). This also holds true for a coil, in that transformers increase proportionally to the turns ratio.

With reference to the voltage outputs for each of the coils, 1100T, 2200T and 5500T, it is seen that they are consistent with the types of voltage outputs for a transformer action. That is to say, as the turns ratio goes up in a transformer so does the voltage. Since the increases in voltage between the number of turns is not exactly 2 to 5 times, one can pick any one of the coils and assume it is accurate and adjust the other coils accordingly. Thus, by fixing the 1100T coil, the other coils become 2837T and 5896T respectively. By fixing the 2200T coil, the other coils become 853T and 4572T respectively. And by fixing the 5500T coil, the other coils become 1026T and 2646T respectively. Also, if the adjustments are made as described here, i.e. that the coils are bigger than originally thought, and they are applied to the voltages for the conventional method of generating power, the voltages do not increase proportionally but are actually smaller than they are supposed to be, additional proof that Lenz's Law has application to conventional generators, but not to this invention.

The proportional changes in the voltage relative to speed can also be seen. Thus, considering the 350 RPM speed as accurate, the 1200 RPM and 1300 RPM speeds will adjust to 906 RPM and 1379 RPM respectively. Considering the 1200 RPM speed as accurate, the 350 RPM and 1300 RPM speed becomes 464 RPM and 1826 RPM respectively. And finally, considering the 1300 RPM speed as accurate, the 350 RPM and 1200 RPM speeds become 330 RPM and 854 RPM respectively.

It is noted that in using the various RPM readings based upon the above, it is seen that, in the conventional way of generating power, there are losses associated with the measured values. The calculated values again show the application of Lenz's Law in the conventional way of generating power, but not to this invention. In fact, whether or not there is an adjustment of RPM speed or coil size, the power generation of this invention is in no way affected by Lenz's Law.

Since Lenz's Law has no effect in this generator, it can be assumed that the voltages increase proportionally to the speed of the magnets rotation. Therefore, one can extrapolate the expected voltages at 1800 RPM, the speed necessary to create 60 Hz. With regard to this generator, for each of the three coils from the 350 RPM, 1200 RPM and 1300 RPM speeds, the following results (values are based on one coil/magnet.):

1. At assumed 350 RPM the voltages range as follows:

A. 5.863v @1100T
B. 15.12v @2200T
C. 31.42v @5500T

2. At assumed 1200 RPM the voltages range as follows:

A. 4.425v @1100T
B. 11.295v @2200T
C. 16.845v @5500T

3. At assumed 1300 RPM the voltages range as follows:

A. 6.217v @1100T
B. 10.716v @2200T
C. 17.668v @5500T

The reason the current is not changing linearly as the laws of physics imply from transformers, i.e. as voltage goes up based on the number of turns, the current goes down proportionally to the voltage gain, is due to the fact

that the inductive reactance is also going up. See the following chart for the inductive reactances for each coil at each speed.

Impedance (Z) or inductive reactance (X(L)) for a circuit with only a coil in it is the AC voltage divided by the AC current, and the inductance (L) is Z/2 × pi × F (frequency). For a circuit with a resistor and a coil
Z = square root of (R (resistance) squared + X(L) squared)).

The following is the chart of impedance Z for all coil sizes at all speeds for the conventional method of generating power and the method of generating power with this invention:

Where:
"T" stands for Turns,
"CM" stands for Conventional Method and
"SI" stands for Subject Invention:

(1) For 350 RPM for 1100T, 2200T and 5500T coils,

1. (a) CM: 0.57v / 56.6 mA = **10.021** ohms = Z
(b) SI: 1.14v / 106.6 mA = **10.694** ohms = Z

2. (a) CM: 0.93v / 32.4 mA = **28.704** ohms = Z
(b) SI: 2.94v / 70.1 mA = **41.94** ohms = Z

3. (a) CM: 2.09v / 17.3 mA = **120.81** ohms = Z
(b) SI: 6.11v / 37.9 mA = **161.21** ohms = Z

(2) For 1200 RPM for 1100T, 2200T and 5500T coils:

1. (a) CM: 1.45v / 60.2 mA = **23.387** ohms = Z
(b) SI: 2.95v / 141 mA = **20.922** ohms = Z

2. (a) CM: 3.225v / 36.2 mA = **89.088** ohms = Z
(b) SI: 7.53v / 73.5 mA = **102.449** ohms = Z

3. (a) CM: 4.81v / 17 mA = **282.941** ohms = Z
(b) SI: 11.23v / 31.4 mA = **357.643** ohms = Z

(3) For 1300 RPM for 1100T, 2200T and 5500T coils:

1. (a) CM: 1.6v / 83 mA = **19.27** ohms = Z

(b) SI: 18.76v / 2.5 mA = **7504** ohms = Z

(**13**) For 400 RPM for 6000T coil with 28 gauge wire and 0.75" core:

(a) CM: 0.64v / 1.7 mA = **376.471** ohms = Z
(b) SI: 7.97v / 7.4 mA = **1077.027** ohms = Z

(**14**) For 1200 RPM for 6000T coil with 28 gauge wire and 0.75" core:

(a) CM: 2.08v / 1.3 mA = **1600** ohms = Z
(b) SI: 20.4v / 5.6 mA = **3642.857** ohms = Z

(**15**) For 1400 RPM for 6000T coil with 28 gauge wire and 0.75" core:

(a) CM: 2.28v / 1.2 mA = **1900** ohms = Z
(b) SI: 28.4v / 2.1 mA = **13523.81** ohms = Z

It is noted that, based upon the variations of wire size, core size and number of turns, the following effects take place:
(a) the smaller the wire size the higher the gains regardless of speed;
(b) the greater the number of turns, generally the higher the gains; and
(c) the smaller the core size the higher the gains.
However, when comparing coils with smaller cores but a higher number of turns, the effects stay about the same.

Finally, the magnets are placed in the rotor so that they are all north or south poles up or out. A pure half-wave generator is created without rectifying the AC signal, which otherwise must be accomplished in a normal AC generator with electronic components in an electronic circuit.

Experimental Values for Producing Power the Conventional Way and with the Subject Invention:

The results were achieved using a small 3" magnet with a diameter of ±2" on a 1.25" high coil of 1" diameter and 3/8" centre/core of steel. (Unknown wire gauge size.)

(a) Conventional method of generating electricity:

1. 0.324 volts
2. 2.782 mA (milli-amps)
3. 0.9014 mW (milli-watts)

(b) Subject invention method of generating electricity:

1. 7.12 volts
2. 17.35 mA
3. 100.87 mW

(c) Associated gains of Volts, Current and Watts:

1. 2,198% over conventional voltage output.
2. 624% over conventional current output.
3. 13,713% over conventional power output.

The following results show the voltage, current and power outputs for an 1100, 2200 and 5500 turn coil of 20 gauge copper wire, 6" in length, 3" in diameter with a 0.75" core of steel. The results are those taken at 350 rpm, 1200 rpm and 1300 rpm.

(A) 350 RPM for an 1100 turn coil

	Volts	**mA**	**mW**
(a) Conventional method:	0.57	56.6	32.3
(b) Subject invention method:	1.14	106.6	121.5
(c) Associated gains	200%	188.3%	376.6%

(B) 350 RPM for a 2200 turn coil

	Volts	**mA**	**mW**
(a) Conventional method:	0.93	32.4	30.1
(b) Subject invention method:	2.94	70.1	206.1
(c) Associated gains	316.1%	216.4%	684%

(C) 350 RPM for a 5500 turn coil

	Volts	**mA**	**mW**
(a) Conventional method:	2.09	17.3	36.2
(b) Subject invention method:	6.11	37.9	231.6
(c) Associated gains	292.3%	219.1%	640%

(D) 1200 RPM for an 1100 turn coil

	Volts	**mA**	**mW**
(a) Conventional method:	1.45	60.2	87.3
(b) Subject invention method:	2.95	141	416
(c) Associated gains	203.4%	234.2%	476%

(E) 1200 RPM for a 2200 turn coil

	Volts	mA	mW
(a) Conventional method:	3.225	36.2	116.75
(b) Subject invention method:	7.53	73.5	553.5
(c) Associated gains	233.5%	203%	474%

(F) 1200 RPM on a 5500 turn coil

	Volts	mA	mW
(a) Conventional method:	4.81	17	81.77
(b) Subject invention method:	11.23	31.4	352.6
(c) Associated gains	235.5%	184.7%	431.3%

(G) 1300 RPM on an 1100 turn coil

	Volts	mA	mW
(a) Conventional method:	1.6	83	132.8
(b) Subject invention method:	4.59	157	704.9
(c) Associated gains	280.6%	189.2%	530.8%

(H) 1300 RPM on a 2200 turn coil

	Volts	mA	mW
(a) Conventional method:	2.75	50.5	138.9
(b) Subject invention method:	7.74	88.5	685
(c) Associated gains	281.5%	175.2%	493.3%

(I) 1300 RPM on a 5500 turn coil

	Volts	mA	mW
(a) Conventional method:	5.061	17.3	87.56
(b) Subject invention method:	12.76	36.4	464.5
(c) Associated gains	252%	210%	530%

The following readings are taken from a coil with 24 gauge wire, 0.5" centre/core of steel and 2300T.

(A) 400 rpm

	Volts	mA	mW
(a) Conventional method:	0.15	3.7	0.56
(b) Subject invention method:	2.45	26.2	64.2
(c) Associated gains	1,633%	708%	11,563%

(B) 1200 rpm

	Volts	mA	mW
(a) Conventional method:	0.37	2.7	1
(b) Subject invention method:	4.1	10.3	42.2
(c) Associated gains	1,108%	381%	4,227%

(C) 1400 rpm

	Volts	mA	mW
(a) Conventional method:	0.58	2.4	1.39
(b) Subject invention method:	8.31	7.8	64.82
(c) Associated gains	1,433%	325%	4,657%

The following readings are taken from a coil made with 24 gauge wire, 0.75" centre/core of copper, 2300T.

(A) 400 rpm

	Volts	mA	mW
(a) Conventional method:	0.23	4.2	0.97
(b) Subject invention method:	0.37	7.2	2.66
(c) Associated gains	137%	171%	235%

(B) 1200 rpm

	Volts	mA	mW
(a) Conventional method:	0.79	3.4	2.69
(b) Subject invention method:	1.43	6.9	9.87
(c) Associated gains	181%	203%	367%

(C) 1400 rpm

	Volts	mA	mW
(a) Conventional method:	0.79	3.2	2.53
(b) Subject invention method:	2.1	2.7	5.67
(c) Associated gains	266%	84%	224%

The following readings were taken from a coil made of 28 gauge wire, 0.5" centre/core of steel and 6000T.

(A) 400 rpm

	Volts	mA	mW
(a) Conventional method:	0.49	2	0.98
(b) Subject invention method:	5.48	13	71.24
(c) Associated gains	1,118%	65%	7,269%

(B) 1200 rpm

	Volts	mA	mW
(a) Conventional method:	1.25	1.5	1.88
(b) Subject invention method:	15.04	4.1	61.66
(c) Associated gains	1,203%	273%	3,289%

(C) 1400 rpm

	Volts	mA	mW
(a) Conventional method:	2.08	1.1	2.29
(b) Subject invention method:	18.76	2.5	46.9
(c) Associated gains	902%	227%	2,050%

The following readings were taken from a coil made of 28 gauge wire, 0.75" steel centre/core and 6000T.

(A) 400 rpm

	Volts	mA	mW
(a) Conventional method:	0.64	1.7	1.09
(b) Subject invention method:	7.97	7.4	58.98
(c) Associated gains	1,245%	435%	5,421%

(B) 1200 rpm

	Volts	mA	mW
(a) Conventional method:	2.08	1.3	2.7
(b) Subject invention method:	20.4	5.6	114.24
(c) Associated gains	981%	431%	4,225%

(C) 1400 rpm

	Volts	mA	mW
(a) Conventional method:	2.28	1.2	2.74
(b) Subject invention method:	28.4	2.1	88.04
(c) Associated gains	1,246%	175%	2,180%

The extrapolated voltages for the items immediately above at the 1800 RPM speed for the method of the subject invention are as follows:

(A) 400-1400 RPM, 0.5" core, 2300T:
(1) 11.025v
(2) 6.15v
(3) 10.68v

(B) 400-1400 RPM, 0.75" core, 2300T:
(1) 1.665v
(2) 2.145v
(3) 2.7v

(C) 400-1400 RPM, 0.5" core, 6000T:
(1) 24.66v
(2) 22.56v
(3)24.12

(D) 400-1400 RPM, 0.75" core, 6000T:
(1) 10.25v
(2) 30.6v
(3) 36.51v

Some of the readings above do not seem consistent with others. This is attributed to the possibility that the wire connections may have been faulty or the proximity of the magnet relative to the core or coil may not have been the same. This was not taken into account at the time the tests were done.

The following figures are derived based on the premise that the subject invention has characteristics of a transformer when the number of turns on the coils change. In nearly all these situations, the subject invention acts exactly like a transformer, while the conventional way of producing electricity does not.

CM = conventional method;
SI = subject invention;

CLAIMS

1. A generator for providing alternating electrical current comprising:

(a) an independently supported rotating drive shaft;

(b) a plurality of spaced apart magnets extending outwardly from the shaft, the magnets each creating magnetic flux and having a polar end with a particular north or south polarity, said magnets being circumferentially spaced and mounted around the shaft, such that the polar ends of the magnets extend away from and circumferentially around the shaft;

(c) a plurality of stationary coil elements, each said coil element comprising electrical windings wound about substantially the entire coil element, each of said coil elements further comprising a solid metal core with two ends extending substantially through the coil element at the centre of the coil element, each element being positioned such that one end of each of the cores is located in spaced, adjacent relation to the magnets, whereby rotation of the shaft causes rotation of the magnets around the shaft and in spaced, adjacent relation to the cores of the coil elements, the magnetic flux of the magnetics cutting the cores of the coil elements, creating alternating current in the coil elements; and

(d) a first housing in which some of the plurality of coil elements are mounted and a second housing in which the remainder of the plurality of coil elements are mounted.

2. The generator as in claim 1 wherein the magnets are spaced 90° apart around the shaft.

3. The generator as in claim 1 wherein magnets with north polar ends alternate with the magnets with south polar ends in spaced, circumferential relation around the shaft.

4. The generator as in claim 1 wherein all the plurality of magnets are magnets with the same polar ends.

5. The generator as in claim 1 wherein the magnets are equidistantly spaced around the shaft.

6. The generator as in claim 1 wherein the plurality of magnets is rotated by the drive shaft between and in spaced apart relation with the housings.

7. The generator as in claim 1 further comprising four magnets extending from the shaft, adjacent magnets being positioned perpendicular to each other, each magnet having either an outwardly extending north or south polar end, and said magnets being positioned such that a north polar end magnet follows a south polar end magnet, in spaced, circumferential relation around the shaft.

8. The generator as in claim 1 further comprising multiple north polar end magnets and multiple south polar end magnets extending from the shaft, said magnets being positioned in spaced, circumferentially relation around the shaft.

9. The generator as in claim 1 in which the shaft is positioned within a rotor and the magnets are circumferentially mounted on the rotor.

10. The generator as in claim 1 in which the shaft is connected to power means for rotating the shaft, whereby upon rotation of the shaft, the magnets are rotated around the shaft in spaced relation to the cores of the coil elements, thereby inducing an alternating electrical field along the length of each of the cores, thereby producing an alternating electric current in the windings of the coil elements.

11. The generator as in claim 10 further comprising means to transmit the alternating electrical current for electrical power usage.

GEOFFREY SPENCE

US Patent 4,772,816 **20th September 1988** **Inventor: Geoffrey M. Spence**

ENERGY CONVERSION SYSTEM

This is a slightly reworded excerpt from this patent which has a substantial electrical output capable of providing it's own electrical input to be self-powering as well as generating kilowatts of excess power. The highly-respected Dr. Harold Aspden comments:

"In my Energy Science Report No. 8I, I also mentioned the apparatus designed by Geoffrey Spence, an inventor based in U.K. This is the subject of his U.S. Patent No. 4,772,816. Electrons injected into a chamber formed between two concentric electrodes are deflected into the inner electrode by a pair of magnets that provide a magnetic field along the central axis of the concentric electrodes. Of itself, this should add no excess energy, because the energy fed into accelerating the electrons is merely absorbed by electrostatic repulsion in charging the central electrode and so the capacitor. However, if that electron flow pulsates and there are connections to draw electron current from that central electrode then the pulsation implies a recurring sequence of charge and discharge. That 'magic capacitor' function is then harnessed.

The questions then are whether the Spence invention really works and whether it is commercially viable? Well, I wrote that Energy Science Report back in 1996, six years ago, and it is only a few months ago that I heard any more of that project. Geoffrey Spence has developed the prototype product to the stage where he has closed the loop in the sense that a portion of the output power was fed back to impart the energy needed to sustain the electron beams. He has a self-sustaining unit that can deliver kilowatts of useful electrical power with no visible energy input."

ABSTRACT

The apparatus uses a magnetic field (**80**) to accelerate a charged particle radially towards a target electrode (**10**). The increased kinetic energy of the particles enables the particle to give up more electrical energy to the target electrode (**10**) than was initially given to it. This charges the target electrode (**10**), and the increased energy is extracted from the apparatus by connecting an electrical load between the target electrode and a point of lower or higher potential.

DESCRIPTION

This invention relates to a process and apparatus for generating a potential difference between two or more electrodes and using charged particles as energy carriers.

Electrical power is usually generated by burning a fossil fuel and converting the energy released into rotary motion which drives electrical generators. This is cost-effective only if carried out on a large scale, the conversion process being inefficient; utilising natural resources, and producing waste products which can cause serious environmental pollution. An additional disadvantage is that the electrical power cannot be supplied directly to road vehicles or ships.

The energy-conversion process of this invention involves no health or pollution hazard and generates electrical power directly by a single-stage process without waste products. The overall energy-conversion factor and power-to-weight ratio are both high, making the apparatus suitable for most fixed and mobile applications.

One known apparatus for doing useful work by operating on electrons with a magnetic field is called the "betatron". This includes a doughnut-shaped vacuum chamber between the poles of a specially-shaped electromagnet. Thermionically-produced electrons are injected into the chamber with an initial electrostatic energy of about 50 keV. As the magnetic field builds up during its positive-going half-cycle, it induces an electromotive force within the doughnut, which force accelerates the electrons and forces them to move in an curved path, by

interaction with the magnetic field. An important distinction between the betatron and the energy converter of this invention is that in the former the magnetic field has got to be able to increase over a very short period, in order to accelerate the electrons sufficiently, whereas in the latter the magnetic field is virtually constant and the electrons fall inwardly to give up both their kinetic energy and electric charge to a central electrode.

The present invention aims at providing an energy converter which may be mobile and which has a permanent magnet or an energised source of magnetic radiation associated with it in order to amplify the electrical energy initially imparted to charge particles fed to, or produced in, a so-called "vacuum" chamber forming part of the generator, which increased energy is extracted from the target electrode on which the particles are incident.

Accordingly the present invention provides an energy converter as per the appended claims.

While the invention is not to be limited to any particular theory of operation, it is based on the fact that, when a charged particle is constrained to move through a radial distance d (irrespective of the path which it actually follows) through a magnetic field of intensity **H**, the work done on the particle is **H** x **d**. For an electron carrying a charge **e**, and moving at a speed **v** over distance **d**, the total force on the electron is the centripetal force the sum of **H** x **e** x **v**, less the force exerted on the electron in the opposite direction by the centrifugal force, which is the sum of (**m** x $\mathbf{v}^2$)/**r**. By making the radius of the centre electrode appreciably greater than the orbit of equilibrium, the centrifugal force can be minimised, thus maximising the centripetal force, and hence the work done in bringing the charge to the electrode.

The process by which the converter of this invention works uses, as a source of charge, electrically-charged particles, for example electrons and/or ions. Two or more electrodes are housed in a low-pressure chamber. A magnetic field as specified below traverses the chamber: it emanates from a permanent magnet, electromagnet or a source of magnetic radiation. An external source of energy is used to give the charge particles initial kinetic energy, for example by heating, acceleration through an electric field, or from nuclear radiation. The energy-conversion process uses the magnetic field to transfer the charged particles along a desired orbit until they impinge on a central electrode (cathode). The work done on the particles (therefore the electrical potential attained by the cathode) is proportional to the resultant magnetic force times the distance over which the force acts. As the particles move within the chamber they cross the magnetic field. This produces a force acting on the particles, the force being proportional to the field strength, speed and electrical charge of the particles, and the sine of the angle of incidence between the path of the particle and the magnetic lines of force. This force has an angular component and a centripetal one, which forces the particles to travel along a spiral orbit.

An opposing centrifugal force also acts on the particles in opposition to the centripetal magnetic force. The electrode potential is proportional to the work required to be done on the charged particles to overcome both the centrifugal force and the electric field around the cathode as the charges accumulate and the potential difference between the electrodes increases. Maximum electrode potential is reached when the centrifugal and repulsive forces are equal to the centripetal force, after which no further charged particles reach the electrode. The radius of the electrode determines the minimal value voltage between the central and an outer electrode: as the central electrode radius is reduced (by sputtering or erosion) the centrifugal force increases, reducing the number of charged particles which can reach the central electrode and therefore the electrode potential, for a given field strength and particle speed. The difference in mass between ions and lighter charged particles, such as electrons, results in different centrifugal forces for given particle kinetic energies. The generator output and efficiency are optimised when the generator uses the maximum magnetic field to minimise the centrifugal force and to maximise the radial distance over which the force acts for a given field strength. Particles having the highest charge-to-mass ratio should be used.

Low pressure gases can be used as a charge source when ionised by particle collision and excitation within the chamber. Doped gases can minimise the energy level for ionising gas atoms/molecules thereby improving efficiency. However, the resultant magnetic force is lower for the heavier ions due to their lower velocity so that the electric field radiated by the high voltage electrode (cathode) can attract oppositely charged particles (+ ions) and subsequently discharge the electrode reducing the output voltage. Various methods can be used to overcome or reduce this effect. For example one method would be to separate the opposite charges and/or to use electrical biased grids to control the flow of opposite charges to the high voltage electrode.

Gaseous systems are generally more complex than single charge systems, providing higher currents at lower voltages, whereas single charge systems, for example electrons used in high vacuum chambers, can generate higher voltages.

The magnetic field can be from one or more permanent magnets and/or from one or more electromagnets; a static magnetic field produces a constant output voltage, while a varying field produces a varying voltage for particles with equal mass and velocity.

An external source is used to accelerate the charged particles to give them initial kinetic energy, which is released as heat when the particles collide with the electrode. When the energy represented by the increased voltage between the electrodes is greater than the energy required to provide the charged particles; and accelerate them, the conversion process is self-sustaining, the output energy being the difference between the sum of the kinetic energy lost and the energy generated. Charge flows from the central electrode via an external load to another electrode. The electrical energy (work) released is a function of the current (sum of charges that flow per second) times the potential difference. Electrical and thermal output can be controlled by varying: the field strength; the particle speed; the particle density (mean free path), and/or by incorporating a grid to control the rate at which particles reach the central electrode. The output is also proportional to the heat lost or gained, since the translational energy of the particle is proportional to its temperature. Heat liberated at the electrode can be returned to the particles to maintain their energy, or be utilised in a heat exchanger for external use. The generator normally uses non-reacting conductive material to prevent chemical reaction by gases, coolants etc. with the electrodes, container walls or other components. Various particle trajectories, directional movements and positioning of the orbiting particles can be used with appropriate magnetic fields. The low-pressure gas can be ionised by any suitable means: one method would be to use an electron/ion gun where the plane and direction of the injected particles is correct for the applied magnetic field. In gas apparatus, the electrons flowing through the external circuit, on reaching the anode, recombine with a gaseous ion to form a neutral gas atom/molecule. This atomic particle is duly re-ionised by collision and/or the electric fields, the energy being directly or indirectly derived from the work done by the resultant force acting on the charged particles.

In order that the invention may be better understood, it will now be described with reference to the accompanying schematic drawings, which are given by way of example, and in which:

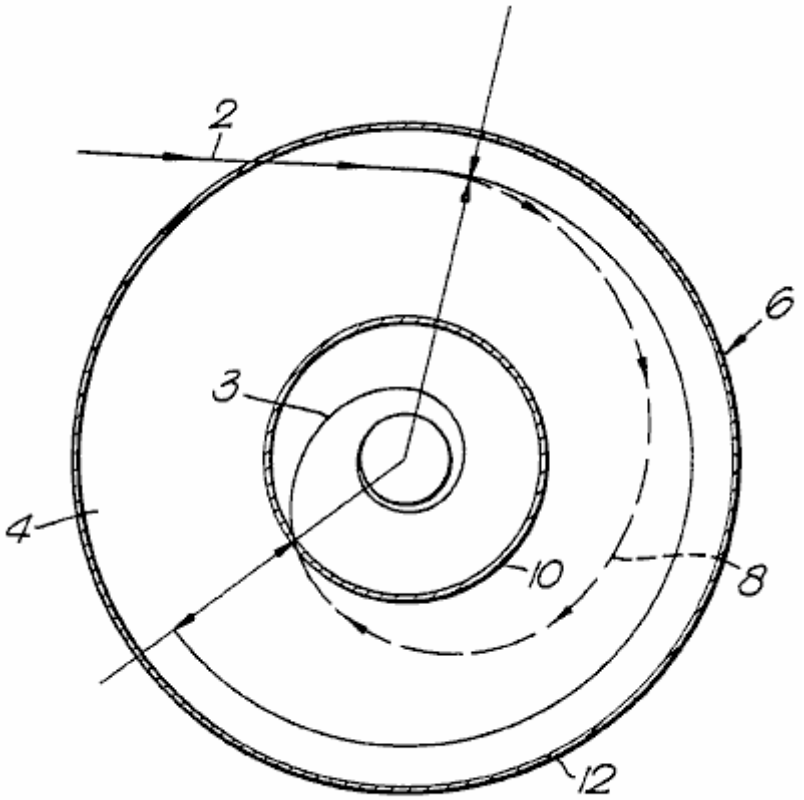

Fig.1.

Fig.1 shows schematically a cross-section of the generator; and the path followed by a particle during the energy-conversion process;

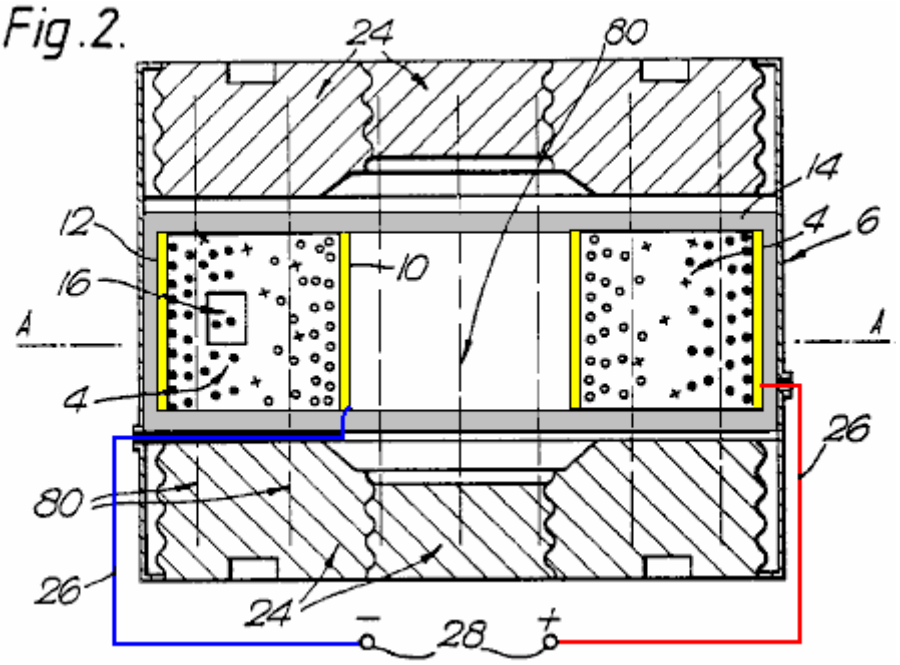

Fig.2 shows an axial cross-section of one type of apparatus for the invention, using permanent magnets; and a grid controlling ion migration to the cathode.

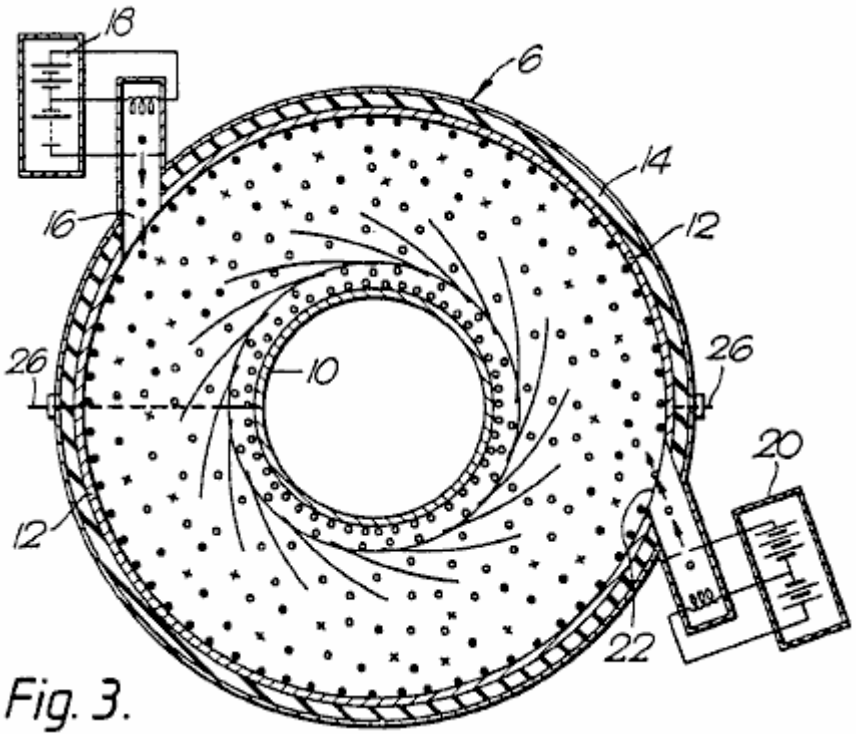

Fig.3 shows a cross-section of the apparatus of **Fig.2** along the line **A--A**;

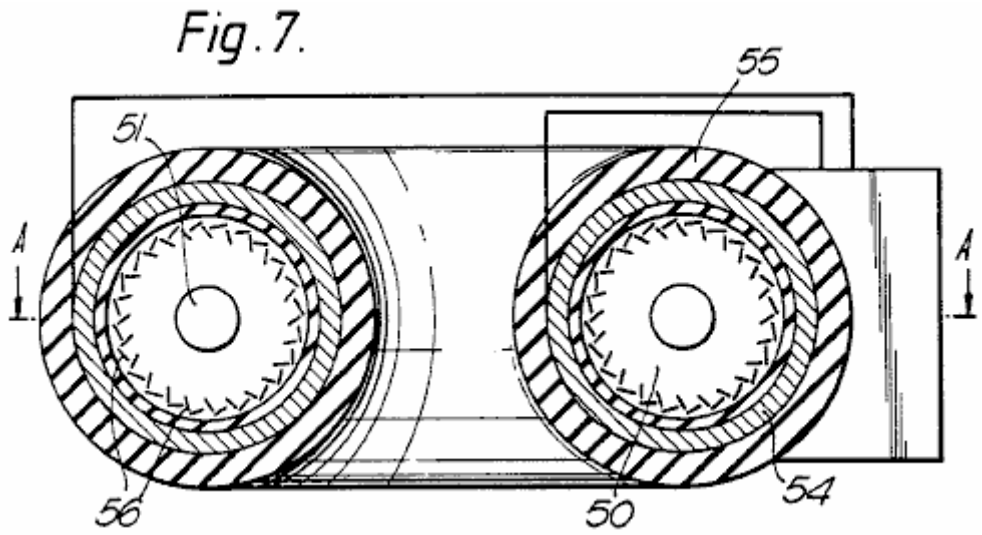

Fig.7.

Fig.7 is a cross-section along a diameter of a doughnut-shaped (toroidal) high-power converter;

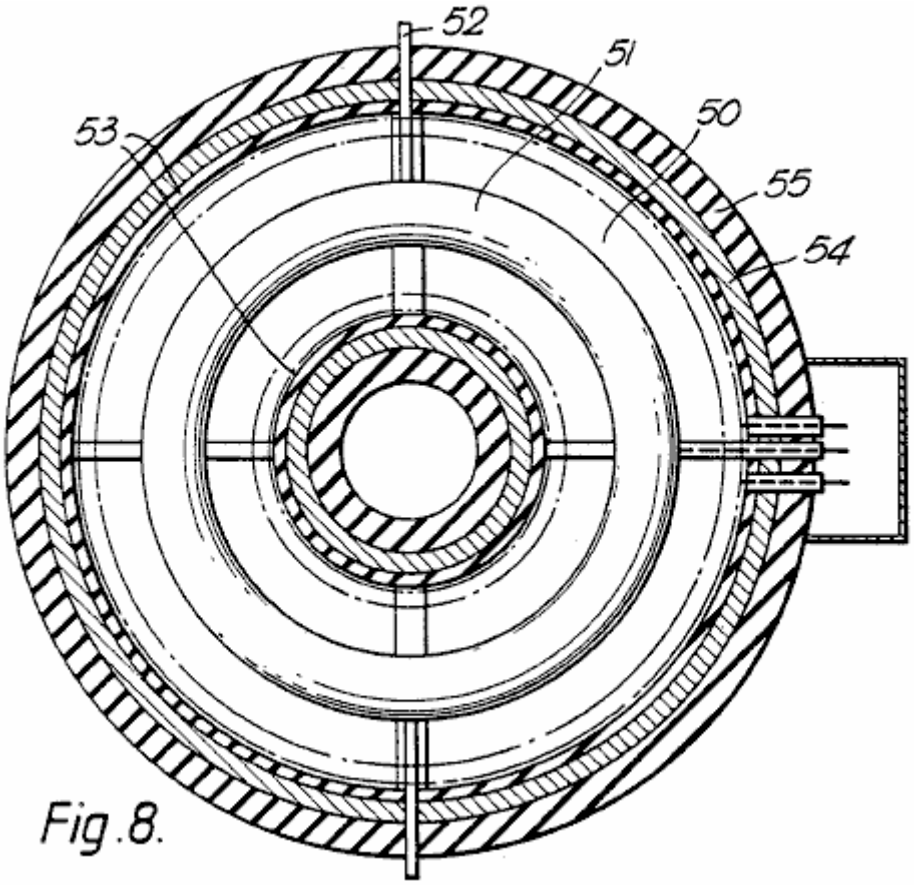

Fig.8.

Fig.8 is a section on line **A--A** of **Fig.7**, and

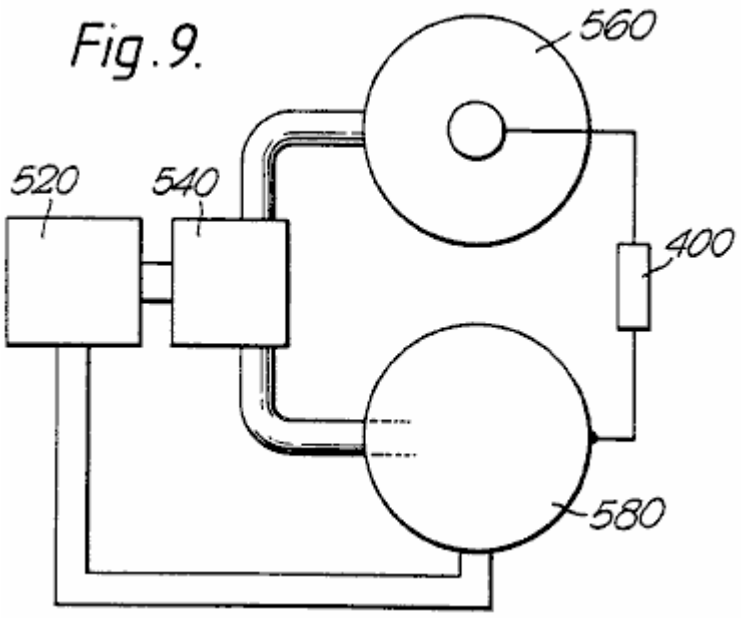

Fig.9.

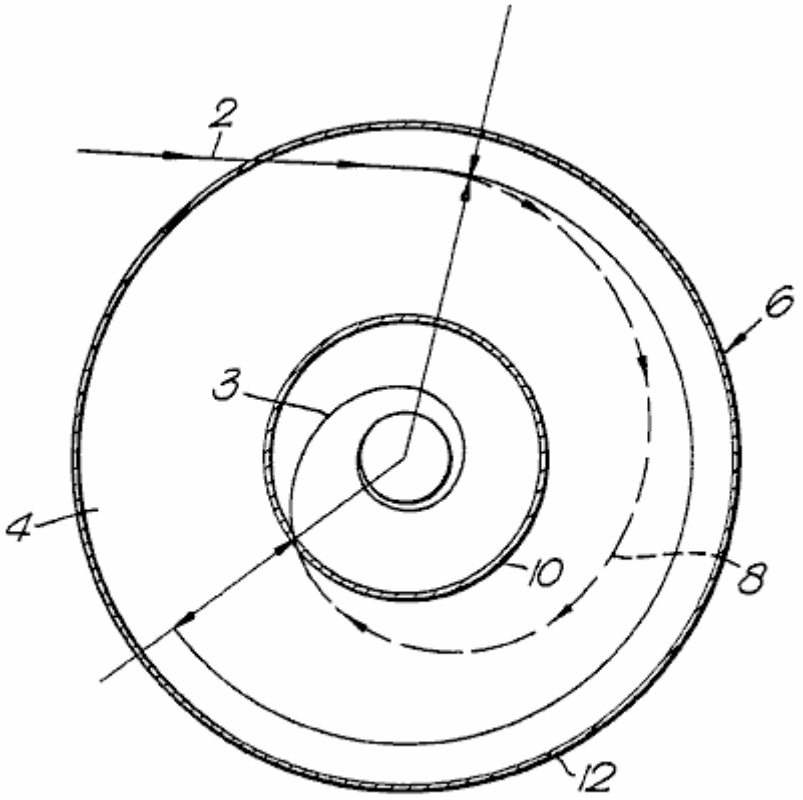
Fig.9 is a scheme of a two-stage converter, using both forms of charged particles concurrently.



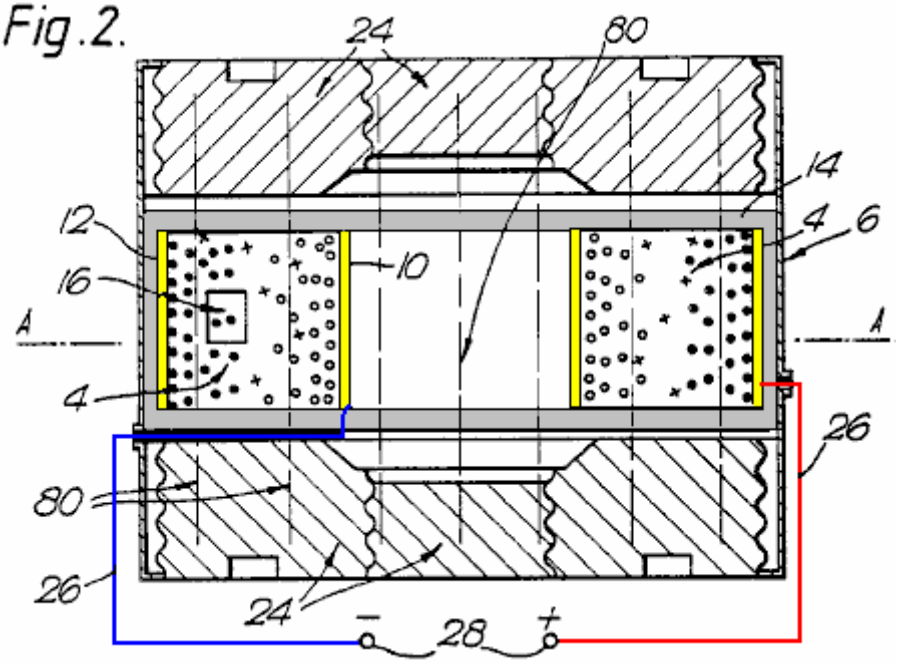


Fig.1.

As shown in **Fig.1**, a charged particle is injected along a trajectory **2** into a magnetic field extending normal to the plane of the drawing. The field permeates the space **4** of the annular cross-section within a cylindrical chamber **6**. The magnetic field produces a force on the particle, extending at right angles to both it's direction of motion and the magnetic field. The resultant centripetal force causes the particle to follow a spiral path **8** ending on the central electrode **10** spaced radially inwards from the outer cylindrical electrode **12**. The extra energy acquired by the particle is a function of the radial distance travelled and the strength of the magnetic field between the electrodes. This energy is given up on impact with the central electrode, in the form of heat and/or work done in bringing the charge against the opposing electric field to the electrode. In the absence of the central electrode **10**, the electrons would follow the orbit of equilibrium **3**, this being the orbit followed by a particle when the centrifugal and centripetal forces balance, resulting in no work being done on the particle.

Fig.2.

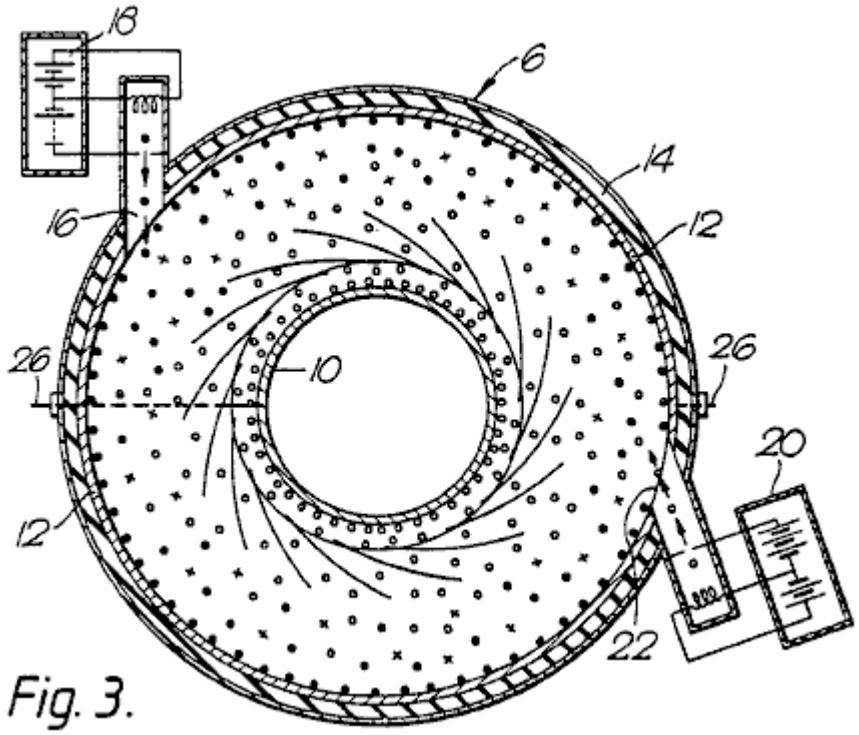

Fig. 3.

As shown more particularly in **Fig.2** and **Fig.3**, the energy converter **1** consists basically of a annular chamber **6** having an outer cylindrical electrode **12**; an inner cylindrical electrode **10**, and two gas-tight walls **14** of electrical insulation material. In the electrode **12** is a port **22** through which an electron gun **20** can inject electrons into space **4**. Additionally or alternatively, an ion gun **18** can inject positively-charged particles through port **16**.

Seated on the major flat surfaces of chamber **6** are magnetic pole-pieces **24** giving rise to a uniform magnetic field **80** which traverses the space **4** parallel with the axis of chamber **6**. The magnets may be ceramic permanent magnets, or they may be electromagnets. In either case, means (not shown) may be provided for adjusting the magnetic field strength.

Heavy conductors **26** connect the two electrodes to terminals **28** across which a resistive load can be placed to dissipate the generator output.

A vacuum pump (not shown) has its inlet in communication with the interior of chamber **6** so that the gas pressure in the generator can be reduced to, and kept at, a desired sub-atmospheric value. Associated with the pump, or separate from it, may be means for ensuring that the gas in the generator is of a desired composition, for instance, one which enhances the possibility of ionising collisions between the charged particles and gas atoms or molecules. One such suitable gas would be neon containing 0.1% argon by volume.

In order to cause the generator to start working, it is necessary to start the vacuum pump and to energise the electron gun or each particle source. The latter involves heating a filament from an external source of power until the required internal energy level (temperature) is reached which in turn causes a piece of thermo-emissive material to emit electrons. If the electrons are to be the charge carriers, they are accelerated by a suitable electric field and projected into the space **4**. Here they are further accelerated by the radial electric field between the electrodes, and at the same time have a deflecting force applied to them by the axial magnetic field through which they pass.

For an ion source, the electrons are accelerated until they impact some atoms or molecules, to produce a stream of ions which likewise pass into the space **4**. With the polarities shown, the electrons are attracted to the central electrode, while the ions are pulled towards the outer electrode, which accounts for the different orientations of sources **18** and **20**.

Any gas molecules which pass close to, or between, the electrodes are ionised by collision and/or the electrostatic field. Output current can then be taken through a load impedance connected across terminals **28**. The impedance is matched to prevent the internal process energy dropping below a value which would prevent the re-ionisation of the gaseous atoms. As each ion is deionised at the anode, the gas atoms will tend to continue to circulate until re-ionised, the resultant force drawing both the ions (shown by solid circles) and electrons (shown by hollow circles) back into their respective orbits.

It is envisaged that, in the case of a converter using electrons, the chamber could be evacuated to a chosen sub-atmospheric pressure and sealed.

In that form of the invention shown in **Fig.4**, each electron source forming one of a circular series **29** of sources has a body **30** of electro-emissive material, such as molybdenum coated by caesium, heated by an electric filament **32** connected in series or parallel across a source of electric power (not shown). Immediately in front of each emitter **30** is a grid **34** of fine wires, all the grids being connected with a source of adjustable voltage so as to control the flow of electrons from the emitter. These electrons are projected through one or more acceleration electrodes **36** across which a potential difference is established along the electron path, so that each incremental electron source injects a stream of electrons having known kinetic energy into a space **38**, indicated by the circle shown in a broken line, traversed by the deflection magnetic field, within which is the central, target, electrode **40**. The stream of electrons injected into the magnetic field may be focused by electric and/or magnetic fields.

In the remaining Figs, those parts already referred to will retain the same references.

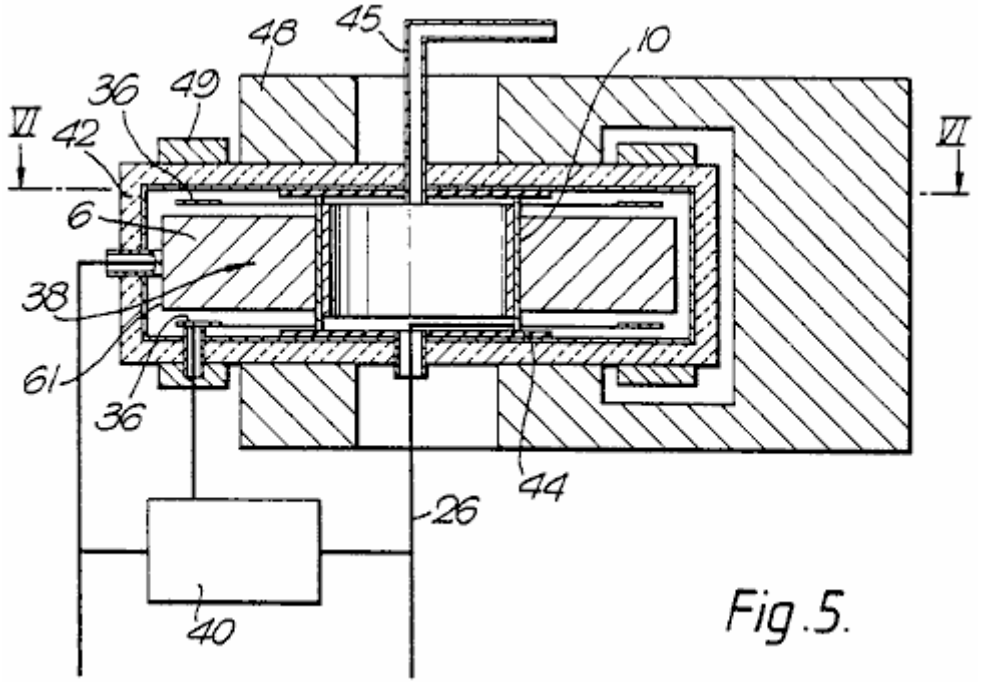

Fig.5.

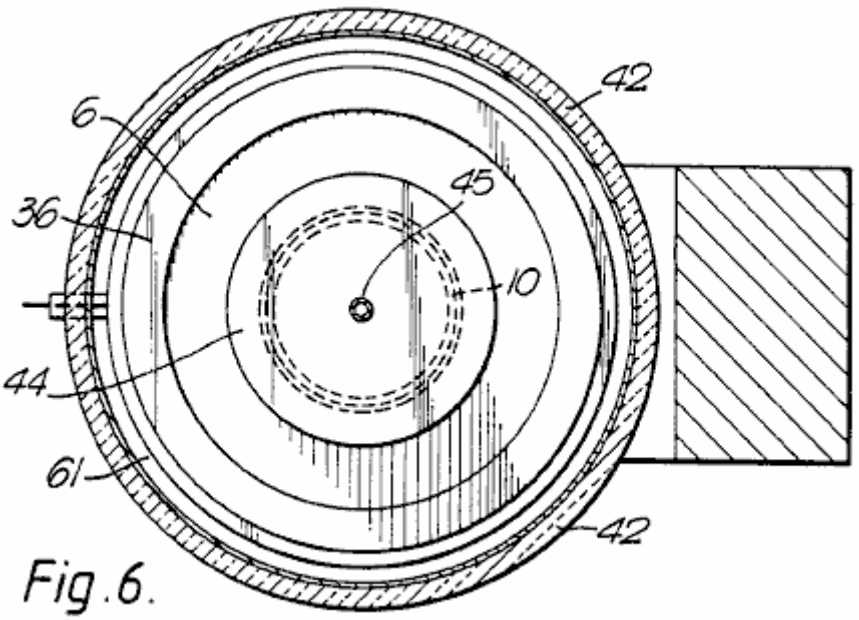
In the "flat disc" configuration shown in **Fig.5**, the annular chamber **6** is enclosed in a body **42** of thermal insulation material. The central electrode **10** is seated on insulators **44** which are pierced by conduits **45** for the passage of a coolant fluid and by an output lead **26**, which may extend along the conduit so that it too is cooled.

Fig.5 shows how the deflection magnet is generally U-shaped, and has two annular pole-pieces **48**, so that the magnetic field is uniform between the surface of electrode **10** and the region **38** radially innermost of the circular electron source, the electric field between the electrode **36** and emission surface **61** providing the electrons initial accelerations (kinetic energy). **Fig.5** also shows how a voltage is tapped off the resistive load **40** (which thus functions as a potentiometer) and is fed through to the acceleration electrode **36**.

Chamber **6** is also provided with two annular magnets **49** (or a circular series of incremental magnets) designed to influence the direction along which the electrons pass into space **38**. The magnets provide local magnetic fields to ensure that the electrons meet the boundary of space **38** tangentially, i.e. with zero radial velocity.



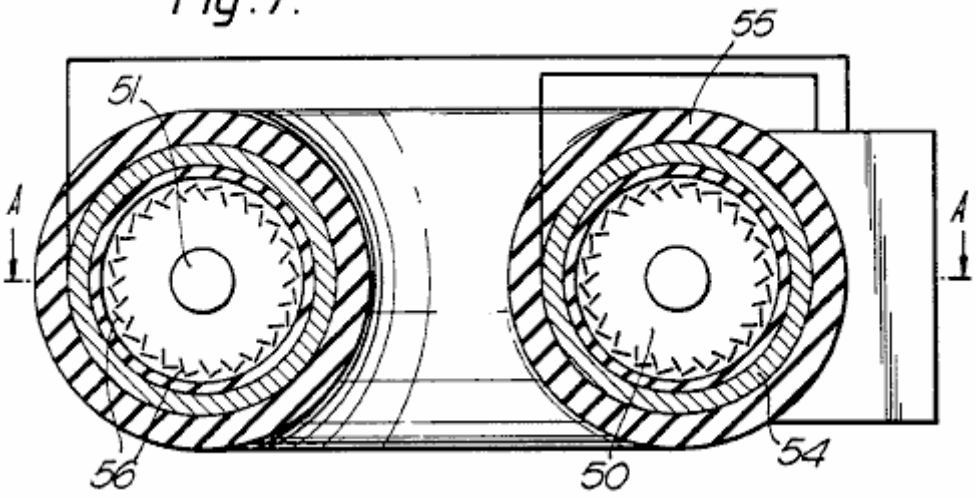


Fig. 6.

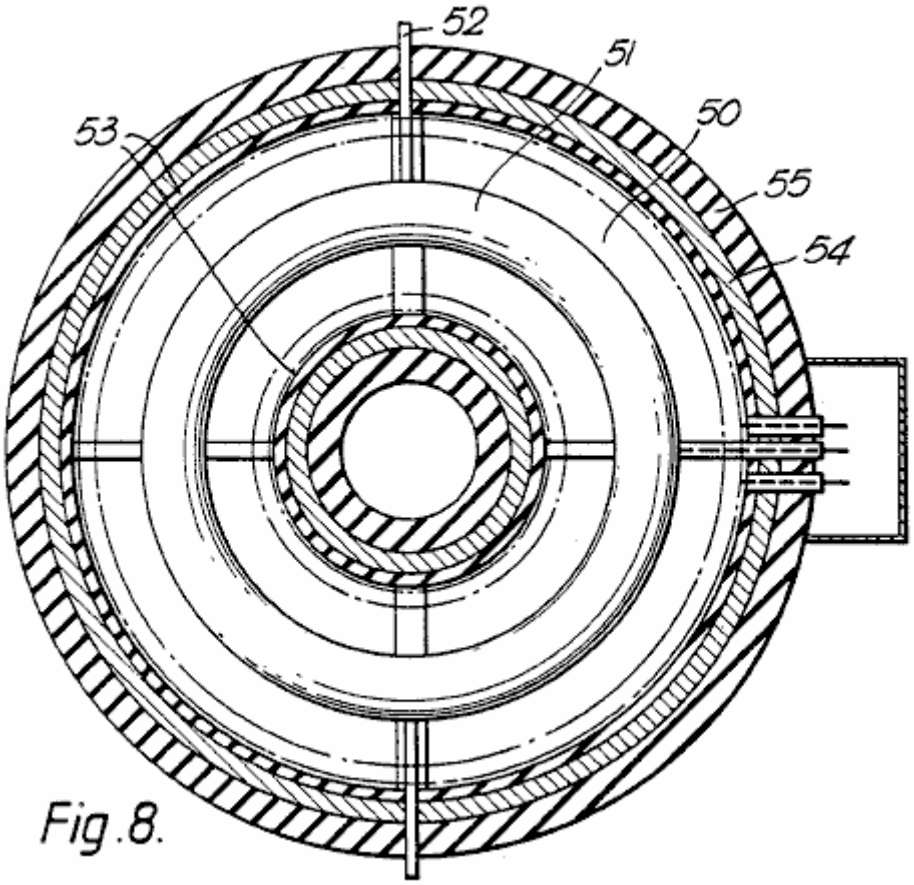
Fig. 7.



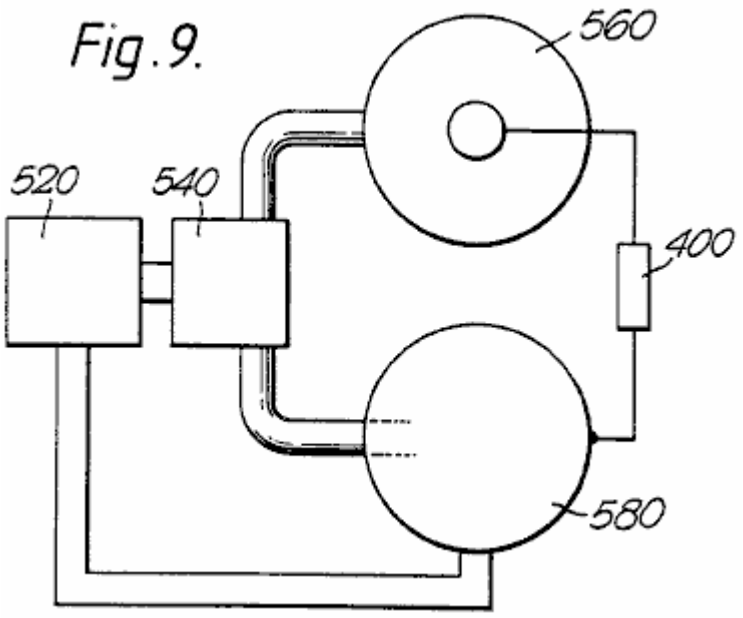


Fig.8.

In that form of the invention shown in **Fig.7** and **Fig.8**, the individual "flat disc" converters of **Fig.5** and **Fig.6** are arranged in a type of "circular" construction, such that the magnetic fields extend along the axis of the resulting toroidal space **50** penetrated by a single toroidal target electrode **51** through which a coolant fluid may pass, along conduits **52**. The cross-section of **Fig.8** shows that the magnetic fields are supplemented by an electric field produced by windings **53** wound on a magnetic core **54** bounded by insulation **55**.

Apart from the fact that the electrodes are common to all converters, each functions individually as described above. Obviously the power source driving the heaters for the electron guns **56**; the electromagnets (if any); the acceleration electrodes and the control grids, have to be of sufficient capacity to supply the greater power needed to drive this "toroidal" configuration. Some changes would need to be made to the physical dimensioning and positioning of the relatively-complex construction, but as all these are readily understood by a competent engineer, they are not further described in this specification.

As already mentioned, the converters of this invention are of two types, i.e. electronic and ionic. **Fig.9** shows diagrammatically how they may be combined to take advantage of their differences. In the two-stage power generation apparatus shown in **Fig.9** the first stage consists of an ioniser **520** supplying a mixture of charged particles, i.e. ions and electrons, to a separator **540**, which supplies electrons to a second stage consisting of a sealed electronic converter **560** in parallel with a gaseous ionic converter **580**.

The separator **540** may use the different particle masses to separate them centrifugally using, for example, the energy conversion system of **Fig.1** (without the target electrode), or it may use electromagnetic deflection fields, or a physical diffusion process, either alone or in combination. As this is not part of the subject-matter of this invention, it will not be described herein in any further detail.

In the generators of **Fig.6** and **Fig.8**, the respective particles are deflected magnetically and accelerated radially, to function as already described above.

Because each generator is designed to operate most effectively with its particular form of charge carrier, it can be designed optimally, thus reducing the energy absorption caused by ions and electrons recombining before each has fallen on its respective target electrode. Because the electronic converter would finish up with a negatively-charged electrode, whereas the converse is true for the ionic converter, the load **400** extracting energy from the apparatus is connected across the two target electrodes. The other two electrodes of the converters may be held at the same potential, as by being connected together, or their potentials may float.

The generator can be designed to produce a wide range of output voltages and currents. The lower-energy generators are light enough to be mobile, so that they can power vehicles or act as stand-by generators. Various electrode and magnet configurations can be used, and the generators can be connected in series or parallel. Cooling jackets are fitted to prevent overheating in high-powered apparatus, and the generator is enclosed within a thermally-insulating jacket to reduce heat losses thereby increasing particle velocities. For high-energy generators, it may be necessary to provide for forced cooling of the inner electrode, as by fins projecting therefrom into a high-speed stream of suitable coolant.

Although the process according to this invention is particularly suited to using external electrical energy, it must be understood that other sources can be used to provide the initial energy input, e.g. solar and waste process heat are some of the varied energy sources which could be utilised. Control of the charge-generation process can be achieved by other means, including one or more electrically-biased grids, as used in thermionic valves.

CLAIMS

1. An energy conversion process for generating an electric potential, the process comprising; providing a source of electric charge carriers of predetermined polarity, accelerating the carriers away from the source, introducing the carriers into a magnetic field transverse to the path of the carriers in a process chamber, the field bounding an inner electrode within the chamber such that the carriers orbit the electrode while accelerating radially toward the electrode; and converting the resulting increased kinetic energy of the carriers

into an electric potential at the electrode before the carriers reach an orbit of equilibrium in which the centripetal force is balanced by the centrifugal force on the carriers.

2. A process according to claim 1 in which the electric potential is created between the inner electrode and an outer electrode radially spaced from the inner electrode.

3. A process according to claim 2 in which the outer electrode provides the said source of the charge carriers.

4. A process according to claim 1 or claim 2 in which the chamber is maintained at a sub-atmospheric pressure.

5. A process according to claim 1 in which the electric potential drives a load connected between the inner electrode and a point remote from the electrode.

6. A process according to claim 1 or claim 2 in which the electric charge carriers comprise electrons or ions.

7. A process according to claim 1 in which further charge carriers of the opposite polarity traverse the magnetic field and accumulate at a second electrode to increase the potential difference between the two electrodes.

8. A process according to claim 1 in which electrically biased grids control the flow of the charge carriers from the source.

9. A process according to claim 1 in which the charge carriers are separated from charge carriers of the opposite polarity before being introduced into the magnetic field.

10. A process according to claim 9 in which the charge carriers of opposite polarity are introduced into a corresponding second magnetic field, whereby a potential difference is produced between respective electrodes in each field.

11. A process according to claim 1 in which the carriers are injected into the magnetic field.

12. A process according to claim 11 in which the injection energy is produced by accelerating the carriers through an electric field.

13. A process according to claim 11 in which the injection energy is produced by accelerating the carriers through a magnetic field.

14. A process according to claim 1 in which the injection energy of the carriers is produced by nuclear emission.

15. A process according to claim 1 in which the injection energy of the carriers is produced by heat.

16. A process according to claim 1 in which the generated electric potential is directly or indirectly used to maintain the generation of charge carriers or the internal temperature of the space traversed by the magnetic field, or the applied magnetic field.

17. A process according to claim 1 in which the generated electric potential is directly or indirectly used to maintain the generation of charge carriers and the internal temperature of the space traversed by the magnetic field and the applied magnetic field.

18. An energy converter including a source of electric charge carriers of a predetermined polarity, a process chamber having an inner electrode, means for accelerating the carriers away from the source and for introducing the carriers into the chamber, means for applying a magnetic field transverse to the path of the carriers and bounding the inner electrode of the chamber such that the carriers orbit the electrode while accelerating radially toward the electrode, the electrode being located at a radius which exceeds the equilibrium radius for the carrier mean velocity and applied field strength and intercepting the carriers such that the increased kinetic energy of the carriers due to centripetal acceleration is converted to an electric potential at the electrode.

19. An energy converter according to claim 18 in which the chamber includes an outer electrode spaced radially from the inner electrode, and means for injecting the charge carriers into the space between the electrodes.

20. An energy converter according to claim 19 in which the outer electrode provides the said source of charge carriers.

21. An energy converter according to claim 19 further comprising an insulating wall bounding the outer electrode.

22. A converter according to claim 18 further comprising means for maintaining the chamber at a predetermined sub-atmospheric pressure.

23. A converter according to claim 19 in which the outer electrode has at least one port through which the charge carriers can be injected into the chamber along a desired trajectory.

24. A converter according to claim 23 in which the outer electrode has plural ports and each port communicates with a thermionic source of the respective carriers.

25. A converter according to claim 18 in which the chamber is a vacuum chamber.

26. A converter according to claim 18 further comprising electrically biased grids for controlling the flow of charge carriers from the source.

27. A converter according to claim 22 or claim 25 in which the evacuated chamber comprises a sealed unit.

28. A converter according to claim 18 further comprising means for adjusting the strength of the applied magnetic field.

29. A converter according to claim 18 in which the chamber is filled with low pressure gas.

ROBERT ALEXANDER

US Patent 3,913,004 **14th October 1975** **Inventor: Robert W. Alexander**

METHOD AND APPARATUS FOR INCREASING ELECTRICAL POWER

This patent shows a method of altering a standard electrical generator intended to be driven by a separate motor, so that it operates without the motor. In an example quoted, a DC input of 48 volts at 25 amps of current (1.2 kW) produces a 110 volt 60Hz AC output of 3.52 kW. That is a Coefficient Of Performance of 2.93 at an output level suited to Off-The-Grid operation of a house.

ABSTRACT

A form of rotating machine arranged in such a way as to convert a substantially constant input voltage into a substantially constant output voltage; involving generally, a rotor that revolves at a substantially constant speed within a stator, and which comprises a transformer core subjected to and having a primary motor-transformer winding and a secondary transformer-generator winding; whereby transformed and generated power are synchronously combined as increased output power.

BACKGROUND

Electrical power is frequently changed in voltage, phase, frequency, and the current is changed from alternating to direct or from direct to alternating. Voltage conversion in AC circuits is usually by means of transformers, and in DC circuits is usually by means of motor-generators. Phase conversion is also accomplished by either transformers or motor-generators, and frequency conversion is most simply done by motor-generators.

Motor-generators have various classifications of use, as follows:

(1) DC to DC, used to charge batteries and to boost voltage.
(2) AC to AC, used for frequency and phase conversion
(3) AC to DC used for all types of service, such as battery charging, generator and motor field excitation, railways, electrolysis, and speed control etc. and
(4) DC to AC used to limited extent for special applications.

To these ends combination motor-generators have been built, such as dynamotors stepping up DC voltage for radio equipment and amplidynes for reproducing a weak signal at a higher power level. When a particular variable frequency A.C. is required of a motor-generator set and the power supply is DC, the equipment will include a DC motor for variable speed and a separate alternator driven by it. Such equipment is special in nature and characterised by separation of the motor and generator and by polyphase (usually three-phase) generator windings and with auto transformers having suitable taps for obtaining the required voltages; and a DC speed controller for the motor. The phase output of such equipment is selective and its single phase capacity necessarily restricted (66%) as compared with its three-phase capacity, in which case transmission efficiency for single phase is poor.

When a higher level power output is desired, the amplidyne is employed with field windings and brushes equipped for the purpose, and in some instances to give a constant current output from a constant voltage input, for example, in inverted rotary converter provided to convert DC to A.C. However, the present invention is concerned with method and apparatus for increasing electrical power and provides a dynamo-electric converter that operates from an electrical energy supply to produce A.C. most efficiently for a useful load.

The method involves simultaneous motor-transformer-generator steps and the preferred embodiment of the apparatus involves a dynamo-electric converter (DEC) in the form of a rotary machine combined in a single rotor revolving within a stator, the rotor being comprised of a transformer core having both a primary motor-transformer winding and a secondary transformer-generator winding, and the stator being comprised of magnetic field poles.

Synchronous converters have been combined in single rotor machines to produce DC from A.C., but that effect is quite different from the effect of the present invention when A.C. is to be produced from DC in a single rotor having primary and secondary armature windings as distinguished from armature windings common to both A.C. and DC circuits. With the present invention, both a transforming and a generating effect are produced in the rotor, all of which is inherently synchronised and delivered through the A.C. outlet leads. A.C. motors and DC generators have been combined in one machine, that is in one rotor, and referred to as synchronous converters.

However, synchronous converters are lacking in their ability to change DC into A.C. when operating from the former as a prime mover to drive a generator simultaneously, and more specifically to drive an alternator synchronously.

SUMMARY OF INVENTION

This method involves the placement of a primary winding in a field to both motor the same and to have a transformer effect with respect to a secondary winding also in a field to have a generator effect. In its preferred embodiment, this dynamo-electric converter is comprised of primary and secondary windings combined in a rotor commutated to alternate a DC energy supply in and thereby motivate the rotor within a stator field. The primary winding is advantageously of fewer turns than the secondary and by means of electromotive force drives the secondary windings of more turns to cut the magnetic lines of force for the generation of electrical energy at a higher voltage level than the DC supply. This DC operated motor is shunt wound with the stator field poles fully energised by the DC energy supply, or is provided with permanent magnet field poles, to efficiently motivate the rotor and efficiently generate electrical energy in the secondary windings. The A.C. output of the secondary windings is inherently synchronised with the transformer function of the primary windings combined in the common slots of the single rotor; and by adding the transformer and generator voltages and amperages the wattage is correspondingly increased at the output.

DRAWINGS

The various objects and features of this invention will be fully understood from the following detailed description of the typical preferred form and application, which is made in the accompanying drawings, in which:

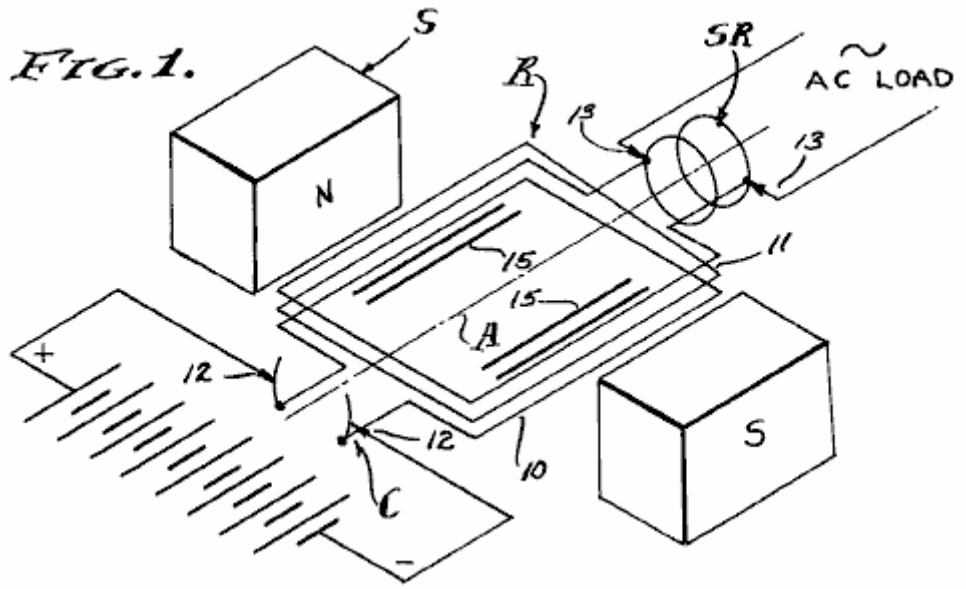

Fig.1 is a diagrammatic schematic view of the dynamo-electric converter components comprising the present invention.

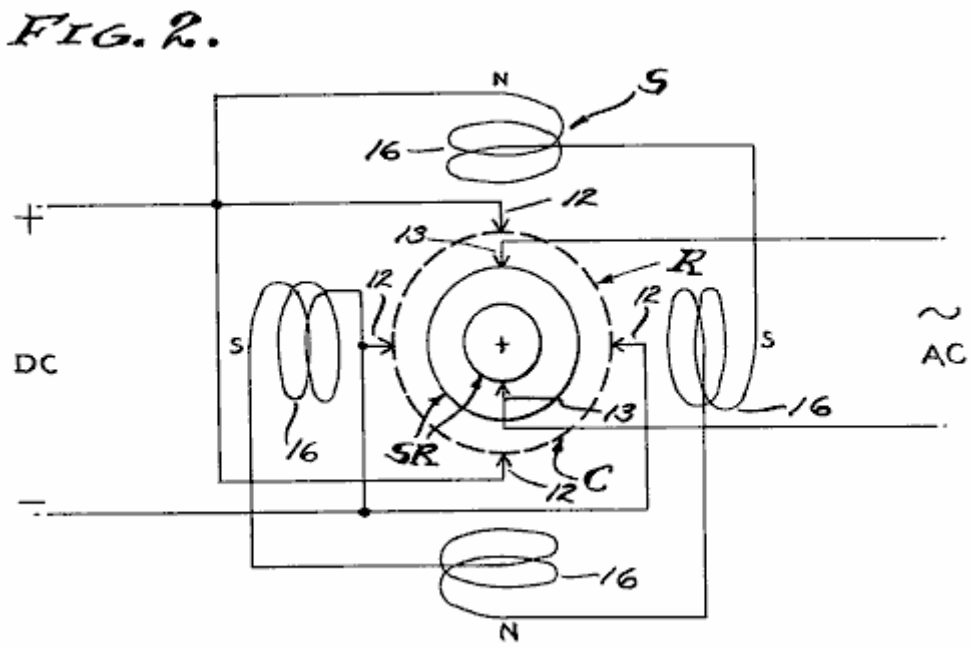

Fig.2 is a diagram of a typical commutator brush, slip ring brush and field pole arrangement which is utilised.

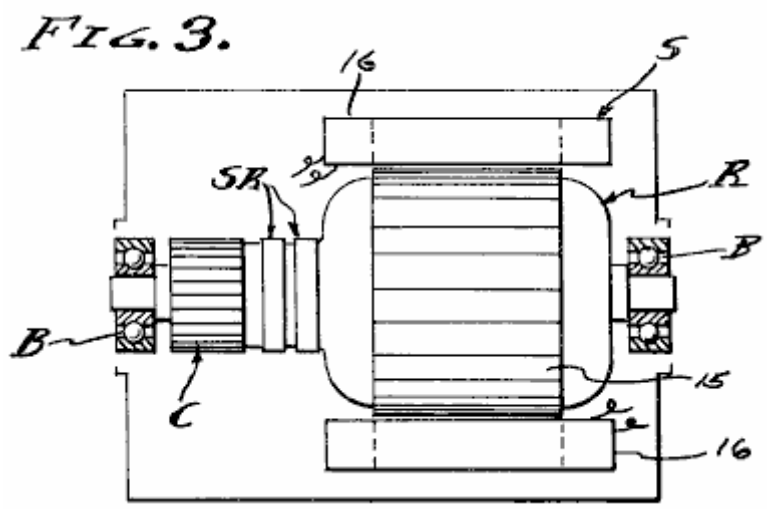

Fig.3 is a longitudinal section through a machine embodying the stator and rotor on bearings with the frame and brushes removed.

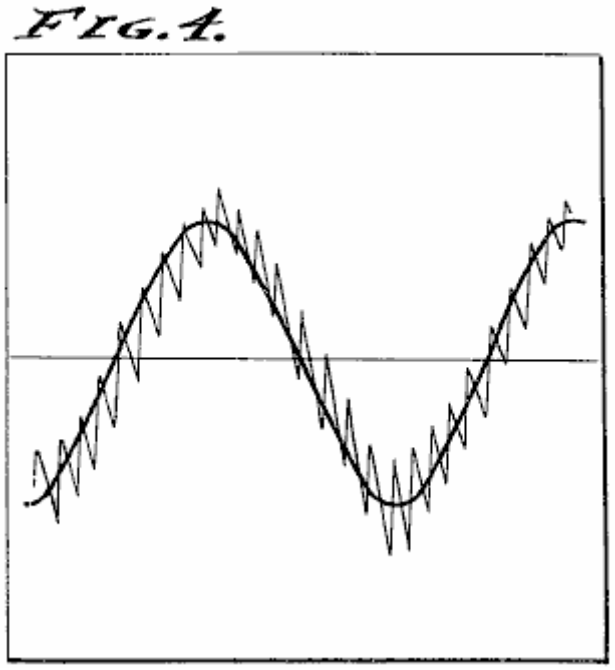

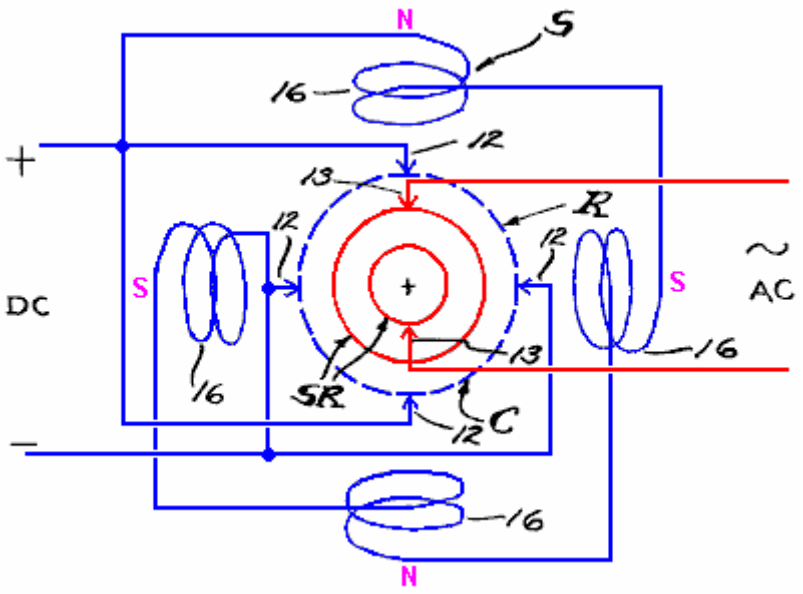

Fig.4 is a typical duplicate of an oscilloscope diagram showing the power output of the dynamo-electric converter.

PREFERRED EMBODIMENT

The dynamo-electric converter is illustrated diagrammatically in the drawings and involves, generally, a rotor **R** carried upon spaced bearings **B** so as to rotate on an axis **A** concentric within a stator **S**. The rotor **R** comprises the armature, while the stator **S** comprises the field, there being a commutator **C** associated with primary windings **10** on the rotor and slip rings **SR** associated with secondary windings **11** on the rotor. Brushes **12** and **13** are engaged slideably with the commutator and slip rings respectively, by conventional means, to conduct DC through the commutator **C** and to conduct AC through the slip rings **SR**. The brushes **12** and interconnected primary windings **10** comprise a motor while the brushes **13** and interconnected secondary windings **11** comprise a generator or alternator.

In practice, the field windings **16** can be separately energised or connected in parallel with the brushes **12** or shunted with respect to the primary motor winding **10**. Motorisation of the armature rotor **R**, or motoring thereof, causes continued polarity reversals on a cycle basis as determined by the speed of rotation, and this of course results in magnetic reversals in the rotor core **15** and a consequent induction in the secondary windings **11**. A feature of this invention is the combining and co-operative relationship of the primary and secondary windings which occupy common slots in and embrace a common portion of the core **15** of the rotor **R**, thereby to have a

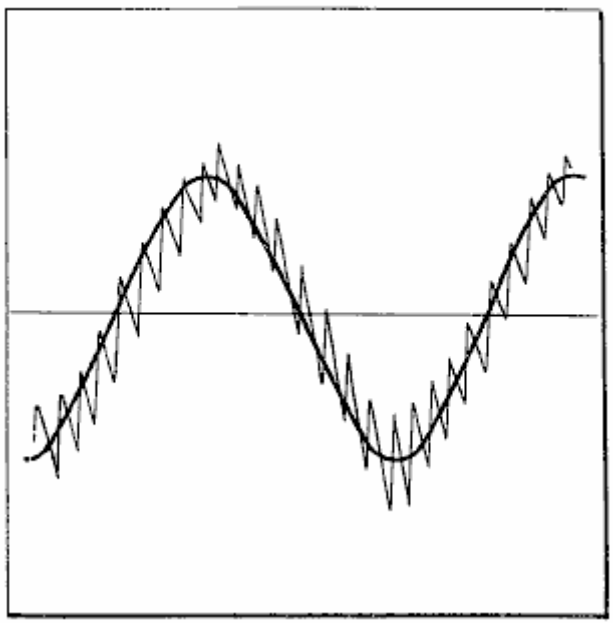
transformer function as well as a generator function as the lines of magnetic force are cut by the secondary windings. The stator **S** has field poles of opposite magnetic polarity, excited independently from the armature, or as permanent magnets, and preferably shunted across the DC input. As shown, there are four equally spaced field poles in a circumferentially disposed series.

In practice, the primary DC motor windings are of fewer turns in the rotor slots than the secondary AC generator windings. For example, the primary motor windings **10** are flat wound between north to south poles of the field while the secondary generator windings are flat wound in the same or common slots of the rotor armature. In a typical unit having a four brush commutator with 20 bars and having a 20-slot armature, the primary windings **10** are comprised of a number of turns of conductor efficiently to draw 48 volts DC at 25 amperes or 1,200 watts to rotate at 1,750 rpm, while the secondary windings **11** are comprised of a number of turns of conductor efficiently to deliver 60 cycle (by transforming and generating) 110 volts AC at 32 amperes or 3,520 watts, the volt meter used to read these values upon an actual reduction to practice being calibrated to read the root-mean-square (RMS) value of the pure sine wave, which is 70.7% of the peak voltage.

The reduction to practice previously referred to as a "typical unit" was constructed of a machine originally designed as a self-exciting 60 cps 110 volt 2.5 kVA generator to be shaft driven by a separate prime mover. Firstly, the prime mover was eliminated. The exciter windings were intended to excite the field at 45 volts DC delivered through the commutator, while the generator windings were intended to independently deliver 110-120 volts AC through the slip rings. The winding ratio between the exciter and generator windings was approximately one to three, and these are the values which determined the values employed in the present reduction to practice. However, it is to be understood that other values can be employed by design, for operation at the desired input and output voltages and amperages. It is also to be understood that the example reduction to practice disclosed herein is not necessarily the optimum design, in that other input-output power balances are contemplated, such as a DC battery input voltage substantially equal to the AC power voltage. In any case, an unexpected increase in power is realised by practising this invention.

This dynamo electric converter inherently operates at a substantially constant angular velocity with the result that the alternating cycles of the output are substantially constant. Also, the DC input voltage can be maintained at a substantially constant level with the result that the AC output voltage is also substantially constant. As shown, the output is single phase AC in which case the effective power in watts delivered is the product of current, voltage and power factor. Since the voltage is substantially constant, the current varies with load applied to the output as it is affected by the power factor. It will be seen therefore, that the apparent power represented by voltage times amperage is drawn directly from the DC input and applied to the primary motor winding **10** to motivate the rotor **R** for the functions previously described. It will also be seen therefore, that the DC input is commutated into AC and transformed by induction from windings **10** into windings **11**.

It will also be seen therefore, that the AC generated by motorisation of the motor is synchronously imposed upon the windings **11**, and all to the end that the two alternating currents are complementary and one added to the other. It will be observed that the output wattage is approximately triple the input wattage, by virtue of the synchronous superimposing of transformed input voltage and generated voltage while utilising the former to operate the rotor in order to generate the latter. A feature of this invention is the separation of the primary and secondary circuits and the consequent isolation of the inverted input DC from the outlet AC and the utilisation of input energy commensurate with output load according to amperage required for the operations to which this DEC machine is applied.



In carrying out this invention, the dynamo electric machine is conventional in design and the primary and secondary windings **10-11** are wound into the common slots of the armature as they are in self exciting generators. However, the primary windings **10** are motor-transformer windings and function totally as such. Similarly, the secondary windings **11** are wound into the armature slots together with the primary windings **10** and are powered with current that is alternated by virtue of the commutation and rotation of the armature, and consequently there is a transformer action between the primary windings **10** and secondary windings **11**, and this transformer function is supplemented by generation of a superimposed current by virtue of the secondary windings **11** cutting the magnetic lines of force provided by the surrounding stator field. Consequently, there is a multiplying of power synchronously applied through the slip rings **SR** to the output brushes **13**, and this increased output power is measurable as previously described and double or almost triple that of the input power.

METHOD

Referring now to this method of increasing electrical power, input alternating current is applied to a primary winding to both motor and alternately magnetise a core. The said primary winding is immersed in a field and consequently is caused to motor and simultaneously to perform the first stage of transforming. A second stage of transforming is then performed by a secondary winding associated with the core to function as both a transformer and a generator winding, and the output current is drawn from it at an increased power value as compared with the input power, since the current induced by transformer action is superimposed upon the current generated in

cutting the magnetic lines of force by motoring the secondary winding through the magnetic field. The direct application of AC power to the primary winding is contemplated, however the present and preferred embodiment employs commutation of DC power which is thereby inverted to AC power in the process of motoring the windings and the core in which they are carried together with the secondary winding. The net result is three fold, in that there is a motoring function, a transforming function, and a generating function, all of which are inherently synchronised to increase the output power with respect to the input power.

FIG. 1.

From the foregoing it will be seen that this method, and the dynamo-electric converter termed a DEC, synchronously superimposes transformed electrical energy and mechanically generated electrical energy when inverting DC to AC as is shown by observing the oscilloscope diagram duplicated in **Fig.4** of the drawings. The DC motor section of the rotor-stator unit will operate at its designed speed well within a small tolerance, by applying known engineering principles, and consequently, the AC generator-alternator section will operate at a substantially uniform frequency of, for example, 60 cycles per second. Thus, the output voltage potential is kept to a maximum while current is drawn as required, within the design capacity of the unit.

Having described only a typical preferred form and application of my invention, I do not wish to be limited or restricted to the specific details herein set forth, but wish to reserve to myself any modifications or variations that may appear to those skilled in the art:

CLAIMS

1. A dynamo-electric converter for inverting direct current voltage to alternating current voltage and including; a magnetic field having poles of opposite polarity, an armature coaxial with the field and having a core with means to receive windings, coaxial bearing means between the field and the armature, a primary motor-transformer winding in said means of the armature core and a commutator connected therewith, direct current input brushes which can be engaged with the said commutator, a secondary transformer-generator winding in said means of the armature core and slip rings connected therewith, and alternating current output brushes which can be engaged with the said slip rings, whereby direct current input power is both transformed and regenerated as alternating output power.

2. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field is a stator comprised of said poles of opposite polarity, and wherein the armature is a rotor supported upon said bearing means coaxially within said field.

3. The dynamo-electric converter as set forth in claim 1, wherein the means to receive windings is a pair of slots in the armature core, said primary and secondary windings being carried in the slots and subjected to the magnetic capabilities of the core.

4. The dynamo-electric converter as set forth in claim 1, wherein the means to receive windings is a multiplicity of slots disposed in a circumferential series about the armature core, said primary and secondary windings being

circumferentially progressive windings respectively and carried in common slots respectively and subjected to the magnetic capabilities of the core.

5. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field poles are permanent magnets.

6. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field poles are electro magnets energised separately from the said primary motor winding.

7. The dynamo-electric converter as set forth in claim 1, wherein the field poles are electro magnets energised in parallel with the direct current input brushes which can be engaged with the commutator.

8. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field is a stator comprised of said poles of opposite polarity, wherein the armature is a rotor supported on said bearing means coaxially within said field, and wherein the means to receive windings is a pair of slots in the armature core, said primary and secondary windings being carried in the slots and subjected to the magnetic capabilities of the core.

9. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field is a stator comprised of permanent magnet poles of opposite polarity, wherein the armature is a rotor supported on said bearing means coaxially within said field, and wherein the means to receive windings is a pair of slots in the armature core, said primary and secondary windings being carried in the slots and subjected to the magnetic capabilities of the core.

10. The dynamo-electric converter as set forth in claim 1, wherein the magnetic field is a stator comprised of permanent magnet poles of opposite polarity, wherein the armature is a rotor supported on said bearing means coaxially within said field, and wherein the means to receive windings is a multiplicity of slots disposed in a circumferential series about the armature core, said primary and secondary windings being circumferentially progressive windings and carried in common slots respectively and subjected to the magnetic capabilities of the core.

11. The dynamo-electric converter is set forth in claim 1, wherein the magnetic field poles are electro magnets of opposite polarity energised in parallel with the direct current input brushes which can be engaged with the commutator, wherein the means to receive windings is a multiplicity of slots disposed in a circumferential series about the armature core, said primary and secondary windings being circumferentially progressive windings respectively and carried in common slots respectively and subjected to the magnetic capabilities of the core.

12. A method for increasing electrical power and comprised of; placing a primary winding within the flux of a magnetic field and applying alternating current therethrough while motoring the same to revolve, simultaneously revolving a secondary winding with the primary winding and through a flux of a magnetic field, and simultaneously transforming the first mentioned alternating current from the primary winding and into the secondary winding while synchronously generating alternating current in the secondary winding.

13. The method of increasing electrical power as set forth in claim 12 wherein the magnetic field is held stationary and the primary and secondary windings revolved together.

14. The method of increasing electrical power as set forth in claim 12 wherein the primary and secondary windings are related to a common armature synchronously inducing into and generating electrical power through the secondary winding.

15. The method of increasing electrical power as set forth in claim 12 wherein the first mentioned alternating current is commutated from direct current to alternating current by revolvement of said primary winding.

16. The method of increasing electrical power as set forth in claim 12 wherein the magnetic field is held stationary and the primary and secondary windings revolved together and related to a common armature synchronously inducing into and generating electrical power through the secondary winding.

17. The method of increasing electrical power as set forth in claim 12 wherein the first mentioned alternating current is commutated from direct current to alternating current by revolvement of said primary winding and the primary and secondary windings related to a common armature synchronously inducing into and generating electrical power through the secondary winding.

18. The method of increasing electrical power as set forth in claim 12 wherein the first mentioned alternating current is commutated from direct current to alternating current by revolvement of said primary winding and wherein the magnetic field is held stationary and the primary and secondary windings revolved together and

related to a common armature synchronously inducing into and generating electrical power through the secondary winding.

19. A dynamo-electric machine including; a first means applying a first alternating current into a primary motor-transformer winding, and a second means inducing a second alternating current into a secondary transformer-generator winding, said secondary winding being carried by said second means to operate through a flux of a field and thereby generating a third alternating current, whereby said second and third alternating currents are synchronously superimposed one upon the other.

20. The dynamo-electric machine as set forth in claim 19 wherein the field is stationary and the primary and secondary windings are rotary.

21. The dynamo-electric machine as set forth in claim 19 wherein the field is stationary and the primary and secondary windings are rotary with commutator bars synchronously applying a direct current to motorise the armature and to apply said first alternating current thereto.

22. The dynamo-electric machine as set forth in claim 19 wherein the transformer means comprises magnetic core means common to the primary and secondary windings.

23. The dynamo-electric machine as set forth in claim 19, wherein the field is stationary and the primary and secondary windings are rotary with commutator bars synchronously applying a direct current to motorise the armature and to apply said first alternating current thereto, and wherein the transformer means comprises magnetic core means common to the primary and secondary windings.

24. A rotary dynamo-electric machine including: means applying alternating current through a primary motor-transformer winding carried by an armature core carrying a secondary transformer-generator winding, a field, and bearing means for rotation of the armature core relative to the field, whereby the alternating current applied to the primary winding motors the armature and is transformed and an alternating current generated and superimposed thereon through the secondary winding for increased output power.

25. The rotary dynamo-electric machine as set forth in claim 24 wherein the primary and secondary windings are each comprised of a number of turns of conductor to transform the first mentioned applied alternating current to the voltage of the alternating current generated through the secondary winding.

26. The rotary dynamo-electric motor as set forth in claim 24 wherein the first mentioned applied alternating current is of different voltage than the increased output power and wherein the primary and secondary windings are each comprised of a number of turns of conductor to transform the first mentioned applied alternating current to the voltage of the alternating current generated through the secondary winding.

27. The rotary dynamo-electric machine as set forth in claim 24 wherein the first mentioned applied alternating current is of lower voltage than the increased output power and wherein the primary and secondary windings are each comprised of a number of turns of conductor to transform the first mentioned applied alternating current to the voltage of the alternating current generated through the secondary winding.

INDUCTION GENERATOR HAVING A PAIR OF MAGNETIC POLES OF THE SAME POLARITY OPPOSED TO EACH OTHER WITH RESPECT TO A ROTATION SHAFT

This patent covers a device which is claimed to have a greater output power than the input power required to run it.

ABSTRACT

An induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft is characterised by a high energy conversion efficiency. The induction generation has a rotation shaft driven by an external means; an even number of (more than three) stator cores provided to encircle the rotation shaft, predetermined gaps being provided between the adjacent stator cores; a first monopole rotor provided in the rotation shaft, surrounded by the even number of stator cores, and having first and second magnetic poles of the same polarity, the first and second magnetic poles being opposed to each other with respect to the rotation shaft in a cross section; a second monopole rotor provided in the rotation shaft so as to face the first monopole rotor at a predetermined distance along the rotation shaft, surrounded by the even number of stator cores, and having third and fourth magnetic poles of the same polarity opposite to the polarity of the first and second magnetic poles, the third and fourth magnetic poles being opposite to each other with respect to the rotation shaft; a plurality of windings provided in the even number of stator cores and connected according to a predetermined configuration.

DESCRIPTION

TECHNICAL FIELD

The present invention relates to an induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft.

Induction generators have been known as one type of electrical appliance from relatively old days and embodied in various forms adapted for individual applications. In addition to applications in power plants, ships and aircraft, induction generators convenient for household or leisure purposes have also been developed and used extensively.

An induction generator converts kinetic energy into electric energy. Due to a necessity for improving efficiency of energy utilisation, there is a demand for a highly efficient energy conversion.

BACKGROUND ART

As is well known, an induction generator is operated on the principle that an electromotive force is induced in a coil, in proportion to the rate at which magnetic flux crosses that coil (Faraday's law of electromagnetic induction). According to Lenz's law, an induced electromotive force is generated in a direction in which a current that acts against a change in the magnetic flux is generated.

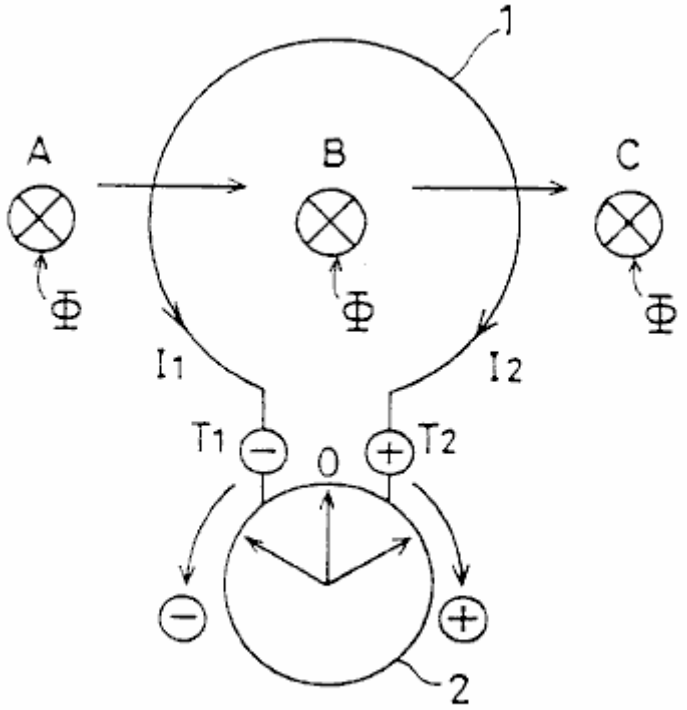

FIG. 1A

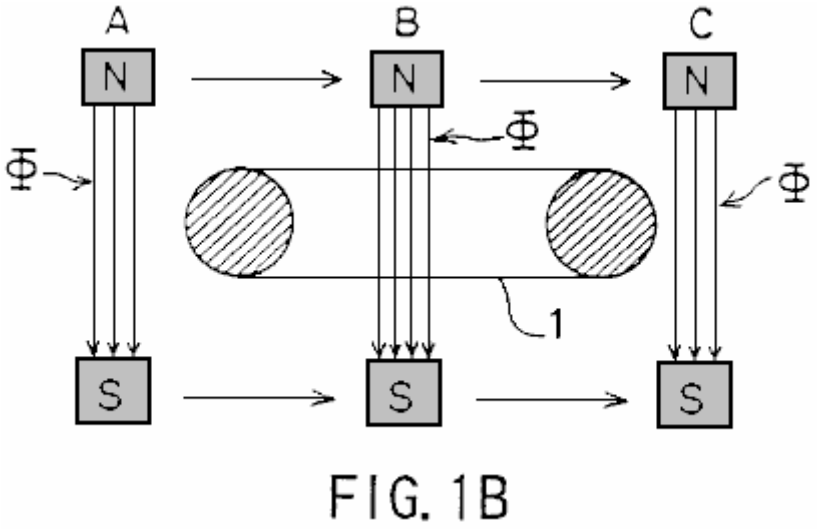

FIG. 1B

For example, as shown in **Fig.1A** and **Fig.1B**, assuming that the magnetic flux **phi** crossing a circular coil **1** at a perpendicular direction moves in the **A to B** direction as indicated by the arrow, a current $\mathbf{I_1}$ flows in accordance with Faraday's law of electromagnetic induction so that the pointer of a galvanometer **2** swings clockwise (+ direction) and then returns to the zero position. When the magnetic flux **phi** moves in the direction **B to C**, a current $\mathbf{I_2}$ flows so that the indicator of the galvanometer **2** swings counterclockwise (- direction) and then returns to the zero position.

Generally, an induction generator is constructed in such a way that an electromotive force is induced according to Flemming's right-hand rule by a conductor cutting magnetic flux lines (**Fig.1A**) or by the magnetic flux lines crossing the conductor (**Fig.1B**).

A rotor in an induction generator is usually constructed as a one-piece body having alternately disposed North poles and South poles. When there are two magnetic poles, the N-pole and the S-pole are opposite to each other. When there are more than two magnetic poles (for example, four magnetic poles or six magnetic poles etc.), the N-pole and the S-pole alternate, resulting in a N-S-N-S- . . . succession.

In this background, a unipolar induction generator is a special case wherein an electromotive force is generated by a conductor cutting the magnetic flux while moving or rotating, and a direct current is supplied through a slip

ring. In other words, a unipolar induction motor is unique in its construction characterised by a non-alternating magnetic field travelling in the same direction.

In the conventional induction generator such as the one described above, improvement in energy conversion efficiency is attained such that the rotor is constructed of a ferrite, or rare-earth, magnet characterised by a high energy product and a small reversing permeability (recoil permeability). Alternatively, the extent of demagnetisation due to generation of a counter magnetic field in an induction coil is reduced allowing the single polarity of the rotor to interact with the stator in forming a magnetic circuit. However, despite these measures, reduction in energy conversion efficiency due to a counter magnetic field of the rotor core, more specifically, due to demagnetisation resulting from the counter magnetic field caused by armature reaction presents a serious problem.

The present invention has been developed in view of the above points, and its object is to provide an induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft, wherein a high energy conversion efficiency is attained.

DISCLOSURE OF THE INVENTION

The present invention provides an induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft, characterised by comprising:

A rotation shaft driven by external means;

An even number of (more than three) stator cores provided to encircle the rotation shaft, predetermined gaps being provided between the adjacent stator cores;

A first single-opposed polarity rotor provided in the rotation shaft, surrounded by the even number of stator cores, and having first and second magnets magnetised such that the even number of stator cores remain facing a first polarity, the first and second magnets being opposed to each other with respect to the rotation shaft in a cross section;

A second single-opposed-polarity rotor provided in the rotation shaft so as to face the first single-opposed-polarity rotor at a predetermined distance along the rotation shaft, surrounded by the even number of stator cores, and having third and fourth magnets magnetised such that the even number of stator cores remain facing a second polarity which is opposite to the polarity of the first polarity, the third and fourth magnets being disposed opposite to each other with respect to the rotation shaft;

A plurality of windings provided in the even number of stator cores and connected according to a predetermined configuration, characterised in that:

A rotating magnetic field which causes electromagnetic induction in the even number of stator cores successively is created by the first, second, third and fourth magnets when the first and second single-opposed-polarity rotors are rotated; and

Periodic increase and decrease in the number of magnetic flux lines crossing a given winding and associated periodic decrease and increase crossing an adjacent winding causes a periodic electromotive force having a rectangular waveform to be output.

In one aspect of the present invention, the plurality of windings connected according to the predetermined configuration form first and second serial circuits:

The first serial circuit outputs a periodic first electromotive force having a rectangular waveform when a rotating magnetic field which causes electromagnetic induction in the even number of stator cores successively is created by the first, second, third and fourth magnets when the first and second single-opposed-polarity rotors are rotated; and

The second serial circuit outputs a periodic second electromotive force of a rectangular waveform 180^0. out of phase with the first electromotive force and having the same period as the first electromotive force, when a rotating magnetic field which causes electromagnetic induction in the even number of stator cores successively is created by the first and second single-opposed-polarity rotors are rotated.

The induction generator of the present invention may also comprise:

Rotation position detecting means for detecting a position of the first and second single-opposed-polarity rotors during their rotation; and

Switching means which alternately causes positive components of the first electromotive force having a rectangular waveform and provided by the first serial circuit, or positive components of the second electromotive force having a rectangular waveform and provided by the second serial circuit to be output at intervals of an electrical angle of 180^0.

In another aspect of the present invention, the plurality of windings comprise a first winding provided in a first stator core of the even number of stator cores, a second winding provided in a second stator core adjacent to the first stator core so as to wind in a direction opposite to a direction in which the first winding is provided, a third winding provided in a third stator core adjacent to the second stator core so as to wind in the same direction as the first winding, a fourth winding provided in a fourth stator core adjacent to the third stator core so as to wind in a direction opposite to a direction in which the third winding is provided, the first through fourth windings being connected with each other according to a predetermined configuration.

In still another aspect of the present invention, the first serial circuit comprises a first winding provided to wind in a first direction in a first stator core of the even number of stator cores, a second winding serially connected to the first winding and provided in a second stator core adjacent to the first stator core so as to wind in a second direction opposite to the first direction, a third winding serially connected with the second winding and provided in a third stator core adjacent to the second stator core so as to wind in the first direction, a fourth winding serially connected to the third winding and provided in a fourth stator core adjacent to the third stator core so as to wind in the second direction; and

The second serial circuit comprises a fifth winding provided to wind in the second direction in the first stator core, a sixth winding serially connected to the fifth winding and provided in the second stator core so as to wind in the first direction, a seventh winding serially connected with the sixth winding and provided in the third stator core so as to wind in the second direction, an eighth winding serially connected to the seventh winding and provided in the fourth stator core so as to wind in the first direction.

In yet another aspect of the present invention, the first through fourth magnets are arc-shaped; and

the even number of stator cores have arc-shaped cross sections.

In still another aspect of the present invention, the arc-shaped first through fourth magnets and the stator cores which have arc-like cross sections have an almost identical circumferential length.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig.1A and **Fig.1B** are diagrams explaining the principle of an induction generator;

Fig.2A and **Fig.2B** are diagrams showing a first embodiment of the present invention;

Fig.3A and **Fig.3B** are diagrams showing a single-opposed-polarity rotor **11N** according to the first embodiment of the present invention;

Fig.4A and **Fig.4B** are diagrams showing a single-opposed-polarity rotor **11S** according to the first embodiment of the present invention;

Fig.5A, **Fig.5B** and **Fig.5C** are diagrams showing how wirings are connected with each other according to the first embodiment of the present invention;

Fig.6A is a diagram schematically showing how a rotating magnetic field according to the first embodiment crosses windings **7c-10c**;

Fig.6B shows a magnetic path;

BEST MODE FOR CARRYING OUT THE INVENTION

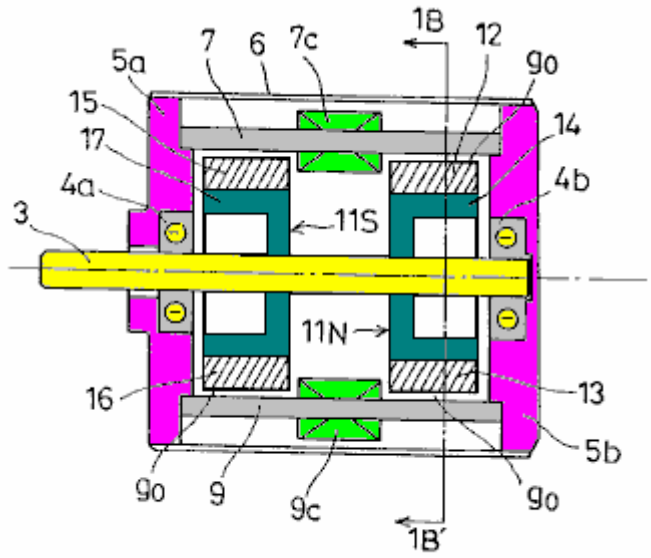

FIG. 2A

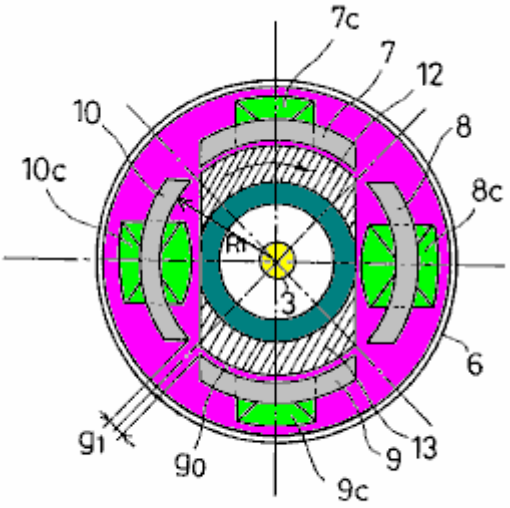

FIG. 2B

Fig.2A and **Fig.2B** show a first embodiment of the present invention. Specifically, **Fig.2A** is a longitudinal sectional view and **Fig.2B** is a cross-sectional view taken in the line **1B-1B'** of **Fig.2A**.

Referring to **Fig.2A** and **Fig.2B**, **3** indicates a rotation shaft formed of a non-magnetic material and driven by an external means; **4a** and **4b** bearings for supporting the rotation shaft **3**; **5a** and **5b** are flanges provided with the bearings **4a** and **4b**, respectively; and **6** is a cylindrical case cover for accommodating the flanges **5a** and **5b**.

Stator cores **7**, **8**, **9** and **10** are arranged so as to encircle the rotation shaft **3**, equidistant gaps $\mathbf{g_1}$ being provided between the adjacent stator cores. Each of the stator cores **7**, **8**, **9** and **10** has the same arc-like cross section.

A single-opposed-polarity N-pole rotor **11N** and a single-opposed-polarity S-pole rotor **11S** are provided on the rotation shaft **3** so as to be opposite to each other. The single-opposed-polarity rotors **11N** and **11S** are surrounded by the stator cores **7**, **8**, **9** and **10**, a small rotation gap $\mathbf{g_0}$ being provided between the single-opposed-polarity rotor and the stator core.

Referring to **Fig.2B**, windings **7c** and **9c** are provided clockwise around the stator cores **7** and **9**, respectively. Windings **8c** and **10c** are wound counterclockwise around the stator cores **8** and **10**, respectively. The windings **7c**, **8c**, **9c** and **10c** are connected with each other in a configuration described later.

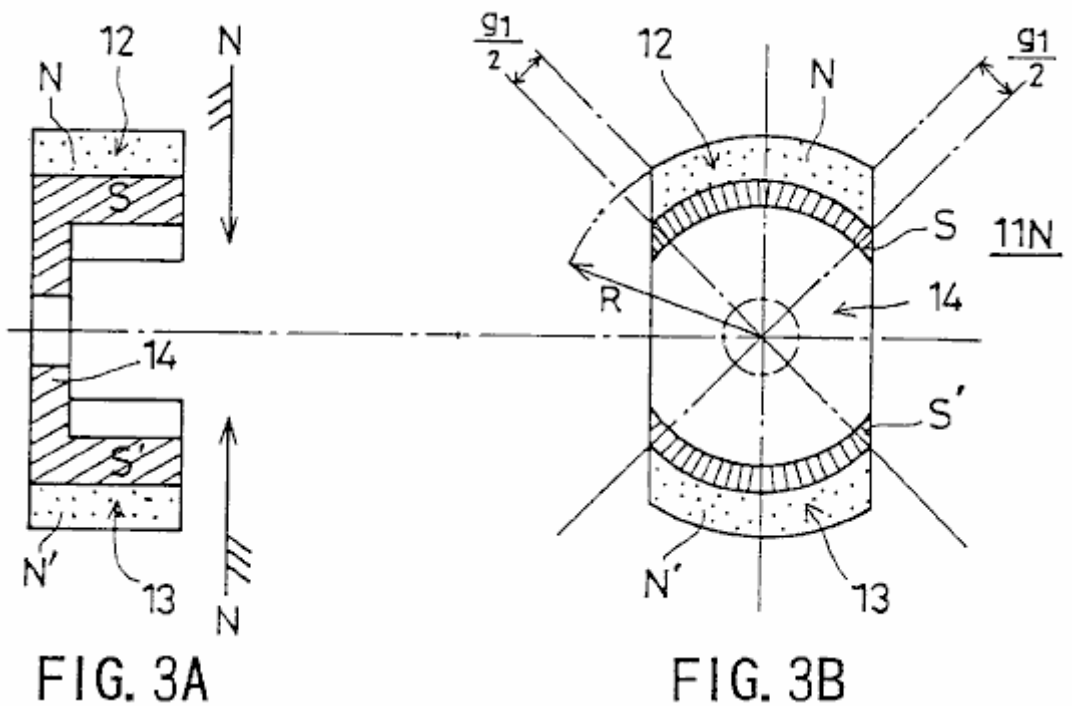

FIG. 3A FIG. 3B

Fig.3A and **Fig.3B** show the single-opposed-polarity rotor **11N**. Specifically, **Fig.3A** is a longitudinal sectional view, and **Fig.3B** is a cross-sectional view. The single-opposed-polarity rotor **11N** has arc-shaped magnets **12** and **13** which are 180^0 displaced from each other and are magnetised such that their surfaces which face the stator cores **7-10** are N-poles while their inner surfaces are S-poles. The arc-shaped magnets **12** and **13** are configured to match the outline of the stator cores **7**, **8**, **9** and **10**. Referring to **Fig.3B**, the symbols **N** and **N'** are used so as to differentiate between the magnets **12** and **13**.

A rotor piece **14** is positioned so as to connect the arc-shaped magnets **12** and **13**. The rotor piece **14** is magnetised by the arc-shaped magnets **12** and **13** so that it's surfaces which face the arc-shaped magnets **12** and **13** are S-poles and is formed of a substance (for example, a silicon steel) constructed of a low carbon steel having mixed therein several percent of non-ferrous metal subjected to a forging-cast process. The iron core embodied by the rotor piece **14** thus constructed is characterised by a well-balanced magnetic field where the permeability approximates a peak value in a unipolar magnetic field that the iron core presents to its surroundings.

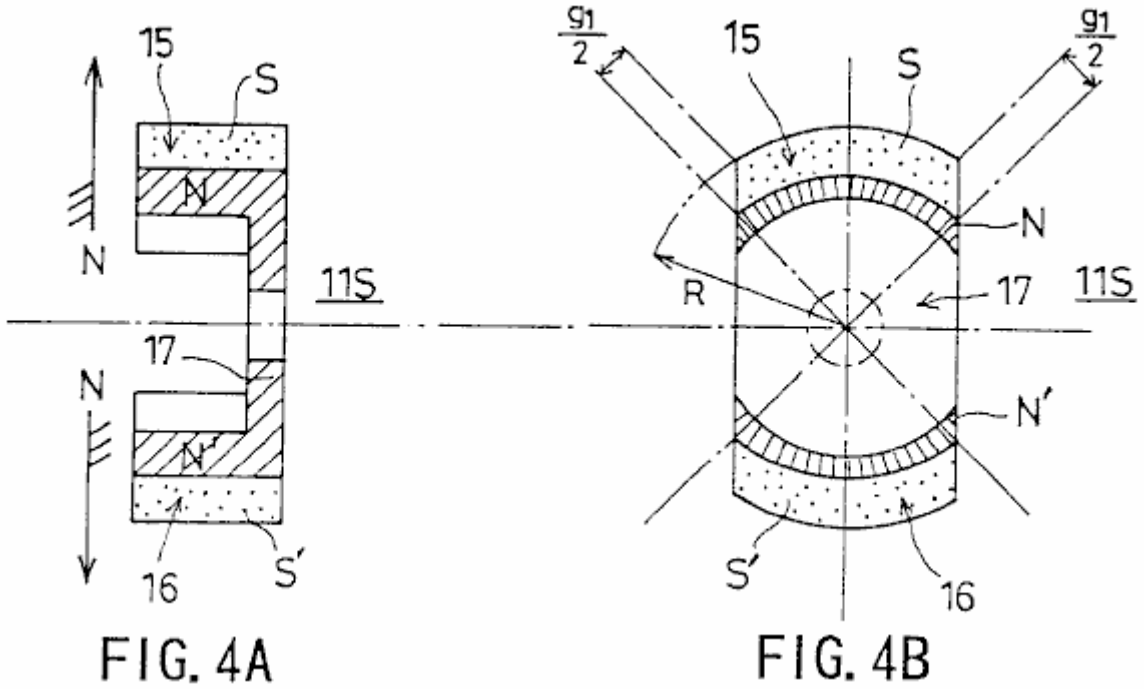

FIG. 4A FIG. 4B

Fig.4A and **Fig.4B** show the single-opposed-polarity rotor **11S**. Specifically, **Fig.4A** is a longitudinal sectional view, and **Fig.4B** is a cross-sectional view.

The single-opposed-polarity rotor **11S** has arc-shaped magnets **15** and **16** which are 180^0 displaced from each other and are magnetised such that the surfaces thereof facing the stator cores **7-10** are S-poles while their inner surfaces are N-poles. The arc-shaped magnets **15** and **16** are configured to match the outline of the stator cores **7**, **8**, **9** and **10**.

A rotor piece 17 is positioned so as to connect the arc-shaped magnets **15** and **16**. The rotor piece **17** is magnetised by the arc-shaped magnets **15** and **16** so that it's surfaces which face the arc-shaped magnets **15** and **16** are N-poles. The rotor piece is made from a substance constructed from a low carbon steel having mixed in it, several percent of non-ferrous metal subjected to a forging-cast process. The iron core embodied by the rotor piece **17** thus constructed is characterised by a well-balanced magnetic field where the permeability approximates a peak value in a unipolar magnetic field that the iron core presents to its surroundings.

The arc-shaped magnets **12**, **13**, **15** and **16** have the same circumferential length, which is also equal to the length of the arc formed by the circumference of the stator cores **7**, **8**, **9** and **10**. More specifically, this length is obtained by dividing the entire hypothetical circumference minus the four $\mathbf{g_1}$ gaps by four. Referring to **Fig.2A** and **Fig.2B**, the rotation gap $\mathbf{g_0}$ is equal to $\mathbf{R_1}$ - **R**, where $\mathbf{R_1}$ is a distance between the centre of the rotation shaft **3** and the inner surface of the stator cores **7-10**, and **R** is a distance between the centre of the rotation shaft **3** and the outer surface of the single-opposed-polarity rotors **11N** and **11S**, as indicated in **Fig.3B** and **Fig.4B**.

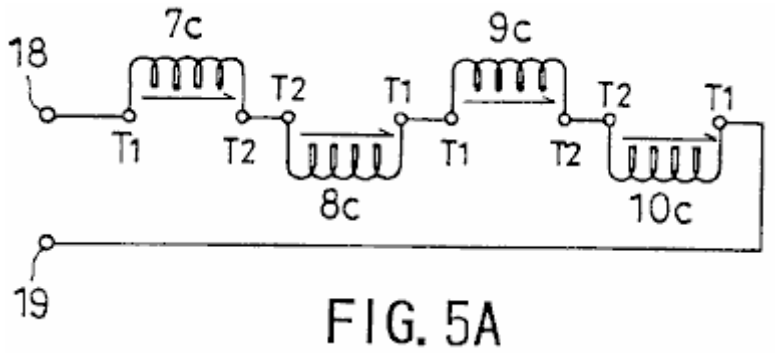

FIG. 5A

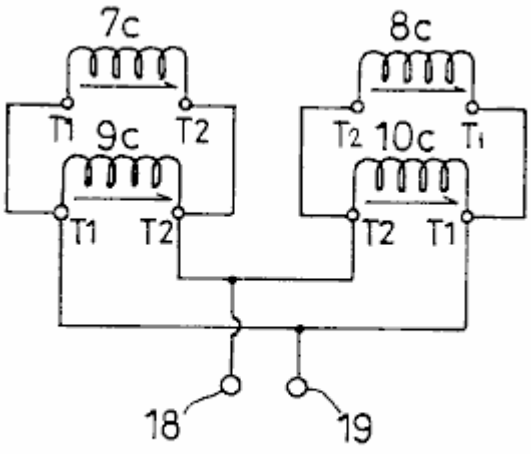

FIG. 5B

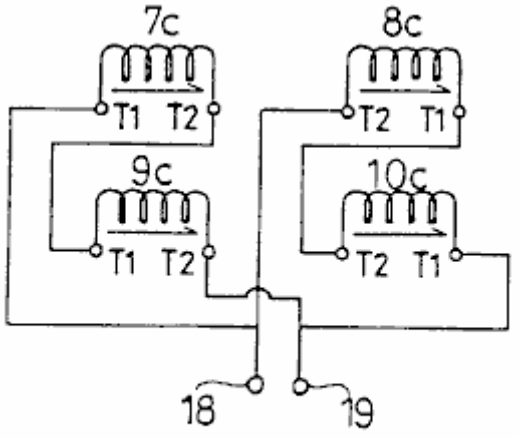

FIG. 5C

Fig.5A, **Fig.5B** and **Fig.5C**, show how the wirings are connected with each other. **T_1** indicates the beginning of a winding, **T_2** the end of a winding, and **18** and **19** output terminals. More specifically, **Fig.5A** shows a serial connection configuration, **Fig.5B** a serial-parallel connection configuration, and **Fig.5C** a parallel connection configuration. The serial connection configuration allows the electromotive force induced in the windings to be added together and provides a high-voltage output. The parallel connection configuration allows currents resulting from the electromotive force induced in the windings to be added together and provides a large-current output.

A description will now be given, with reference to **Fig.6A**, **Fig.6B** and **Fig.7**, of power generation operation of the serial connection configuration.

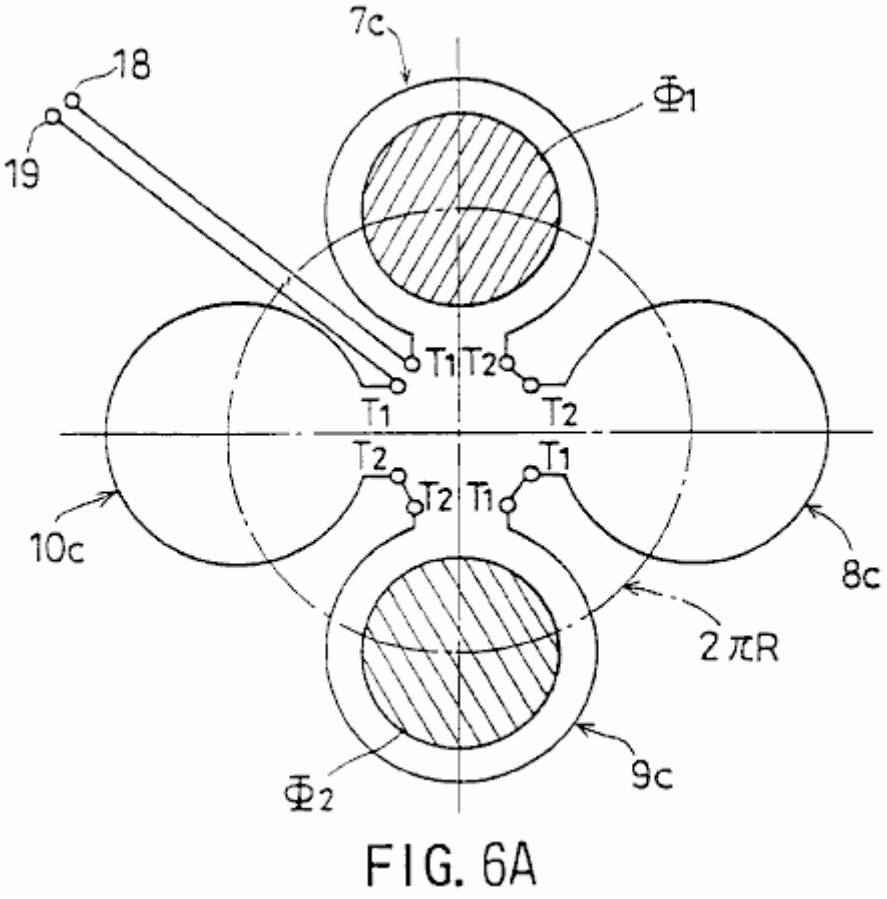

FIG. 6A

Fig.6A is a diagram showing schematically how the rotating magnetic field provided by the single-opposed-polarity rotors **11S** and **11N** crosses windings **7c-10c**. **Fig.6B** shows a magnetic path.

Referring to **Fig.6A**, **Phi_1** and **Phi_2** indicate rotating magnetic flux rotating along the circumference 2Pi x R. **Fig.6B** shows the arc-shaped magnets **12** and **15** directly opposite the stator core **7** over their entire length, and the arc-shaped magnets **13** and **16** directly opposite the stator core **9** over their entire length.

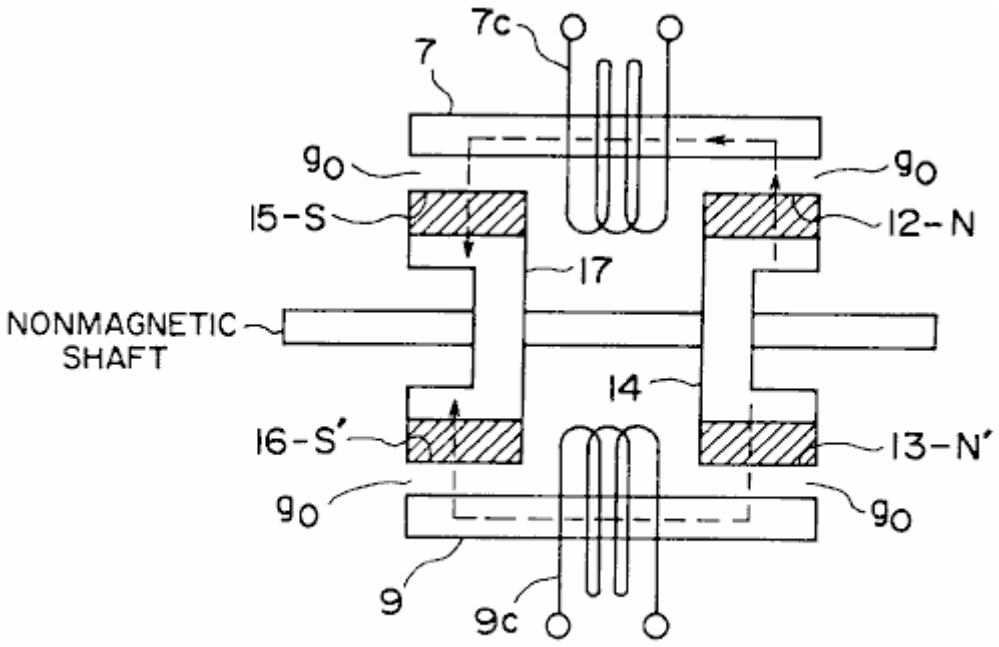

FIG. 6B

As shown in **Fig.6B**, the magnetic flux **Phi_1** forms a magnetic path as follows:

The rotor piece **14** (S) - the arc-shaped magnet pole **12** (N) - stator core **7** - the rotation gap **g_0** - the arc-shaped magnet **15** (S) - the rotor piece **17** (N).

The magnetic flux **Phi_2** forms a magnetic path as follows:

The rotor piece **14** (S) - the arc-shaped magnet **13** (N) - the rotation gap **g_0** - the stator core **9** - the rotation gap **g_0** - the arc-shaped magnet **16** (S) - the rotor piece **17** (N).

Thus, a parallel magnetic path is formed. In this state, the magnetic flux **Phi_1** crosses the winding **7c**, and the magnetic flux **Phi_2** crosses the winding **9c**.

A description focused on the rotation of the magnetic flux **Phi_1** is given. Specifically, a description will be given of a change in the way the magnetic flux **Phi_1** crosses the windings.

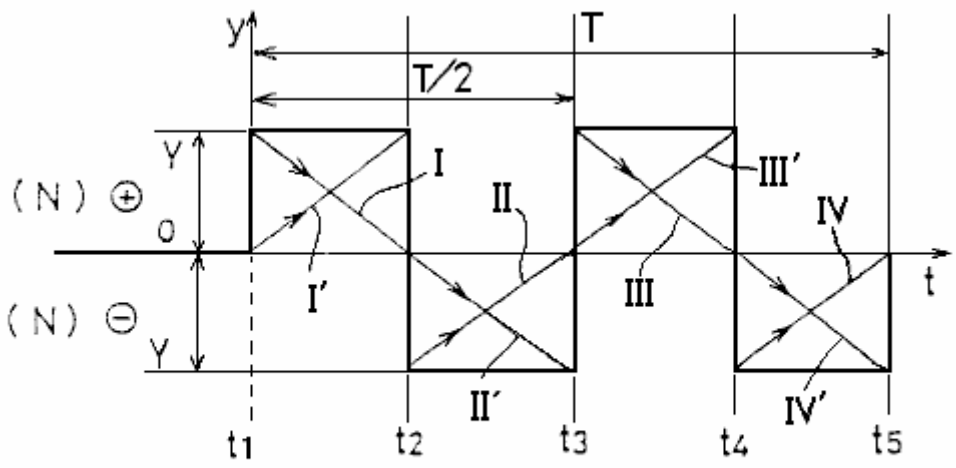

FIG. 7

Referring to a waveform of an output voltage shown in **Fig.7**, the entirety of the magnetic flux **Phi_1** crosses the winding **10c** at a time **t_1**. At a time **t_2**, the entirety of the magnetic flux **Phi_1** crosses the winding **7c**. At a time **t_3**, the entirety of the magnetic flux **Phi_1** crosses the winding **8c**. At a time **t_4**, the entirety of the magnetic flux **Phi_1** crosses the winding **9c**. At a time **t_5**, the entirety of the magnetic flux **Phi_1** crosses the winding **10c**. In this way, the magnetic flux **Phi_1** rotates at a constant speed during a time **T**, in a clockwise direction in **Fig.6A**.

Between the time **t_1** and the time **t_2**, an electromotive force having a descending triangular waveform, indicated by **I** in **Fig.7**, is generated in the winding **10c** due to a decrease in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **10c**. An electromotive force having an ascending triangular waveform, indicated by **I'** in **Fig.6**, is generated in the winding **7c** due to an increase in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **7c**. Accordingly, a positive rectangular waveform obtained by the sum of these triangular waveforms is output to the output terminals **18** and **19**.

Between the time **t_2** and the time **t_3**, an electromotive force having an ascending triangular waveform, indicated by **II** in **Fig.7**, is generated in the winding **7c** due to a decrease in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **7c**. An electromotive force having a descending triangular waveform, indicated by **II'** in **Fig.7**, is generated in the winding **8c** due to an increase in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **8c**. Accordingly, a negative rectangular waveform obtained by the sum of these triangular waveforms is output to the output terminals **18** and **19**.

Between the time **t_3** and the time **t_4**, an electromotive force having a descending triangular waveform, indicated by **III** in **Fig.7**, is generated in the winding **8c** due to a decrease in the number of magnetic flux lines of the magnetic flux **Phi** of the magnetic flux **Phi** crossing the winding **8c**. An electromotive force having an ascending triangular waveform, indicated by **III'** in **Fig.7**, is generated in the winding **9c** due to an increase in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **9c**. Accordingly, a positive rectangular waveform obtained by the sum of these triangular waveforms is output to the output terminals **18** and **19**.

Between the time **t_4** and the time **t_5**, an electromotive force having an ascending triangular waveform, indicated by **IV** in **Fig.7**, is generated in the winding **9c** due to a decrease in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **9c**. An electromotive force having a descending triangular waveform, indicated by **IV'** in **Fig.7**, is generated in the winding **10c** due to an increase in the number of magnetic flux lines of the magnetic flux **Phi** crossing the winding **10c**. Accordingly, a negative rectangular waveform obtained by the sum of these triangular waveforms is output to the output terminals **18** and **19**.

While the magnetic flux **Phi_1** makes one rotation, an electromotive force having a synthesised rectangular waveform and a period of **T/2** is output, as shown in **Fig.7**. Since the magnetic flux **Phi_2** also makes one rotation while the magnetic flux **Phi_1** makes one rotation and produces an output of an electromotive force having a similar rectangular waveform, the magnitude of the electromotive force obtained between the terminals **18** and **19** is actually double that indicated in **Fig.7**.

In this way, this embodiment makes it possible to cancel a counter magnetic field and provide an induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft and characterised by a high energy conversion efficiency. Our operating practice has confirmed that the generator having the construction of this embodiment provides an energy conversion efficiency which is high enough to require only 1/5.2 of the driving torque for the conventional generator.

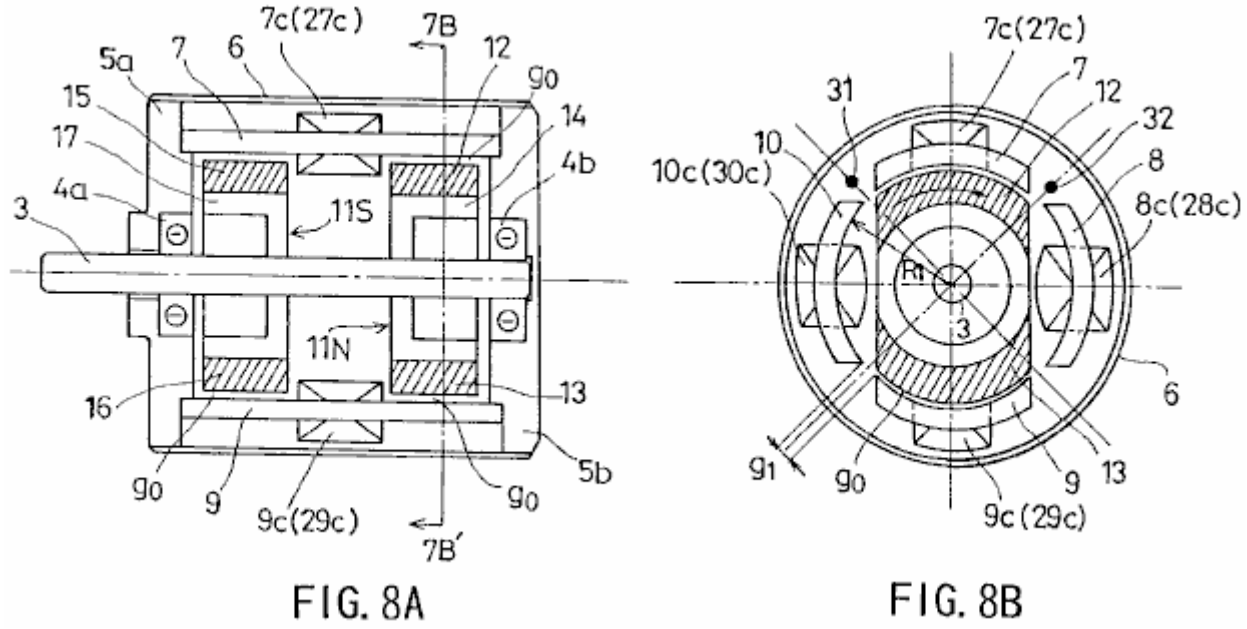

FIG. 8A FIG. 8B

Fig.8A and **Fig.8B** show a second embodiment of the present invention. Specifically, **Fig.8A** is a longitudinal sectional view, and **Fig.8B** is a cross-sectional view taken in the line **7B-7B'** of **Fig.8A**.

Referring to **Fig.8A** and **Fig.8B**, **3** indicates a rotation shaft formed of a non-magnetic material and driven by an external source; **4a** and **4b** are bearings which support the rotation shaft **3**, **5a** and **5b** are flanges housing the bearings **4a** and **4b**, and **6** is a cylindrical case cover for accommodating the flanges **5a** and **5b**.

Stator cores **7**, **8**, **9** and **10** are arranged so as to encircle the rotation shaft **3**, equidistant gaps $\mathbf{g_1}$ being provided between the adjacent stator cores. Each of the stator cores **7**, **8**, **9** and **10** has a same arc-like cross section.

A single-opposed-polarity N-pole rotor **11N** and a single-opposed-polarity S-pole rotor **11S** are provided on the rotation shaft **3** so as to be opposite to each other. The single-opposed-polarity rotors **11N** and **11S** are surrounded by the stator cores **7**, **8**, **9** and **10** a small rotation gap $\mathbf{g_0}$ being provided between the single-opposed-polarity rotor and the stator core.

Referring to **Fig.8B**, windings **7c** and **9c** are provided clockwise around the stator cores **7** and **9**, respectively. Windings **27c** and **29c** are provided counterclockwise around the stator cores **7** and **9**, respectively. Windings **8c** and **10c** are provided counterclockwise in the stator cores **8** and **10**, respectively. Windings **28c** and 30c are wound clockwise around the stator cores 8 and 10, respectively. The windings 7c, 8c, 9c, 10c, **27c**, **28c**, **29c** and **30c** are connected with each other according to a configuration described later.

A magnetic sensor (for rotation position detection) **31** is provided between the stator cores **7** and **10**, and a magnetic sensor (for rotation position detection) **32** is provided between the stator cores **7** and **8**. The magnetic sensors **31** and **32** detect the magnetic field so as to determine the position of the single-opposed-polarity rotors **11N** and **11S** during their rotation.

The single-opposed-polarity rotors **11N** has a configuration as shown in **Fig.3A** and **Fig.3B**, and the monopole rotor **11S** has a configuration as shown in **Fig.4A** and **Fig.4B**.

The single-opposed-polarity rotor **11N** has arc-shaped magnets **12** and **13** which are 180^0 displaced from each other and are magnetised such that their surfaces facing the stator cores are N-poles while their respective inner surfaces are S-poles. The arc-shaped magnets **12** and **13** are configured to match the outline of the stator cores **7**, **8**, **9** and **10**.

A rotor piece **14** is positioned so as to connect the arc-shaped magnets **12** and **13**. The rotor piece **14** is constructed from a low-carbon steel having several percent of non-ferrous metal, using a forging-cast process. The iron core rotor piece **14** constructed by this means, has a well-balanced magnetic field where the permeability approximates a peak value in a unipolar magnetic field that the iron core presents to its surroundings.

The single-opposed-polarity rotor **11S** has arc-shaped magnets **15** and **16** which are positioned 180^0 apart from each other and are magnetised so that their surfaces which face the stator cores are S-poles while their inner

surfaces are N-poles. The arc-shaped magnets **15** and **16** are shaped and positioned so as to match the outline of the stator cores **7**, **8**, **9** and **10**.

A rotor piece **17** is positioned so as to connect the arc-shaped magnets **15** and **16**. The rotor piece **17** is constructed from a low-carbon steel having several percent of non-ferrous metal, using a forging-cast process. The iron core rotor piece **17** constructed by this means, has a well-balanced magnetic field where the permeability approximates a peak value in a unipolar magnetic field which the iron core presents to its surroundings.

The arc-shaped magnets **12**, **13**, **15** and **16** have the same circumferential lengths, which is equal to the length of the arc formed by the circumference of the stator cores **7**, **8**, **9** and **10**. More specifically, this length is obtained by dividing by four, the entire hypothetical circumference minus the four gaps $\mathbf{g_1}$. Referring to **Figs. 3A, 3B, 4A, 4B** and **8**, the rotation gap $\mathbf{g_0}$ is equal to $\mathbf{R_1}$ -**R**.

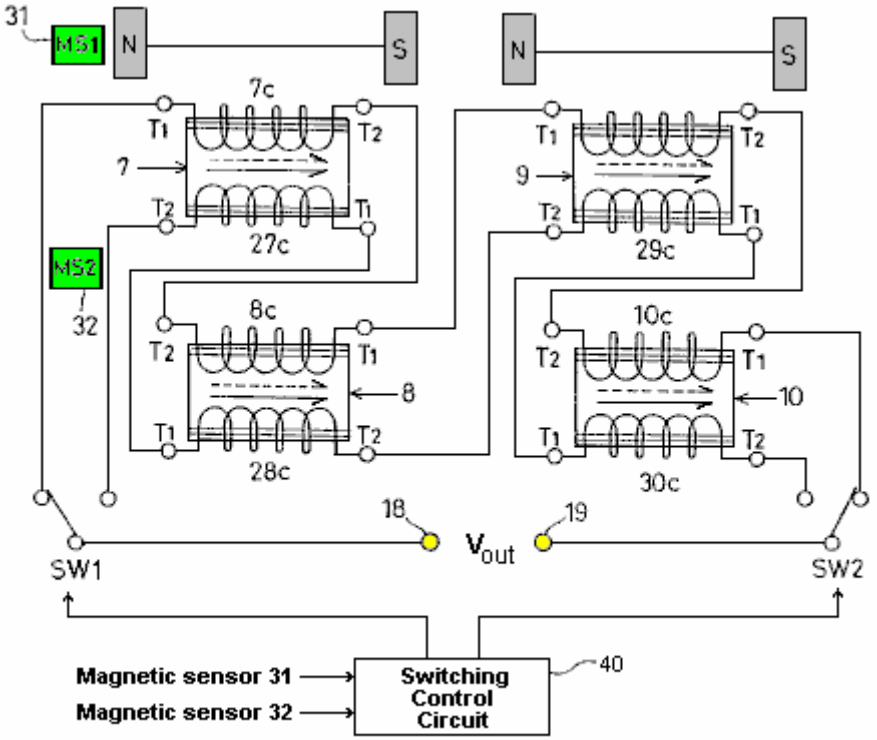

FIG. 9

Fig.9 shows how the wirings are connected with each other. $\mathbf{T_1}$ indicates the beginning of a winding, $\mathbf{T_2}$ the end of a winding, and **18** and **19** are the output terminals.

Two serial circuits are formed out of the windings. Switches **SW1** and **SW2** are used for selection of the respective serial circuits. A switching control circuit **40**, which processes a detection signal from the magnetic sensors **31** and **32**, drives the switches SW1 and SW2 selectively in accordance with the detection signal.

As shown in **Fig.9**, the first serial circuit comprises the winding **7c** provided clockwise in the stator core **7**, the winding **8c** serially connected with the winding **7c** and provided counterclockwise in the stator core **8** adjacent to the stator core **7**; the winding **9c** serially connected with the winding **8c** and provided clockwise in the stator core **9**; and the winding **10c** serially connected with the winding **9c** and provided counterclockwise in the stator core **10** adjacent to the stator core **9**.

As shown in **Fig.9**, the second serial circuit comprises the winding **27c** provided counterclockwise in the stator core **7**; the winding **28c** serially connected with the winding **27c** and provided clockwise in the stator core **8**; the winding **29c** serially connected with the winding **28c** and provided counterclockwise in the stator core **9**; and the winding **30c** serially connected with the winding **29c** and provided clockwise in the stator core **10**.

According to the construction described above, a rotating magnetic field which causes electromagnetic induction in the stator cores **7-10** successively is created by the arc-shaped magnets **12**, **13**, **15** and **16** when the single-opposed-polarity rotors **11N** and **11S** are rotated. As has been already explained with reference to **Fig.6A**, **Fig.6B** and **Fig.7**, as the magnetic flux lines crossing one of the windings **7c-10c** increase in number, the magnetic flux lines crossing the adjacent one of the windings **7c-10c** decrease in number. That is, the magnetic

flux lines periodically increase and decrease with respect to a given winding so that a first electromotive force, having a rectangular waveform similar to the one shown in **Fig.7** and a period that is 1/2 the period of the rotation, is output from the first serial circuit (**7c-10c**).

As the magnetic flux lines crossing one of the windings **27c-30c** increase in number, the magnetic flux lines crossing the adjacent one of the windings **27c-30c** decrease in number. That is, the magnetic flux lines periodically increase and decrease with respect to a given winding so that a second electromotive force of a rectangular waveform 180^0 out of phase with the first electromotive force and having the same period as the first electromotive force is output from the second serial circuit (**27c-30c**). That is, the second electromotive force is 180^0 out of phase with the electromotive force shown in **Fig.7**.

Referring to **Fig.10**, in accordance with the detection signal from the magnetic sensors **31** and **32**, the switches **SW1** and **SW2** effect switching at 90^0 intervals. By that means, the positive components **I** and **III** of the first electromotive force having a rectangular waveform and provided from the first serial circuit, and the positive components **II** and **IV** of the second electromotive force having a rectangular waveform and provided from the second serial circuit are alternately selected at 180^0 intervals and output to the output terminals **18** and **19**.

This means that, this embodiment ensures a high-efficiency energy conversion wherein a counter magnetic field is cancelled, and a DC electromotive force having a positive level is properly synthesised and output. It is of course possible to synthesise and output a negative DC electromotive force by shifting the switching timing by 180^0.

INDUSTRIAL APPLICABILITY

As has been described, according to the present invention, the rotation of the first and second single-opposed-polarity rotors generates a rotating magnetic field which causes an induction in an even number of stator cores successively. As the magnetic flux lines crossing one of the first-through-fourth windings increase in number, the magnetic flux lines crossing the adjacent one of the first-through-fourth windings decrease in number. That is, the magnetic flux lines periodically increase and decrease with respect to a given winding. The electromotive force generated as the magnetic flux lines crossing a winding increase in number and the electromotive force generated as the magnetic flux lines crossing an adjacent winding decrease in number are synthesised so that a periodic AC electromotive force having a rectangular waveform is generated out of the synthesis and output. In this way, a high-efficiency energy conversion wherein a counter magnetic field is cancelled is provided.

According to the first serial circuit of the present invention, the rotation of the first and second single-opposed-polarity rotors generates a rotating magnetic field which causes an induction in an even number of stator cores successively. As the magnetic flux lines crossing one of the first through fourth windings increase in number, the magnetic flux lines crossing the adjacent one of the first through fourth windings decrease in number. That is, the magnetic flux lines periodically increase and decrease in a given winding. Accordingly, the first electromotive force having a rectangular waveform is output. According to the second serial circuit, as the magnetic flux lines crossing one of the fifth-through-eighth windings increase in number, the magnetic flux lines crossing the adjacent one of the fifth-through-eighth windings decrease in number. That is, the magnetic flux lines periodically increase and decrease in a given winding. Accordingly, the second electromotive force 180^0 out of phase with the first electromotive force and having the same period as the first electromotive force is output. In accordance with the detection signal from the rotation position detecting means, the switching means selectively causes the positive components of the first electromotive force provided by the first serial circuit, or the positive components of the second electromotive force provided by the second serial circuit to be output at 180^0 intervals. In this way the DC electromotive force is synthesised and output. This results in a high-efficiency energy conversion where a counter magnetic field is cancelled.

In addition to extensive applications in power plants, ships, aircraft etc., the present invention may find household applications or may be conveniently adapted for leisure uses.

CLAIMS

1. An induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft, characterised by comprising:

a rotation shaft driven by external means;

an even number of (more than three) stator cores provided to encircle said rotation shaft, predetermined gaps being provided between the adjacent stator cores;

a first single-opposed-polarity rotor provided on said rotation shaft, surrounded by said even number of stator cores, and having first and second magnets magnetised such that said even number of stator cores remain facing a first polarity, said first and second magnets sandwiching a magnetic body between them and being opposed to each other with respect to said rotation shaft in a cross section;

a second single-opposed-polarity rotor provided on said rotation shaft so as to face said first single-opposed-polarity rotor at a predetermined distance along the rotation shaft, surrounded by said even number of stator cores, and having third and fourth magnets magnetised such that said even number of stator cores remain facing a second polarity which is opposite to the polarity of said first polarity, said third and fourth magnets sandwiching a magnetic body between them and being disposed opposite to each other with respect to said rotation shaft;

a plurality of windings provided in said even number of stator cores and connected according to a predetermined configuration, characterised in that: a rotating magnetic field which causes electromagnetic induction in said even number of stator cores successively is created by the first, second, third and fourth magnets when said first and second single-opposed-polarity rotors are rotated; and

two windings adjacent to each other are wound in opposite directions and connected in series so that a rectangular waveform is formed by synthesising the electromotive forces generated by the two windings, so that an electromotive force having a triangular waveform caused by periodic increase and decrease in the number of magnetic flux lines crossing one of the two windings and another electromotive force having a triangular waveform caused by associated periodic decrease and increase in the number of magnetic flux lines crossing the other one of the windings are synthesised so as to generate a periodic voltage having a rectangular waveform.

2. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 1, characterised in that:

said plurality of windings connected according to the predetermined configuration form first and second serial circuits;

said first serial circuit outputs a periodic first electromotive force having a rectangular waveform when a rotating magnetic field which causes electromagnetic induction in said even number of stator cores successively is created by said first, second, third and fourth magnets when said first and second single-opposed-polarity rotors are rotated; and

said second serial circuit outputs a periodic second electromotive force of a rectangular waveform 180^0 out of phase with the first electromotive force and having the same period as the first electromotive force, when a rotating magnetic field which causes electromagnetic induction in said even number of stator cores successively is created by said first and second single-opposed-polarity rotors are rotated.

3. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 2, further comprising:

rotation position detecting means for detecting a position of said first and second single-opposed-polarity rotors during their rotation; and

switching means which alternately causes positive components of said first electromotive force having a rectangular waveform and provided by said first serial circuit, or positive components of said second electromotive force having a rectangular waveform and provided by said second serial circuit to be output at intervals of an electrical angle of 180^0 to thereby produce a DC output.

4. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 1, characterised in that:

said plurality of windings comprise a first winding provided in a first stator core of said even number of stator cores, a second winding provided in a second stator core adjacent to the first stator core so as to wind in a direction opposite to a direction in which the first winding is provided, a third winding provided in a third stator core adjacent to the second stator core so as to wind in the same direction as the first winding, a fourth winding provided in a fourth stator core adjacent to the third stator core so as to wind in a direction opposite to a direction in which the third winding is provided, the first through fourth windings being connected with each other according to a predetermined configuration.

5. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 2, characterised in that:

said first serial circuit comprise a first winding provided to wind in a first direction in a first stator core of said even number of stator cores, a second winding serially connected to said first winding and provided in a second stator core adjacent to the first stator core so as to wind in a second direction opposite to the first direction, a third winding serially connected with said second winding and provided in a third stator core adjacent to the second stator core so as to wind in the first direction, a fourth winding serially connected to said third winding and provided in a fourth stator core adjacent to the third stator core so as to wind in the second direction; and

said second serial circuit comprises a fifth winding provided to wind in the second direction in said first stator core, a sixth winding serially connected to said fifth winding and provided in said second stator core so as to wind in said first direction, a seventh winding serially connected with said sixth winding and provided in said third stator core so as to wind in said second direction, an eighth winding serially connected to said seventh winding and provided in said fourth stator core so as to wind in said first direction.

6. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 1, characterised in that:

said first through fourth magnets are arc-shaped; and

said even number of stator cores have arc-shaped cross sections.

7. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 6, characterised in that said arc-shaped first through fourth magnets and said stator cores which have arc-shaped cross sections have an almost identical circumferential length.

8. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 2, characterised in that:

said first through fourth magnets are arc-shaped; and

said even number of stator cores have arc-shaped cross sections.

9. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 3, characterised in that:

said first through fourth magnets are arc-shaped; and

said even number of stator cores have arc-shaped cross sections.

10. The induction generator having a pair of magnets of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 4, characterised in that:

said first through fourth magnets are arc-shaped; and

said even number of stator cores have arc-shaped cross sections.

11. The induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 5, characterised in that:

said first through fourth magnets are arc-shaped; and

said even number of stator cores have arc-shaped cross sections.

12. The induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 8, characterised in that said arc-shaped first through fourth magnets and said stator cores which have arc-shaped cross sections have an almost identical circumferential length.

13. The induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 9, characterised in that said arc-shaped first through fourth magnets and said stator cores which have arc-shaped cross sections have an almost identical circumferential length.

14. The induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 10, characterised in that said arc-shaped first through fourth magnets and said stator cores which have arc-shaped cross sections have an almost identical circumferential length.

15. The induction generator having a pair of magnetic poles of the same polarity opposed to each other with respect to a rotation shaft as claimed in claim 11, characterised in that said arc-shaped first through fourth magnets and said stator cores which have arc-shaped cross sections have an almost identical circumferential length.

LARRY JAMISON

Patent Application EU 82,400,992.2 22nd December 1982 Inventor: Larry T. Jamison

ENERGY SOURCE EMPLOYING ELECTRICAL ENERGISER

This patent application shows the details of a device which it is claimed, can produce electricity without the need for any fuel. It should be noted that while construction details are provided which imply that the inventor constructed and tested several of these devices, this is only an application and not a granted patent.

ABSTRACT

An energy producing system is provided which produces energy for use, for example, in an electric vehicle or in a home power plant. The system includes an electrical energiser (**60**) including a double-wound rotor and a double-wound stator, for producing electrical energy which is stored in the system, e.g. in a battery (**66**) storage arrangement, which provides initial energisation of the system. the stored energy is supplied to an electric motor (**68**) which drives the energiser (**60**) to thereby create additional energy. the energiser is able to supply the needs of the system as well as to power a load.

BACKGROUND OF THE INVENTION

The present invention relates to energy producing systems and, more particularly, to an electrical energiser-motor system for providing energy, e.g., for an automotive vehicle or as part of a home energy plant.

With the advent of the so-called “energy crisis” and the consequent search for alternative energy sources to substitute for oil, considerable attention has been focused on automotive vehicles as chief users of oil products. One aspect of this search has fostered renewed interest in electrically driven vehicles such as electric cars and the like. A principal shortcoming of prior-art electrical vehicles has been the need to recharge the batteries which provide the power for the electrical motor drive system.

The present invention overcomes this problem through the provision of an electrical energiser-motor system which produces more energy than is expended, thereby enabling the excess energy to be stored in the battery system, to be drawn upon as required. Thus, the need for recharging of the batteries associated with conventional electrical vehicles is eliminated with the system of this invention. It should be noted that while the system of the invention has enormous potential in connection with its use in electrical vehicles, the system is clearly not limited to such use and would obviously be advantageous when used, for example, as the energy source for a home energy plant, as well as in many other applications.

In accordance with the invention, and energy producing system of the type described above is provided which comprises and electrical “energiser” comprising at least one double-wound stator and at least one double-wound shaft-mounted rotor located within a housing, electrical energy being collected from the rotor through a suitable electrical take-off device and being available for utilisation by the system, and an electric motor, powered by the energiser for driving the rotor shaft of the energiser. A battery arrangement is initially used to supply energy to the system and, as stated above, the excess energy generated by the energiser over and above that required by the system and the system load, is stored through charging of the batteries. The motor includes an armature with a plurality of winding slots in it and a plurality of windings being wound into two circumferentially spaced slots in the armature, i.e. such a winding is wound through a first slot (e.g. slot 1) and returned through a second spaced slot (e.g. slot 5). depending on the energy demands, the energiser may include a pair of stators and rotors, with the rotors being mounted on a common shaft. The motor is preferably energised through an arrangement of a commutator and plural brushes, while a slip ring and associated brushes connected to an output bridge circuit form the energy take-off for the energiser.

Other features and advantages of the invention will be shown in the detailed description of the preferred embodiments which follows.

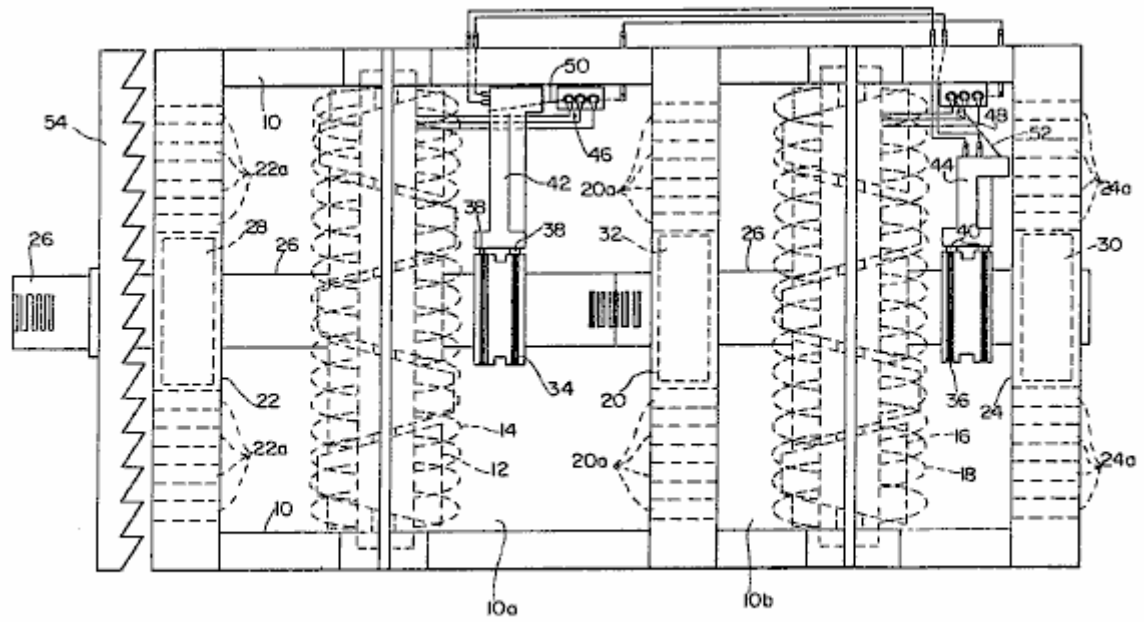

FIG. 1

Fig.1 is a partially sectioned elevational view of the electrical “energiser” of the invention.

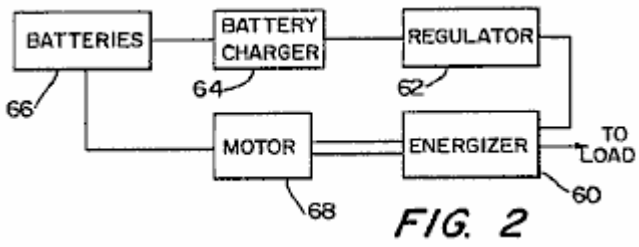

FIG. 2

Fig.2 is a block diagram of the overall energy-producing system of the invention

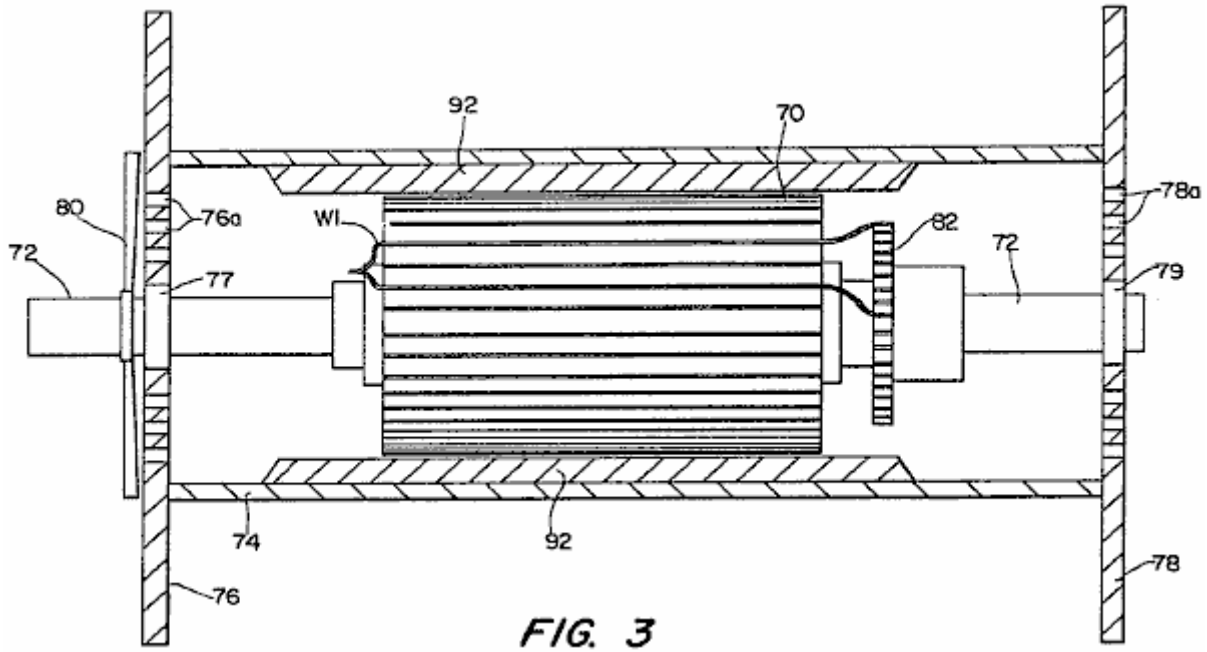

FIG. 3

Fig.3 is a partially sectioned side elevational view of a modified electrical motor constructed in accordance with the invention.

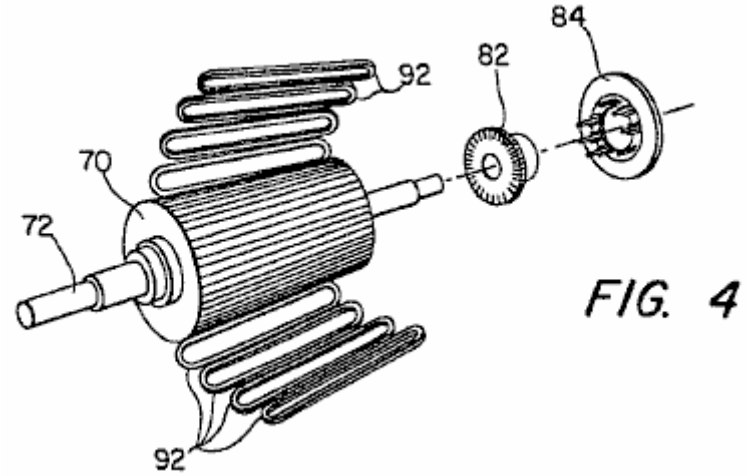

FIG. 4

Fig.4 is an exploded perspective view of the basic components of the motor of **Fig.3**.

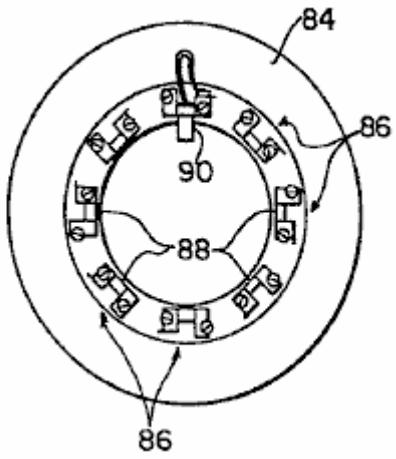

FIG. 5

Fig.5 is an end view of the brush holder also illustrated in **Fig.4**.

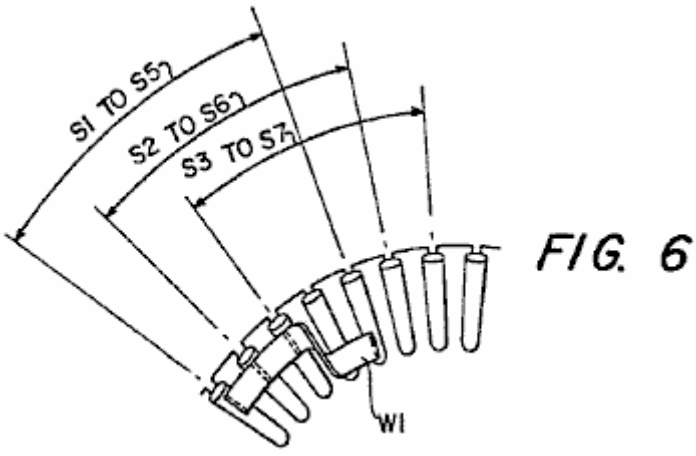

FIG. 6

Fig.6 and **Fig.7** show details of the winding pattern of the motor of **Fig.3**.

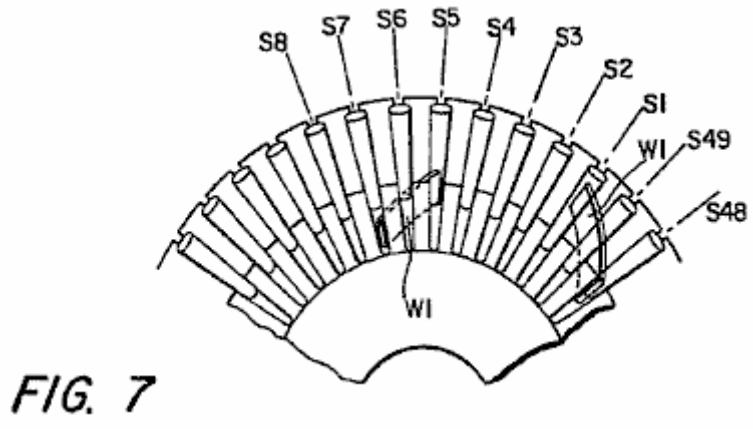

FIG. 7

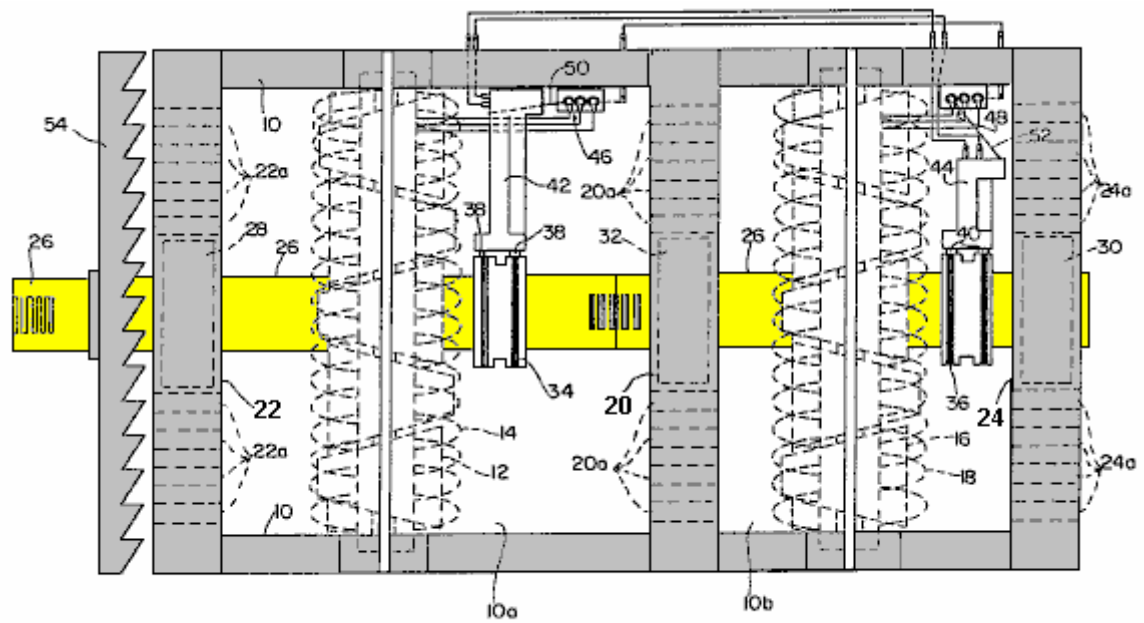

FIG. 1

Referring to **Fig.1**, a preferred embodiment of the "energiser" device of the invention is shown. The device includes a housing **10**, in which are located, in a first chamber or compartment **10a**, a first rotor **12** and a first stator **14** and, in a second compartment **10b**, a second rotor **16**, and a second stator **18**. It should be noted that although two stator-rotor combinations are used in this embodiment, a single stator-rotor combination can be used for some applications. Housing **10** is divided into the compartments **10a** and **10b**, by a centre plate **20** and it includes a pair of end plates **22** and **24**. Both the rotors **12**, **16** and the stators **14**, **18** are double wound and the rotors **12**, **16** are nested inside their respective stators **14** and **18** and mounted for rotation on a common shaft **26**. Shaft **26** extends longitudinally through housing **10** and is mounted on bearings **28** and **30**, supported by end plates **22** and **24**, and a further bearing **32** which is supported by central plate **20**.

A pair of slip rings **34** and **36**, are mounted on shaft **26** and connect with their corresponding brush pairs **38** and **40**.
Slip rings **34** and **36** are connected to rotors **12** and **16** respectively, and permit the current flowing in the rotor windings to be collected through the associated pairs of brushes **38** and **40**. Brush pairs **38** and **40** are mounted on respective brush holders **42** and **44**. The terminals of respective bridge circuits **46** and **48** are connected to stators **14** and **18**, while conversion bars 50 and 52 are connected to brush holders **42** and **44**, as indicated.

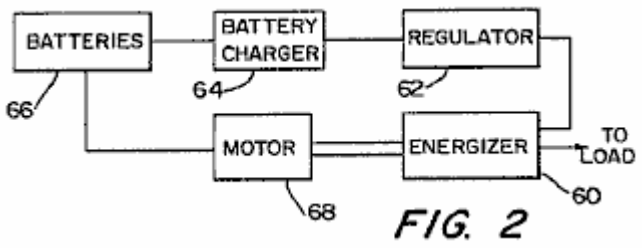

FIG. 2

A cooling fan **54**, is also mounted on shaft **26** and a plurality of apertures **201**, **22a** and **24a** are provided in centre plate **20** and end plates **22** and **24**, to promote cooling of the device. The energiser of **Fig.1** is preferably incorporated in a system such as shown in a highly schematic manner in **Fig.2** where the output of the energiser is used to supply the energy for driving a motor. To this end, the energiser, which is denoted by **60** in **Fig.2**, is connected through a regulator **62**, to battery charger **64** for batteries **66** connected to a motor **68**. These batteries **66** are used to provide the initial energisation of the system as well as to store energy produced by the energiser **60**. It will be understood that the energiser **60** provides energy enough to power motor **68** (which, in turn, drives energiser **60** through rotation of shaft **26**) as well as to provide storage for energy in the system. It will also be appreciated that the system illustrated schematically in **Fig.2** includes suitable controls (switches, rheostats, sensors, etc.) to provide initial energisation as well as appropriate operational control of the system.

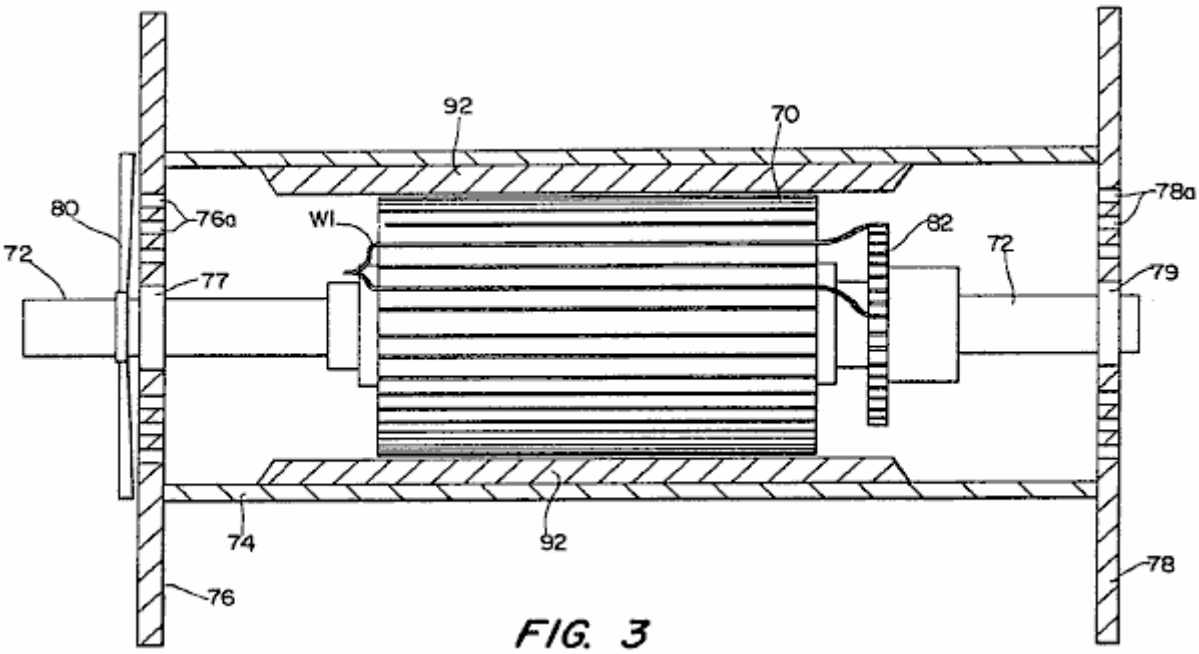

FIG. 3

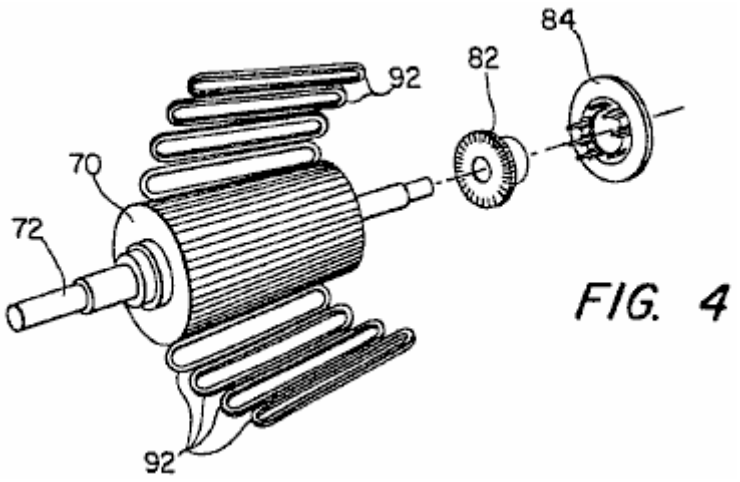
In a preferred embodiment, motor **68** is of the form shown in **Fig.3**. As illustrated, the motor is of a generally conventional form (with exceptions noted below) and comprises an armature **70**, mounted on a shaft **72** within housing **74**. Housing **74** includes a pair of end plates **76** and **78**, which mount shaft bearings **77** and **79**. Apertures **76a** and **78a** are provided in end plates **76** and **78** and a cooling fan **80** is mounted on shaft **72** to provide cooling.



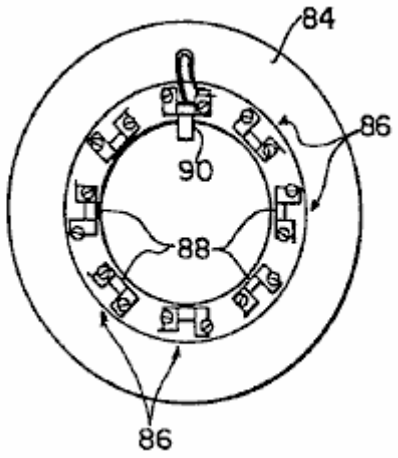


FIG. 4

A commutator **82** is also mounted on shaft **72**, and co-operates with associated brushes (not shown in **Fig.1**), to conduct current to the windings of armature **70**. This co-operation is shown best in **Fig.4** which is an exploded view, illustrating the armature **70**, commutator **82** and a brush holder **84**.

FIG. 5

As shown in **Fig.5**, the brush holder **84** includes eight brush mounts **86**, each of which defines a slot **88** in which a pair of brushes is mounted. One brush **90** is shown in **Fig.5**, it being understood that two such brushes are mounted in each slot **88** so that sixteen brushes are required.

The motor of **Fig.3** to **Fig.6** includes eight pole shoes (not shown) which are secured to housing **74** and which serve to mount eight field coils or windings **92** (see **Fig.3** and **Fig.4**) spaced out around the periphery of armature **72**.

An important feature of the motor of **Fig.3** to **Fig.6** concerns the manner in which the windings for armature **70** are wound. As illustrated in **Fig.3**, **Fig.6** and **Fig.7**, a typical winding **W1** is wound in two slots, with the illustrated winding being doubled back and continuing from armature slot **S1** to armature slot **S5** (see **Fig.3** and **Fig.6**). Similarly, the winding in slot **S2** continues to slot **S6**, the winding of slot **S3** continues to slot **S7**, and so on for the forty-nine windings.

In a specific preferred embodiment, the motor described above is a 48-volt, 412 horsepower motor having a top operating speed of 7,000 rpm. A rheostat control (not shown) is used to control the input voltage and, as discussed above, the motor is powered from the energiser of **Fig.1**. It will be appreciated that the energy take-off from the system is preferably from the output shaft of the motor, although the electrical energy may also be tapped off from the energiser output.

Although the invention has been described in relation to exemplary embodiments, it will be understood by those skilled in the art, that variations and modifications can be effected in these embodiments without departing from the scope and spirit of the invention.

CLAIMS

1. An energy-producing system providing an output for utilisation by a utilising device, the system comprising:

An electrical energising means comprising a housing (**10**); at least one double-wound stator (**14** or **18**) located within the housing; at least one double-wound rotor (**12** or **16**) located within the housing; a rotor shaft (**26**), supported in the housing, and on which the double-wound rotor is mounted; and an energy take-off mechanism (**34** or **36**) including a mechanism for collecting electrical energy from the rotor, mounted on the shaft and connected to the rotor, the mechanism having at least one stationary output.

A motor (**68**), including a connection to the electrical energiser through which to draw the power to operate the motor and drive the rotor shaft of the energiser, the motor having an armature (**70**) with a plurality of winding slots (**S1** to **S49**) in it, and a plurality of windings (**W1**) wound in those slots, at least some of the windings being wound in two slots spaced out around the circumference of the armature (for example, **S1** and **S5**), and an energy supply mechanism (**66**) for supplying electrical energy to the motor at least during initial energisation of the motor, and connected to the energiser for supplying energy to the motor during its operation.

2. A system as in Claim 1, where the energiser includes a pair of these rotors (**12**, **16**) and a pair of stators (**14**, **18**), the rotors being mounted on a common shaft (**26**).

3. A system as in Claim 1, where the energy take-off includes a slip ring (**34** or **36**) and at least one brush (**38** or **40**) for collecting electrical current from the rotor windings, the brush being connected to a bridge circuit (**46** or **48**).

4. A system as in Claim 1, where the motor contains a commutator (**82**) through which energy is supplied to the armature windings.

5. A system as in Claim 4, where the same winding (W1) is wound in the first and fifth slot positions of the motor armature, and the ends of that winding are connected to two positions spaced out around the circumference of the commutator (see **Fig.3**).

TERUO KAWAI

United States Patent 5,436,518 25th July 1995 Inventor: Teruo Kawai

MOTIVE POWER-GENERATING DEVICE

Please note that this is a re-worded excerpt from this patent. It describes a motor which has an output power greater than its input power.

SUMMARY OF THE INVENTION

It is an object of the invention to provide a motive power generation device in which the occurrence of a force acting in a direction opposite to the direction of movement of a rotor and/or a stator is prevented, so as to permit efficient use of electric energy to be applied to electromagnets, as well as magnetic energy generated by a permanent magnet.

In order to achieve the above object, the first invention comprises a permanent magnet disposed around a rotational output shaft which is mounted on a bearing, a magnetic body positioned concentrically with the permanent magnet for rotation with the output shaft, the magnetic body being subjected to the magnetic flux of the permanent magnet, a plurality of electromagnets permanently mounted on the support member so that they are spaced a predetermined distance around the periphery of the magnetic material, each magnetic circuit of the electromagnets being independent of one another and the excitation change-over mechanism of the electromagnets which can sequentially magnetise one of the electromagnets which is positioned forward, with regard to a rotational direction, of the output shaft, so as to impart to the electromagnet a magnetic polarity magnetically opposite to that of the magnetic pole of the permanent magnet, whereby a magnetic flux passing through the magnetic body converges in one direction thereby applying a rotational torque to the output shaft.

According to the first invention, when one of the electromagnets which is positioned ahead in the rotational direction of the rotational output shaft, a magnetic field created by the excited electromagnet and a magnetic field created by the permanent magnet interact with each other. Thus, the magnetic flux passing through the magnetic body converges toward the exited electromagnet, so as to rotate the rotational output shaft by a predetermined angle toward the excited electromagnet. When the rotational output shaft has been rotated by the predetermined angle, the above excited electromagnet is de-magnetised, and another electromagnet currently positioned ahead with respect to the rotational direction of the rotor output shaft is excited or magnetised. Sequential excitation of the electromagnets in the above manner permits rotation of the output shaft in a predetermined direction. In this regard, it should be noted that the electromagnets are excited so as to have a magnetic polarity opposite to that of the magnetic pole of the permanent magnet and that the magnetic circuit of the excited electromagnets is independent from those of adjacent electromagnets. Thus, the magnetic flux generated by the excited electromagnet is prevented from passing through magnetic circuits of adjacent electromagnets, which, if it occurs, might cause the electromagnets to be magnetised to have the same polarity as that of the magnetic pole of the permanent magnet. Accordingly, no objectionable force will be generated which might interfere with rotation of the output shaft.

In order to achieve the above object, the second invention comprises a permanent magnet mounted on a movable body arranged movably along a linear track, a magnetic body mounted on the permanent magnet, the magnetic body being subjected to a magnetic flux of the permanent magnet, a plurality of electromagnets spaced an appropriate distance along the linear track, the electromagnets having magnetic circuits which are independent of one another and the excitation mechanism arranged to magnetise each of the electromagnets sequentially when each is positioned forward of the movable body, (with respect to the direction of movement) so as to impart to the excited electromagnet a magnetic polarity opposite to that of the magnetic pole of the permanent magnet, whereby a magnetic flux passing through the magnetic body converges in a predetermined direction so as to cause linear movement of the movable body.

According to the second invention, when the electromagnet positioned ahead of the forward end of the movable body with regard to the direction of the movement of the movable body is excited, a magnetic field generated by the excited electromagnet and magnetic field generated by the permanent magnet interact with each other. Thus, a magnetic flux passing through the magnetic body converges toward the excited electromagnet, so as to displace the movable body a predetermined distance toward the excited electromagnet. When the movable body has been moved the predetermined distance, the movable body is positioned below the above excited electromagnet, and another electromagnet is positioned ahead of the forward end of the movable body. When this occurs, excitation of the electromagnet positioned above the movable body is interrupted, and excitation of the electromagnet now positioned ahead of the forward end of the movable body is initiated. Sequential excitation of

the electromagnets in the above manner permits movement of the movable body in a predetermined direction It should be noted that no objectionable force which would interfere with movement of the movable body is created for the same reason as that explained in relation to the first invention.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Preferred embodiments of the invention will be explained in detail below with reference to the attached drawings.

According to a first embodiment of the invention, a rotational output shaft **11** is mounted in a bearing between front and rear side plates **10a** of a support member **10** through bearings **11a**, as shown in **Fig.1** and **Fig.2**. A ring of permanent magnets **13** are fitted over the opposite ends of the output shaft, inside the side plates **10a** and these move with the rotor shaft **11**. The permanent magnets are magnetised in the axial direction. A magnetic body **14** is rigidly mounted between each of the side plates **10a** of the rotor shaft **11** and the permanent magnets **13**. Each of these magnetic bodies **14** has alternate notches **14a** and magnetic teeth **14b**. It should be noted that the flux of the permanent magnets **13** passes through the respective magnetic bodies **14**. For example, **Fig.1** shows the magnetic body **14** with three notches **14a** and three magnetic teeth **14b**. The permanent magnets **13** and magnetic bodies **14** are positioned co-axially with the rotor output shaft **11**. The corresponding permanent magnets **13** and magnetic bodies **14** are shown connected together by bolts **15** so as to form a rotor **12** which is attached to the rotational output shaft **11**.

It should be noted that the support member **10** and rotational output shaft are both made from a non-magnetic material. The support member **10** may be formed, for example, from stainless steel, aluminium alloys, or synthetic resins, while the rotational output shaft **11** may be formed from stainless steel, for example. Thus, the magnetic circuit formed by the permanent magnet **13** and magnetic body at one axial end of the rotational output shaft **11** and the magnetic circuit formed by the permanent magnet **13** and magnetic body at the opposite axial end of the output shaft, are independent of one another. The magnetic bodies **14** may be formed from magnetic materials having a high magnetic permeability, such as various kinds of steel materials, silicon steel plate, permalloys, or the like.

The stator contains electromagnets **16a** through **16l**, which are positioned between the side plates **10a**. The electromagnets are evenly spaced around the magnetic pieces **14** so that they surround the magnetic bodies. As shown in **Fig.1**, twelve electromagnets may be used. The magnetic circuit of each of the electromagnets **16a**

through **16l** is arranged so as to be independent of each other, so that no flux of a magnetised electromagnet passes through the iron cores of the adjacent electromagnets.

The iron cores of the electromagnets **16a** through **16l** are positioned parallel to the rotor axis shaft **11**, and positioned with only a slight gap between them and the magnetic bodies **14**.

Some of the electromagnets **16a** through **16l** are located at a position corresponding to boundary portions **14c1** through **14c6** between the notch **14a** and the magnetic tooth **14b**. For example, as shown in **Fig.1**, electromagnets **16a, 16b, 16e, 16f, 16i** and **16j** are positioned opposite the boundary portions **14c1, 14c2, 14c3, 14c4, 14c5,** and **14c6**, respectively.

Fig.5A shows a path of magnetic flux created by the permanent magnet **13** when the electromagnets are not excited or magnetised, while, **Fig.5B** shows a path of magnetic flux created by the permanent magnet **13** and a path of magnetic flux created by the windings of the electromagnets when the electromagnets are magnetised. As will be clear from **Fig.5A** and **Fig.5B**, both paths of magnetic flux represent a uni-polar distribution in which N-pole or S-pole evenly appears at the opposite axial ends. When the electromagnets are magnetised, the magnetic fields of the permanent magnet and electromagnets co-operate or interact with each other so as to generate a rotational torque.

Excitation change-over mechanism **17** for sequentially exciting or magnetising the electromagnets **16a** through **16l** is basically consisted of a conventional excitation circuit for supplying direct current to each windings of the electromagnets **16a** through **16l**. In this embodiment, the change-over portion for changing electric feed to the electromagnets **16a** through **16l** includes a plurality of optical sensors **18** and a light shield plate **19** for turning the optical sensors ON and OFF as shown in **Fig.6**.

The optical sensors **18** are spaced apart from one another with a space between them for permitting the light shield plate **19** to pass through a light emitting element and a light receiving element. The optical sensors **18** are disposed in the outer surface of one of the side plates **10a** equally spaced apart along the circumference, so that they are positioned to correspond to the electromagnets **16a** through **16l** (for example, the optical sensor **18** is shown to be disposed in the outer surface of the rear side plate). The light shielding plate **19** is fixed to the rotational output shaft **11** at the end thereof, the light shielding plate protruding from the rear side plate **10a** on which the optical sensors are mounted.

According to the illustrated embodiment, when a particular optical sensor **18** is blocked by the light shielding plate **19**, the electromagnet corresponding to such optical sensor **18** is supplied with electricity.

The operation of the first embodiment described above will be explained with reference to **Fig.4A** through **Fig.4H**.

When the electromagnets **16a** through **16l** are not supplied with electricity by means of the excitation changeover mechanism **17**, the electromagnets **16c, 16d, 16g, 16h, 16k** and **16l** opposed to the magnetic teeth **14b** with a small gap between them merely serve as a magnetic material disposed within the magnetic field of the permanent magnet **13** (refer to shaded portion in **Fig.4A**), so as to absorb the magnetic teeth **14b**, and the rotor **12** remains stationary.

When the electromagnets **16a, 16e** and **16i** positioned adjacent to the boundary portion **14c1, 14c3** and **14c5** formed between the respective notches **14a** and the magnetic teeth **14b** are magnetised or excited simultaneously by means of the excitation change-over mechanism, as shown in **Fig.4B**, the magnetic field of the permanent magnet **13** and the magnetic fields of the electromagnets **16a, 16e** and **16i** interact with each other, so that a magnetic flux **14d** passing through the magnetic body **14** instantaneously converges to the electromagnets **16a, 16e,** and **16i**. In this way, the rotor **12** is imparted with a rotational torque in a direction in which the magnetic flux **14d** will be widened, i.e., counterclockwise direction as viewed in **Fig.4B**.

Fig.4C through **Fig.4G** illustrate change in the width of the magnetic flux **14d** in accordance with rotation of the rotor **12**. When the width of the magnetic flux becomes maximised, i.e., when only the magnetic teeth **14b** are opposed to the electromagnets **16a, 16e** and **16i**, while the notches **14a** are displaced completely away from the electromagnets **16a, 16e** and **16i**, the width of the magnetic flux **14d** is maximised. Thus, an absorption force acting between the permanent magnet **13** and the electromagnets **16a, 16e** and **16i** is maximised. On the other hand, the rotational torque acting on the rotor **12** becomes zero.

Before the rotational torque acting on the rotor **12** becomes zero, i.e., as the boundary portion **14c1, 14c3** and **14c5** approach another electromagnets **16b, 16f** and **16j** positioned ahead of (with regard to the rotational direction), respectively, the electromagnets **16a, 16e** and **16i** are demagnetised and the electromagnets **16b, 16f** and **16j** are excited or magnetised by means of the excitation change-over mechanism **17**. Thus, the magnetic

flux **14d** converges toward the electromagnets **16b, 16f** and **16j**, as shown in **Fig.4H**, so that a rotational torque acts upon the rotor, as described above.

Then, the electromagnets **16c, 16g** and **16k** are excited. When the boundary portion **14c1, 14c3** and **14c5** approach another electromagnets **16d, 16h** and **16l** positioned ahead with respect to the rotational direction, in response to rotation of the rotor **12**, the electromagnets **16c, 16g** and **16k** are de-magnetised and the electromagnets **16d, 16h** and **16l** are energised or excited.

As explained above, sequential excitation or energising of the electromagnets **16a** through **16l** causes interaction between the magnetic flux of the permanent magnet **13** and the electromagnets **16a** through **16l**, whereby a rotational torque is applied to the rotor **12**.

When this occurs, a rotational torque is generated between one of the magnetic poles of the permanent magnet **13** (for example, N-pole) and the magnetic poles (for example, S-poles) of the electromagnets **16a** through **16l** positioned at their respective axial ends. A rotational torque is also generated between the other magnetic pole (for example, S-pole) of the permanent magnet **13** and the other magnetic pole (for example, N-pole) of each of the electromagnets **16a** through **16l** positioned at the other axial end.

It should be noted that, at one magnetic pole, for example N-pole, of the permanent magnet **13**, certain of the electromagnets **16a** through **16l** are magnetised only to S-pole, thus preventing formation of a magnetic circuit, due to passage of magnetic flux from the excited electromagnets through either of the adjacent electromagnets, which tends to bring about N-poles magnetically similar to the permanent magnet **13**. It is also noted that, at the other magnetic pole, for example S-pole, of the permanent magnet **13**, certain of the electromagnets are magnetised only to N-pole, thus preventing formation of a magnetic circuit, due to passage of magnetic flux from the excited electromagnets through adjacent electromagnets, which tends to bring about S-poles magnetically similar to the permanent magnet **13**. The magnetic flux of the permanent magnet **13** passes through the magnetic bodies **14** so as to be converged to the excited electromagnets (refer to the magnetic flux **14d** shown in **Fig.4** through **Fig.4H**), thus forming dead zones, through which no magnetic flux passes, in the magnetic bodies **14** at a position opposite to the un-excited electromagnets. Accordingly, no force is generated which would tend to prevent rotation of the rotor **12**.

In view of electric energy applied to the electromagnets **16a** through **16l**, substantially all the electric energy applied is used to contribute to the rotation of the rotor **12**. On the other hand, and in view of magnetic energy of the permanent magnet **18**, all the magnetic energy contributes to the rotation of the rotor **12**.

It is also noted that, since the notches **14a** and the magnetic teeth **14b** are alternately disposed in the outer periphery of the magnetic materials **14** in an acute angle configuration seen in **Fig.4A** to **Fig.4H**, and the electromagnets are disposed at a position each corresponding to the boundary portions between the notches and the magnetic teeth, it is possible for the line of the magnetic force, generated in each gap between the boundary portions and the electromagnets when the electromagnets are excited, to be inclined to a substantial degree, so that a sufficient degree of rotational torque may be obtained upon initial excitation of the electromagnets.

The result obtained during an actual running test of the motor according to the first embodiment is shown in **Fig.1** to **Fig.3**.

Pure steel was used as a magnetic material. The magnetic material was 30 mm in thickness and formed to have magnetic teeth of 218 mm diameter and notches of 158 mm diameter. A ferrite magnet was used as a permanent magnet. The magnetic force of the magnet was 1,000 gauss. Electric power of 19.55 watts was applied to the electromagnets at 17 volts and 1.15 amperes. The above conditions produced a rotational speed of 100 rpm, with a torque of 60.52 Kg-cm and an output of 62.16 watts.

Alternative embodiments will be explained below with reference to **Fig.6** through **Fig.9**.

The modified embodiment shown in **Fig.6** is similar to the motor presented as the first embodiment as shown in **Fig.1** through **Fig.3**, with the exception that each electromagnet **160** used as part of the stator, comprises an iron core **161** having a pair of legs **162** which extend towards the outer periphery of the magnetic bodies (outer periphery of the magnetic teeth **14b**), each of the legs being wound with coils **163**. The remaining components are basically identical to those in the motor shown in **Fig.1** through **Fig.3**. In **Fig.6**, the components similar to those in **Fig.1** through **Fig.6** are denoted by like reference numerals. It should be noted that each coil **163** is supplied with electricity so that one leg **162** (left-hand side in **Fig.6**) of each of the iron cores **161** is magnetised to be S-pole which is magnetically opposite to the magnetic pole (N-pole) of the confronting magnetic body **14**, while the leg **162** disposed at the other end of each of the iron cores is magnetised to be N-pole which is magnetically opposite to the magnetic pole (S-pole) of the confronting magnetic body **14**.

According to this modified embodiment, it is possible to significantly reduce leakage of the magnetic flux created by the electromagnets **160** in gaps each defined between the surfaces of the magnetic poles of the electromagnets **160** and the outer peripheries of the magnetic teeth **14b** of the magnetic bodies **14**.

An alternative embodiment shown in **Fig.7** is similar to the motor shown in **Fig.1** through **Fig.8**, with the exception that: an additional magnetic body **14** is mounted on the rotational output shaft **11** at it's axial midpoint; two permanent magnets **130** are freely mounted on the output shaft **11** in the manner shown in **Fig.6**; and each iron core **165** is provided with three legs **166** positioned at the opposite axial ends and midpoint thereof and extending toward the respective outer periphery of the magnetic bodies, with the legs **166** positioned at axial opposite ends of the respective iron cores **165** being wound with a coil **167**, which form electromagnets **164**. The remaining components are substantially the same as those in the motor shown in **Fig.1** through **Fig.3**. It should be noted here, that the rotational output shaft **11** may be formed from either magnetic materials or non-magnetic materials.

As shown in **Fig.7**, each of the coils **167** is supplied with electricity so that the legs **166** positioned at the opposite axial ends of each of the iron cores **164** is magnetised to be S-pole which is magnetically opposite to the magnetic pole (N-pole) of the confronting magnetic body **14**. By this, the leg **166** positioned at the midpoint of the iron core **165** is magnetised to be N-pole which is magnetically opposite to the magnetic pole (S-pole) of the confronting magnetic body **14**.

In this embodiment, it is also possible, as in the modified embodiment shown in **Fig.6**, to significantly reduce the leakage of the magnetic flux generated by the electromagnets **164**. In addition to this, it is also possible to obtain a rotational torque between the leg **166** positioned at the midpoint of the iron core and the magnetic body **14** positioned at the axial midpoint of the rotational output shaft **11**. Accordingly, a higher rotational torque may be obtained with the same amount of electrical consumption, in comparison with the embodiment shown in **Fig.6**.

A further embodiment shown in **Fig.8** is similar to the motor shown in **Fig.1** though **Fig.3**, with the exception that a permanent magnet magnetised in the radial direction, rather than in the axial direction is employed. The permanent magnet **131** of an annular configuration has, for example, N-pole in the outer periphery and S-pole in the inner periphery. The permanent magnet **131** is received within a cavity **14e** provided in the respective magnetic body **14** at the intermediate portion thereof as disposed at the opposite axial ends of the rotational output shaft **11**. The remaining components are identical to those in the motor shown in **Fig.1** though **Fig.3**. The components identical to those in the motor shown in **Fig.1** though **Fig.3** are denoted by the same reference numerals. It should be noted that this embodiment may also employ the electromagnets **160** shown in **Fig.6**.

In this embodiment, the rotational output shaft **11** may be formed from magnetic materials, rather than non-magnetic materials.

Further embodiment shown in **Fig.9** is similar to the motor shown in **Fig.1** though **Fig.3**, with three exceptions. The first exception is that a permanent magnet magnetised in the radial direction, rather than in the axial direction is employed. The permanent magnet **131** having an annular configuration has, for example, N-pole in the outer periphery and S-pole in the inner periphery. The permanent magnet **131** is received within a cavity **14e** provided in the respective magnetic body **14** at the intermediate portion thereof as disposed at the axial opposite ends of the rotational output shaft **11**. The second exception is that an additional magnetic body **14** is disposed at the axial midpoint of the rotational output shaft **11**. Finally, the third exception is that the iron core **165** is provided with three legs **166** disposed at the axial opposite ends and the midpoint thereof, respectively, and extending toward the outer periphery of the magnetic body **14**, with the legs positioned at the opposite axial ends being wound with respective coils so as to form an electromagnet **164**. The remaining components are identical to those in the motor shown in **Fig.1** though **Fig.3**. The components identical to those in the motor shown in **Fig.1** though **Fig.3** are denoted by the same reference numerals.

As shown in **Fig.9**, each coil is supplied with electricity so that the legs **166** disposed at opposite axial ends of the iron core **165** are magnetised to be S-pole which is magnetically opposite to the magnetic pole (N-pole) of the confronting magnetic body **14**. By this, the leg **166** disposed at the midpoint of the iron core **165** is magnetised to be N-pole which is magnetically opposite to the magnetic pole (S-pole) of the confronting magnetic body **14**.

According to the embodiment described above, the rotational output shaft **11** may be formed from magnetic materials rather than non-magnetic materials. With this embodiment, it is possible to obtain the same effect as that obtained with the embodiment shown in **Fig.7**.

Further the alternative embodiments shown in **Fig.10A** to **Fig.10C** are similar to the motor shown in **Fig.1** though **Fig.3**, with the exception that: like the embodiments shown in **Fig.8** and **Fig.9**, an annular permanent magnet **131** is employed which is received in a cavity **140e** provided in the central portion **140** of the magnetic body **140**; the magnetic body **140** is provided with notches **140a** in the outer peripheral portion thereof, so that the gap G

between the magnetic body **140** and the electromagnet becomes gradually broader in the rotational direction of the rotor; and the electromagnets confronting to the gap G with an intermediate width as positioned between the electromagnets confronting to the gap G with a narrower width and the electromagnets confronting to the gap G with a broader width are excited or magnetised in a sequential manner. The remaining components are identical to those in the motor shown in **Fig.1** though **Fig.3**. In **Fig.10A** to **Fig.10C**, the components identical to those in **Fig.1** though **Fig.3** are denoted by the same reference numerals. In this regard, it should be noted that reference numeral **140d** indicates magnetic flux passing through the magnetic body **140**, so as to illustrate converged condition of such magnetic flux upon excitation of the electromagnets.

In the embodiment Just described above, it is possible to rotate the rotor in the counter clockwise direction as viewed in **Fig.10A**, for example, by exciting the electromagnets **16a, 16d, 16g** and **16j**, as shown in **Fig.10A**, then, the electromagnets **16c, 16f, 16i** and **16l**, as shown in **Fig.10B**, and then the electromagnets **16b, 16e, 16h** and **16k**. According to this embodiment, it is possible to obtain a stable rotational force, as well as a higher rotational torque, even though number of rotations is reduced in comparison with the above embodiment.

As shown in **Fig.10A**, four notches **140a** are provided. It should be noted, however, that two or three notches may be provided. It is also possible to attach the magnetic material **140** to the rotational output shaft **11** in an eccentric manner in its entirety, without providing notches **140a**.

Fig.11A through **Fig.11H** are illustrative diagrams showing the operation of the second embodiment of the invention when developed into a linear motor type.

According to this embodiment, a movable body **21** is adapted to be moved along a linear track **20** of a roller conveyor type. The track includes a frame on which a plurality of rollers are positioned in parallel relative to one another. A permanent magnet **22** is mounted on the movable body **21**. A magnetic body **23** of a plate-like configuration is fixed to the permanent magnet **22** in the upper surface, so as to form a movable element. It should be noted that magnetic flux from the permanent magnet **22** passes through the magnetic body **23**. A plurality of electromagnets **25a, 25b, 25c, 25d** and so on are disposed above the movable element **24** along the linear track positioned parallel to each other. These electromagnets constitute a stator **25**. Magnetic circuits of the electromagnets **25a, 25b, 25c, 25d**, and so on, are independent from one another, so that the electromagnets are magnetised in a sequential manner by means of excitation change-over mechanism (not shown), so as to have a magnetic polarity opposite to the magnetic pole of the permanent magnet **22**. Power output shafts **21a** are attached to a side surface of the movable body **21**.

Operation of the above second embodiment will be explained below.

As shown in **Fig.11A**, and when no electricity is supplied to the electromagnets, the electromagnets **25a** and **25b** positioned Just above the movable element **24** are subjected to magnetic field of the permanent magnet **22** (refer to shaded portion in **Fig.11A**). Thus, such electromagnets magnetically absorb the magnetic body **23**, so that the movable element **24** remains to be stopped.

As shown in **Fig.11B**, and when the electromagnet **25c**, positioned ahead with respect to the direction in which the movable element **24** moves, is excited, the magnetic field of the permanent magnet **22** and the magnetic field of the electromagnet **25c** interact with each other, so that magnetic flux **23a** passing through the magnetic body **23** converges instantaneously toward the electromagnet **25c**. By this, the movable element **24** is magnetically absorbed to the electromagnet **25c**, so that it is moved along the linear track **20** under the propulsive force acting in the direction in which the width of the magnetic flux **23a** becomes broader, i.e., in the direction of an arrow mark shown in **Fig.11B**.

Fig.11C through **Fig.11E** illustrate a change in width of the magnetic flux **23a** in response to movement of the movable element **24**. At the point at which the width of the magnetic flux **23a** becomes maximised, i.e., when the forward end of the magnetic material **23** of the movable element **24** is positioned just before passing by the electromagnet **25c**, the width of the flux **23** becomes maximised. At this time, magnetic absorption acting between the permanent magnet **22** and the electromagnet **25c** becomes maximised, but the propulsive force acting on the movable element becomes zero.

Before the propulsive force acting on the movable element **24** becomes completely zero, i.e., when the forward end of the magnetic body **23** of the movable element **24** is about to pass the electromagnet **25d**, the excitation changeover mechanism is actuated so as to stop excitation of the electromagnet **25c** and so as to initiate excitation of the electromagnet **25d**. Thus, the magnetic flux **23a** converges to the electromagnet **25d**, as shown in **Fig.11F**, so that a propulsive force acts on the movable element **24**, as in the previous stage.

Subsequently, and in response to further movement of the movable element **24**, the width of the magnetic flux **23a** is reduced as shown in **Fig.11G** and **Fig.11H**, and thus a similar operation will be repeated.

The sequential excitation of the electromagnets, as explained above, causes interaction between the magnetic fields of permanent magnet **22** and electromagnets, whereby a propulsive force is applied to the movable element **24**.

It should be noted that, when the magnetic polarity of the permanent magnet **22** confronting the electromagnets is assumed to be N-pole, the electromagnet **25c** is magnetised solely to be S-pole, so as to prevent formation of a magnetic circuit by virtue of passage of magnetic flux from the electromagnet **25c** through to the adjacent electromagnets **25b** and **25d**, which formation, if it occurs, tends to cause the polarity of the electromagnets to be N-pole identical to the magnetic pole of the permanent magnet **22**. Accordingly, and in a manner similar to that in the first embodiment, no force is generated which tends to interfere with movement of the movable element **24**.

In the present invention, a plurality of electromagnets serving as a stator are so arranged that their respective magnetic circuits become independent from one another. The electromagnets are also arranged so that they are solely magnetised or excited to have a magnetic polarity opposite to the magnetic pole of the confronting permanent magnet. Thus, each electromagnet is prevented from becoming magnetised to the same polarity as that of the permanent magnet, which may occur when magnetic flux from a particular electromagnet passes through to adjacent electromagnets. Accordingly, no force will be exerted which tends to interfere with the intended movement of a rotor or a movable element. As a result, electric energy applied to the electromagnets may be efficiently utilised, while, at the same time, magnetic energy contained in the permanent magnet may-also be efficiently utilised.

The coils constituting the electromagnets are consistently supplied with electric current with the same polarity, without any change, so that heating of coils may be prevented. Further, it is possible to obviate the problems of vibration and noise which might occur due to a repulsive force being generated when polarity of an electric current supplied to the coils is changed.

JOSEPH NEWMAN

Patent WO8300963 **17th March 1983** **Inventor: Joseph W. Newman**

ENERGY GENERATION SYSTEM HAVING HIGHER ENERGY OUTPUT THAN INPUT

This patent covers a device which is claimed to have a greater output power than the input power required to run it.

ABSTRACT

A system for generating obvious work motion, or electromagnetic energy (fields of force) or electric current utilising the electromagnetic energy which makes up a matter and results in a greater output of energy, than the initial input of conventional energy means and teachings. A first exemplary embodiment (**Fig.1**) of the generator uses a contained fluid (**117**) surrounding a series of aligned magnets (**120**); while a second exemplary embodiment (**Fig.3**) uses a special material (**201**) held stationary between two static magnets (**202**, **203**), the special material having its atoms aligned but maintaining the resulting magnetic field at least substantially within its boundary surface; while third and fourth exemplary embodiments (**Fig.5** and **Fig.6**) utilise a relatively heavy coil (**205**) made up of relatively large diameter wire of relatively great length and number of loops and length and a relatively small energising current to drive a rotatable permanent magnet (**200**).

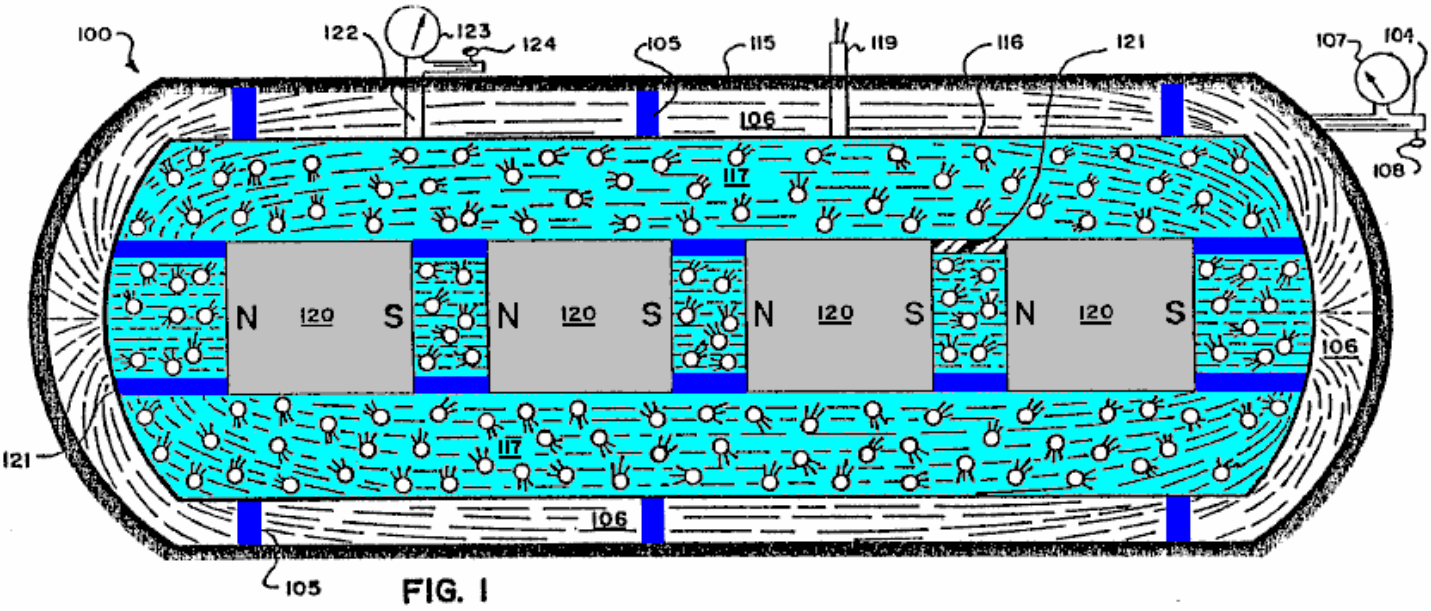

FIG. 1

DESCRIPTION

BACKGROUND OF THE INVENTION

1. Field of the Invention:
The present invention relates generally to devices or systems (including methods) for generating usable energy such as for example electrical energy from electromagnetic fields, electrical energy or electromagnetic fields from matter, and more particularly to devices or systems (including methods) for producing electrical current flow for use as electrical power, and magnetic fields of force which cause motion (obvious work) or electrical current flow or for increasing electromagnetic potential energy available for use or mechanical energy available for use.

2. Prior Art:
There have been many devices proposed over the years for producing electrical-energy, with mechanical friction, thermo-electricity, photoelectricity, piezoelectricity, electrochemistry and electromagnetic induction being the chief forms of primary energy capable of producing electricity. Of these, the only significant source of commercial electrical power has been the mechanical actions of electric generators, and for mobile electric power the chemical action of batteries has been important. Usable motion has resulted from the interactions between the input of electrical energy and the magnetic and/or electromagnetic fields of force (electric motors) and heat or light as a result of input of electrical current through conventional mechanical systems, heaters, lightbulbs, etc.

All of the prior art systems are designed accordingly to rigid mathematical laws taught both in physics and electrical engineering which coincide with the hypothesis rigidly accepted by the industrial and scientific communities concerning the Second Law of Thermodynamics (1850).

From the foregoing generally accepted hypothesis it has also been generally accepted and rigidly taught in physics and electrical engineering that the electric current flowing in a closed circuit from a battery, electric generator, etc.

is used up in the mechanical device being operated by this flow of electric current, and that all such electric current producing systems would only put out at most work equal to the work initially put into the system, or in accordance with generally accepted laws stating that a particular electrical generating system was only capable of a given output of energy and no more.

These beliefs have till this date still remained rigid in both the industrial and scientific communities in spite of proof of Einstein's equation $E=mC^2$ Nuclear reactors convert matter into usable electromagnetic energy in the form of heat, which converts water into steam to turn conventional turbines for production of electric current by conventional electrical generating means. This system is extremely inefficient using less than 1% of the energy of the atom and producing a deluge of contaminated materials which has caused a serious problem as to safe disposal.

Additionally, the basic electrical generators is use throughout the world today utilise the principle of causing relative movement between an electrical conductor (for example a rotor) and a magnetic field produced by a magnet or an electromagnet (for example a stator), all using the generally accepted hypothesis that the greater the relative speed or movement between the two are concerned and the more normal or perpendicular the relative movement of the conductive material to the lines of force of the electromagnetic field, the greater will be the efficiency of the prior art electrical generator. Additionally, all of the prior art systems are based on the generally accepted hypothesis that the greater the electrical conductivity of the material being moved through the field, the more efficient will be the electrical generation.

From the foregoing generally accepted hypotheses, it also has been generally accepted that there should always be movement between, for example, the rotor and stator elements, and that only generally accepted electrical conductors, that is materials with high electrical conductivity, will effectively serve in an electrical generation system.

However, in one of the systems (**Fig.3**) of the present invention, electrical generation can occur with relatively static elements and with materials that are not generally considered to be of high electrical conductivity, although, of course, the present invention likewise can utilise relatively moving elements as well as materials of generally accepted high electrical conductivity, if so desired, as occurs in the systems of the present invention illustrated in **Fig.5** and **Fig.6**.

The prior art has failed to understand certain physical aspects of matter and the makeup of electromagnetic fields, which failure is corrected by the present invention.

BRIEF DESCRIPTION OF DRAWINGS

For a further understanding of the nature and objects of the present invention, reference should be had to the following detailed description, taken in conjunction with the accompanying drawings, in which like parts are given like reference numerals and wherein:

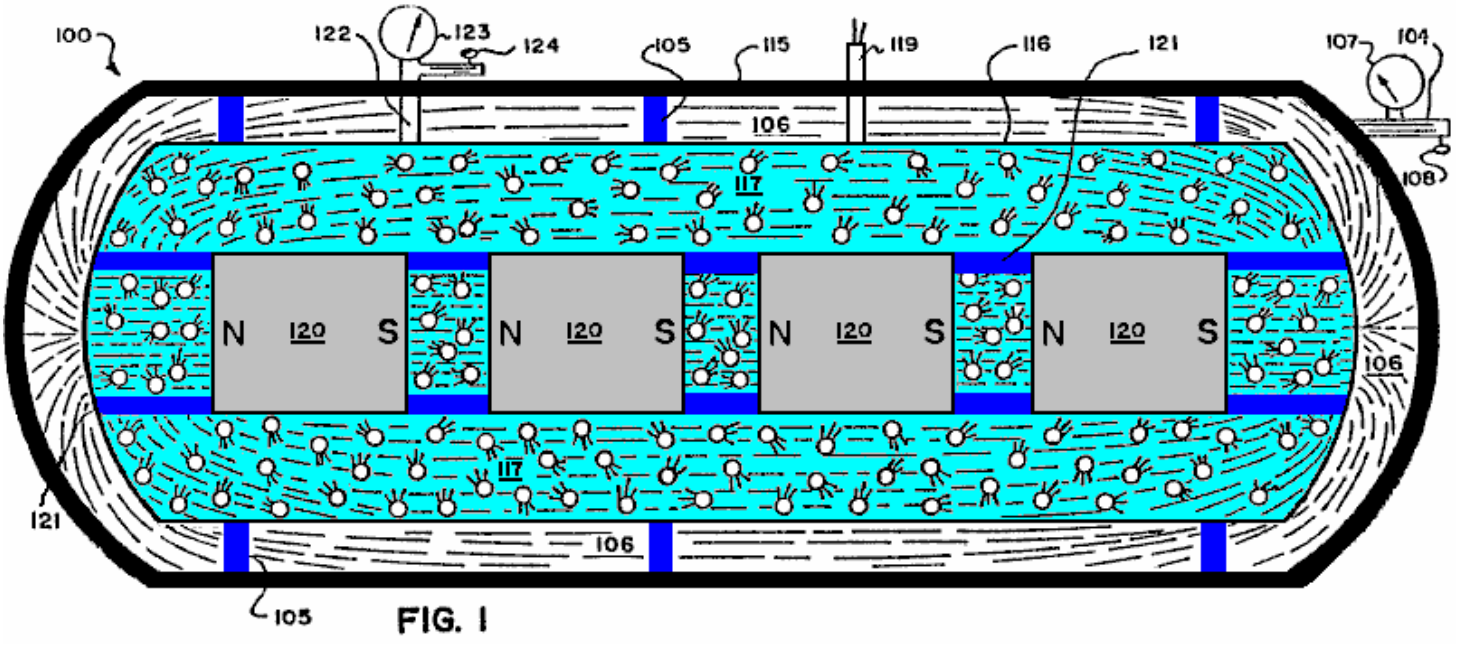

FIG. 1

Fig.1 is a schematic, side view in generalised, representational form of a first embodiment of an electrical generator based on the principles and guidelines of the present invention.

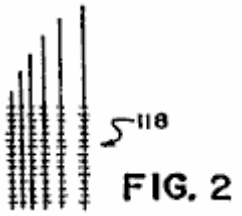

FIG. 2

Fig.2 is a close-up view in general form of an electrical charge pick-up element which can be used in the generator illustrated in **Fig.1**.

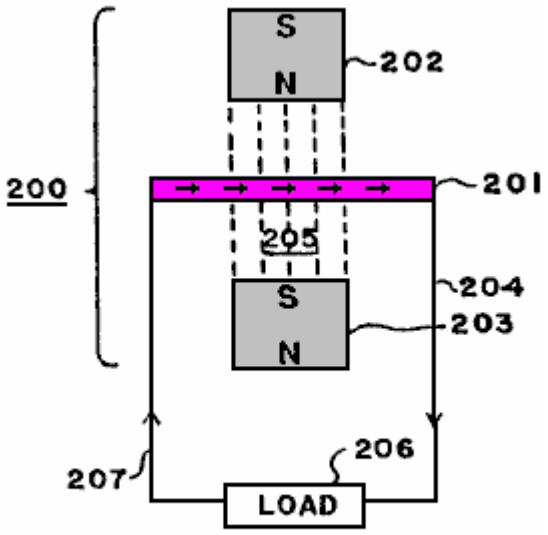

FIG. 3

Fig.3 is a schematic view in generalised, representational form of a second embodiment of an electrical generator based on the principles and guidelines of the present invention.

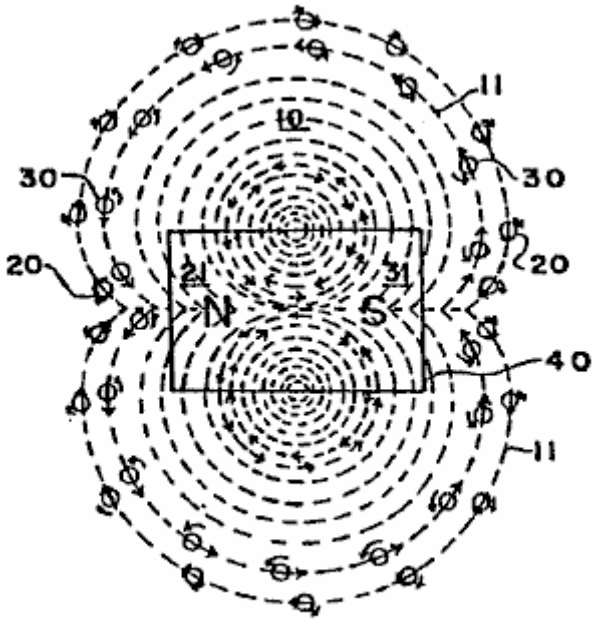

FIG. 4

Fig.4 is a schematic view in generalised, representational form of the negative and positive particles exhibiting gyroscopic actions which emanate from a magnet to form an electromagnetic field.

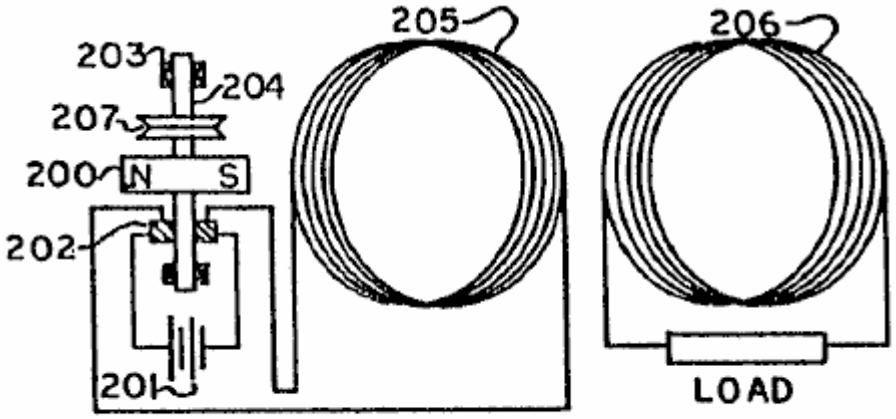

FIG 5

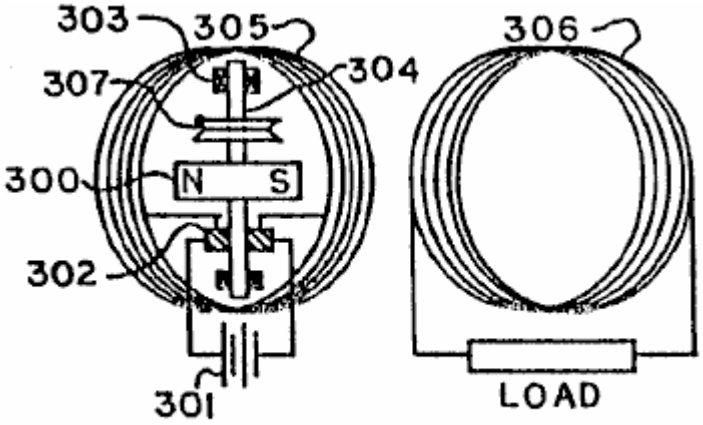

FIG 6

Fig.5 and **Fig.6** are schematic views in generalised, representational form of third and fourth embodiments of a combined electrical generator and motor utilising a static, relatively large coil energised by a relatively low current

driving a rotatable magnet, wherein in the embodiment of **Fig.5** the rotatable magnet is positioned along side of the coil and in the embodiment of **Fig.6** the rotatable magnet is positioned within the open core of the coil.

DETAILED DESCRIPTION OF-PREFERRED EMBODIMENTS:

Basic Principles and Guidelines

In accordance with the principles of the present invention and as generally illustrated in **Fig.3**, an electromagnetic field **10** comprises flows of quanta or particles **20**, **30** of electrical energy flowing from each of the poles **21**, **31** of a magnet (or electromagnet) **40** to the other pole, following the "lines of force" **11** of the electromagnetic field. These particles **20**, **30**, believed to be travelling at the speed of light, are always coming out of one end **21**, **31**, respectively, of the magnet **40** and going into the other pole **31**, **21**, respectively, flowing from a relatively high energy source to a low energy source.

These particles **20**, **30** are, it is believed, negative and positive charges and have a spin producing a gyroscopic motion and follow the mechanical laws of gyroscopic action.

The mass of each of the particles **20**, **30** equals the energy of the particle divided by the speed of light squared. The peripheral speed of the gyroscopic spin of the particles is believed to be the speed of light.

For purposes of illustration only and as a matter of nomenclature, the positive charge particle **20** is going in one direction ('-'N" to "S") with a clockwise spin, and the negative charge particle **30** is going in the opposite direction with a counter-clockwise spin. Of course, if a particle such as **20** or **30** is flipped around one-hundred-and-eighty degrees, it becomes the opposite charge or type of particle.

The electromagnetic field **10** is thus the orderly flow of the positive and negative charges **20**, **30** moving at the speed of light from the north and south poles **21**, **31**, to the south and north poles **31**, **21**, respectively, and follow the paths of what is termed in the art as the "lines of force" **11** of the electromagnetic field **10**.

As is known from the laws of gyroscopes, a gyroscopic particle or body moves at right angles to the direction of an applied force. Therefore, when a force is applied to the electrical energy particles **20**, **30**, they will move at right angles to that force.

It should also be noted from known gyroscopic laws that the electrical energy particles **20**, **30**, when they move with their gyroscopic axis straight into an object, tend to knock that object straight, but, if that object hits the particles at an angle to the axis other than at zero or one-hundred-and-eighty degrees, the particles are moved off at an angle from the straight.

Additionally, it is noted that a magnetic field caused by a current flowing through a wire comes from negative and positive particles, such as **20**, **30**, with a net flow of such particles going in the same direction but with opposite spin.

In the system and method of the present invention, the foregoing principles serve as guidelines in the present invention.

Reference is further had to pages DD23 through DD27 of the Disclosure Document and to page 8, line 26 through page 11, line 23 of the prior application Serial number 25,907 and its Figures 7 - 10.

From the foregoing disclosures, many different devices, structures, and methods are possible to embody the principles and guidelines of the system of the present invention, which will in general utilise a material or substance or structure to place a force at the proper angle to the gyroscopic particles **20**, **30** wherein the particles **20**, **30** follow a path or paths which do not cancel one another out, thereby producing electrical current at appropriate outputs for further use or for increasing available potential electrical energy for ultimate use.

-First Embodiment (**Fig.1**)

One possible, exemplary embodiment using the principles of the system of the present invention is schematically shown in the generalised illustration of **Fig.1**.

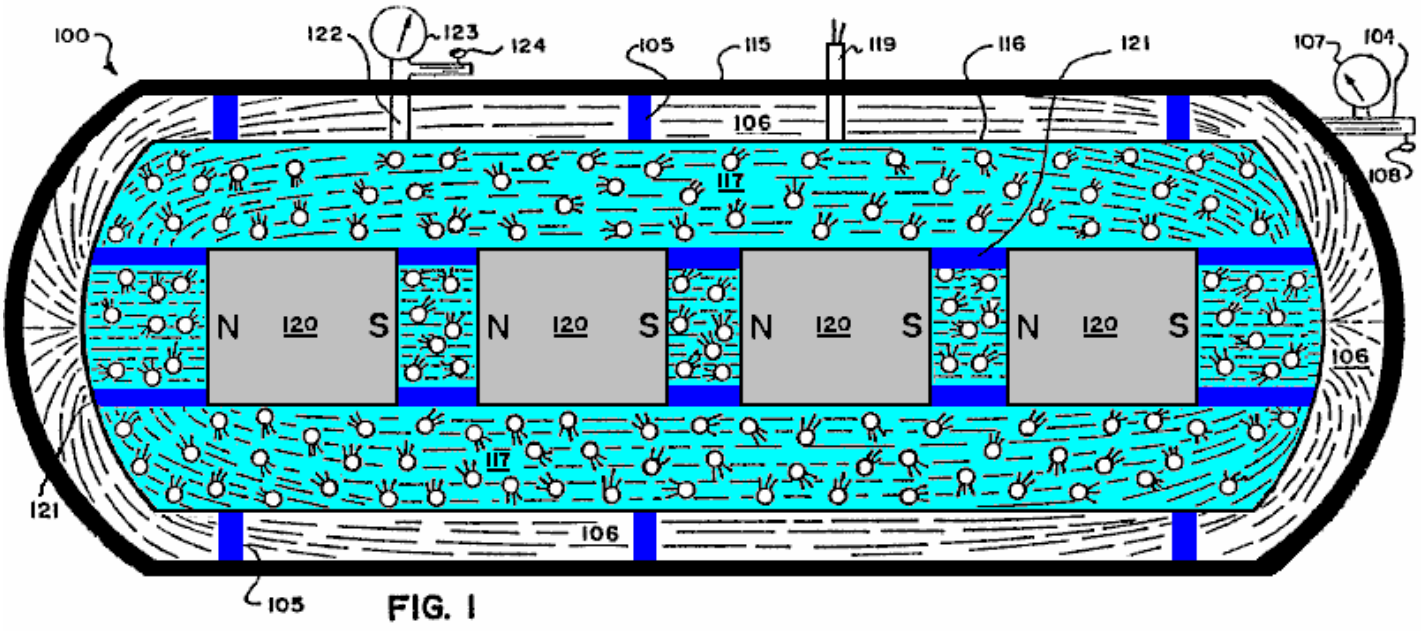

FIG. 1

As illustrated in **Fig.1**, there is provided an electrical current generator **100** comprising an outer keeper housing **115** and an inner, pressure containing, closed housing **116** supported therein by insulating supports **105**. A vacuum exists in the area **106** between the two housings **115**, **116**, which vacuum is regulated and induced by means of the vacuum line **104** with its gauge **107** and its control valve **108**. The outer housing **115** acts as a keeper for magnetic fields of force, and can be made for example of soft iron, while the vacuum in area **106** prevents the leakage or discharge of static electrical charges which might build up on the exterior of the inner housing **116**.

A gas or gas-liquid mixture **117** which may also include solid particles such as for example lead or brass filings, is included within the inner housing **116** surrounding a series of aligned magnets **120** carried by insulating braces or supports **121** and producing a high, combined electromagnetic field. The magnets **120**, which can for example be cryogenic magnets, have their "north" and "south" poles aligned (as illustrated by the "**Ns**" and "**Ss**") so that their magnetic fields reinforce one another.

The level of the gas or gas-liquid mixture **117** in the housing **116** is regulated by means of the line **122** with its gauge **123** and control valve **124**. Electric current output wires **119** are provided and extend down to electrically connect with a wire pick-up system **118** (shown in close-up in **Fig.2**), which can be for example in the form of very small wires forming a closely spaced network or mesh or of a porous conducting metal body or sheet, located in and extended throughout the fluid **117** in the housing **116**.

It is noted that a thimbleful of gas contains a fantastically large number of extremely tiny bodies which are in continuous, random motion moving at extremely high speeds. Hence, the fluid **117** continuously applies a force to the gyroscopic particles (analogous to particles **20**, **30** of **Fig.3**) moving at the speed of light ' in the high electromagnetic field (produced by the magnets **120**) as they continuously collide with each other, which results in the fluid **117** becoming electrically charged. The charged fluid **117** discharges its electrical charge to the pick-up wire network **118** positioned in the fluid, and the electric current so produced and generated is taken off for use via the electrical output wires **119**.

As an alternative to having internally contained magnets **120**, the electromagnetic field needed in the fluid **117** could be produced by a source located outside of the confines of the fluid **117** as long as a significant field was produced within the fluid **117**.

-Second Embodiment (Fig.3)

A further exemplary, generalised embodiment utilising the principles of the system of the present invention is shown in schematic form in **Fig.3**.

The electrical current generator **200** of **Fig.3** comprises an extended member **201** of a special material having its atoms especially aligned to produce electric current when positioned in an electromagnetic field but which does not on its own exhibit any substantial magnetic field outside of its boundary surfaces but substantially contains the field within itself. This is in contrast to "magnetic" materials which likewise have atom alignment but which also exhibit or produce a substantial magnetic field in the area surrounding it.

The generator **200** further comprises for example two magnets **202**, **203**, with their north and south poles facing each other, with the member **201** positioned between them, and with the three elements **201-203** held static with respect to each other. Because of the special nature of the material of the member **201** and its special atom alignment, it will produce a direct current through output line **204** as a result of the gyroscopic actions of the particles of the electromagnetic field **205** produced by the facing magnets **202**, **203**, on the especially aligned atoms in member **201**, which phenomenon occurs even when and even though the member **201** is completely static with respect to the magnets **212**, **203**.

However, it may be desirable in some applications to allow or produce some relative movement between the generator elements **201-203**. The output line **204** extends to an appropriate "load" **206** for using the electrical current generated by the generator **200**. A return line **207** completes the circuit back to the member **201**.

Based on experiments to date, it is believed that brass and lead are materials which can have their atoms especially aligned to interact with the gyroscopic particles (analogous to particles 20, 30) flowing between the magnets 202, 203 and will substantially contain within their surface boundaries the magnetic field produced by the aligned atoms or molecules.

With respect to producing the proper material with atom alignment for the member **201**, it is noted that most materials seem to align their atoms in random directions when formed by conventional methods of production. However, it can be observed that certain materials can be made magnetic by putting the material in an electromagnetic field while cooling from a temperature of around a thousand degrees Centigrade. The magnetism is the result of atom alignment of the material in a given direction (see pages DD19 through DD21 of the Disclosure Document). All materials are affected so as to align parallel or across lines of force when in a powerful electromagnetic-field. Accordingly, if a material while being formed is cooled in an extremely powerful electromagnetic field, the atoms of the material will take a particular alignment. The atom alignment direction could be varied depending on whether the electromagnetic field was aligned with the material or at a ninety degree angle to the material. This would result in the atoms of a material having their particular electromagnetic spin direction primarily along the same axis.

However, merely having atom alignment is not sufficient. Additionally the material for the invention should be such that it exhibits very little if any magnetic field in the area surrounding it. Thus it should be noted that the exterior electromagnetic field that occurs from the atom alignment of the conventional magnet is not duplicated in the material of the invention, because the electromagnetic energy resulting from atom alignment in the material of the invention will be primarily contained within the boundaries of the material It is believed that lead, made superconductive by immersion in a bath of for example liquid helium, is such a special material and could for example serve as the material for member **201**.

This then results in having a material which would place a force at the proper angle on the gyroscopic type particles moving in the electromagnetic field so as to cause an EMF to be produced even when the material was sitting still. (See also first paragraph of page DD23 and paragraphs four, A through E, of page DDl9 of the Disclosure Document).

It is believed that high, contained pressures, as well as other methods, can also probably produce atom alignment as the atoms of a conductor or any material will react to sufficient external force. (See first paragraph of page DD35 of the Disclosure Document). This possibility is also indicated by the fact that hard knocks or impacts will demagnetise a magnet.

The proper procedure of material production in achieving atom alignment with internally contained fields of force will cause the controlled release of electrical energy in electromagnetic fields of force when the material of the invention is placed in the lines of force of the electromagnetic field.

-Third and Fourth Embodiments (Fig.5 and Fig.6)

A. Related Principles

1. Numerous scientific tests and experiments made by the inventor indicate that the magnetic field resulting from an electrical current flowing through a conductor is the result of atom alignment within that conductor at an extremely high speed with an ability to reverse atom alignment just as rapidly without the magnetic hysteresis associated with conventional materials considered "magnetic." Prior to this time it has been believed and taught by the scientific community that the magnetic field associated with an electric current carrying conductor was the result of the electric current itself and not of the conductor material, for example copper, which was considered to be "nonmagnetic." Even the inventor was influenced and mislead by these teachings and attempted to mechanically explain and justify the prior teachings, as is seen on page DD-27 of the Disclosure Document which is an important part of this patent application.

However, as taught in the present invention, what mechanically happens is that the gyroscopic particles making up the electric current moving in a conductor interact with the electromagnetic makeup of the atoms of the conductor, causing them to align extremely rapidly, thereby then releasing some of their electromagnetic make-up in the form of a magnetic field exactly as explained in great detail for conventional magnetic materials in the Disclosure Document.

This is easily proven and understood by taking for example, a size 14-gauge conductor one foot long, winding it into a coil and connecting the coil to a meter and a 1.5 volt battery. The total current registered on the meter will be 1.5 amps and the strength of the magnetic field created from the short conductor will be extremely small. Next, the same type of test is run again but with the length of the conductor increased to for example two thousand feet, but still in a coil. The total current registered on the meter will now be considerably less, but the strength of the magnetic field given off from the conductor will now be extremely large!

This shows that the magnetic field is not from the electric current flow, but is the result of the interactions of the gyroscopic particles which make up the electric current interacting with the atoms of the conductor! This causes the gyroscopic particles of the electric current not to be able to make the circuit back to the battery so quickly, and therefore the meter shows less current used.

The magnetic field is the result of the atom alignment of the conductor. The more atoms in a conductor (up to a point), the stronger the magnetic field produced from a given amount of electric current input. Again, this is proven by changing the diameter of the conducting wires, and, with the lengths being the same, the strongest magnetic field will result from the conductor with the largest diameter. The reason for this is that there are more conducting atoms to interact with the gyroscopic particles of the electric current moving through the conductor, which results in a greater number of conducting atoms being aligned, thereby then releasing some of their electromagnetic make-up, exactly as has been explained in great detail in the Disclosure Document as being possible for all matter.

If the magnetic field produced was strictly based on the amount of current going through a conductor, as taught in the prior art, then the strongest magnetic field would result when current went through a large diameter and short length conductor, because the current flow through the entire circuit is greatest at that time. However, experiments prove that the shorter a conductor is made, the greater the current flow through the entire circuit and the less strength of the magnetic field surrounding that conductor. The longer that same conductor is made (up to a point), the greater the magnetic field surrounding the total mass of the conductor and the less current that makes the complete circuit of the entire system. Reason: more atoms!

2. Numerous scientific tests and experiments made by the inventor also indicate that the magnetic field created when an electric current moves in a conductor does not use up measurable energy when performing obvious or non-obvious work, force or power. This is true no matter how strong or how immense the power of the motor or electromagnets is.

Reason: the magnetic field coming from the conductor is the result of extremely quick atom alignment within that conductor. Therefore the energy in the magnetic field is the energy that makes up the atoms of the conductor! This energy is literally Einstein's equation of E=MC2, and therefore the energy is believed to be moving at the speed of light.

This energy use cannot be measured by today's measuring instruments. This has been explained in great detail in the
Disclosure Document and is believed to be true of all matter!

3. The same is true for the electric current that comes from a conventional battery. The electromagnetic energy coming from the battery is the energy that makes up the atoms of the material of the battery! Again this energy use is not measurable by today's measuring instruments. Electric meters of all types are simply mechanical

devices which measure the amount of electric current that comes into that instrument. They do not measure the amount of mass that has been converted into electromagnetic energy.

Present teachings in science state that the electric energy flowing from a battery is used up in the device operated by that flow of electric current. This is not true at all! The electromagnetic energy released from the atom make-up of a battery has a relatively infinite capacity to do obvious work, force, or power.

This is easily proven even with a small motor and a 1.5 volt battery. With a battery connected to motor to operate it and with a meter to take readings, the motor is then physically stopped from turning by physically holding or restraining the shaft. At that moment the motor is performing no obvious work, force or power, but the meter will register a greater flow of current. The magnets of the motor can be taken out and the reading will still be the same. If the electric current was being used to operate the motor, the meter would register more current when the motor was running.

The electric current not only will operate the motor but, once it flows through the complete circuit back to the battery, it also does additional work based on Faraday's Laws of Electrolysis within the battery itself. What has happened is that the electromagnetic energy released from the atoms of the material of the battery once they have completed the circuit, then take a "short cut" and move large pieces of the mass of one material of the battery over to the other material of the battery. The inventor has stated and shown throughout the Disclosure Document that the effect of gravity was the non-obvious effect of electromagnetic energy. Once the materials of the battery have combined, the extreme desire for the two materials to merge is physically reduced. These materials will attempt this merger anyway possible and, if the electric current initially released from a battery is not allowed by mechanical means to complete the circuit back within itself, the electromagnetic energy then in the mechanical means will perpetually (in a relative, theoretical sense) perform obvious work, force or power. The reason: the force which initiated this flow of current (electromagnetic make-up of atoms of material) is constant, similar to hydraulic pressure, with the noticeable exception that it is moving it is believed at the speed of light and will interact with the electromagnetic make-up of the atoms of other materials, causing them to release some of their electromagnetic make-up in the form of a magnetic field. This then multiples the capacity for doing obvious or non-obvious work, force or power, which can then react with another conducting coil or with the electromagnetic energy within the magnetic field of a conventional magnet and multiply this effect even further, and on and on and on for a relatively unlimited source of energy.

The same is true in not letting the current get back to a conventional generator. If a mechanical means is set up so that the electric current is "trapped," without completing a circuit, the gyroscopic particles of the current have a capacity for continuous work without increasing the power input into the generator system. However, if the circuit is complete and the electric current moving in the system does absolutely no obvious work, power or force, the gyroscopic particles making up the current on getting back to the generator will then increase the need for more power input into the system. Reason: the opposing effect of magnetic fields as defined in Lentz's Law. This law is simply an observation of this effect, which before now has never been fully understood.

4. Numerous scientific tests and experiments made by the inventor also indicate that there is a correlation between the electromagnetic spin orientation of the atoms of non-conductors, semi-conductors, and conductors, and the varying results achieved with an electric current in attempting to move through these materials, or when moving these materials through a magnetic field attempting to induce electric current. The property of resistance to electric current movement is generally speaking the same type factor already explained above for electric current producing a magnetic field when moving in a conductor.

The gyroscopic particles in a moving electric current interact with the atoms of the material through which the current is moving. Each atom can efficiently only interact with sun exact maximum amount of electric current, and, if exceeded, there is an interruption of orderly movement. Then the angle of release of the gyroscopic particles from the atoms are such that the electromagnetic release from those atoms are in the form of heat, exactly as explained in great detail in the Disclosure Document. This effect is easily observed by the fact that resistance decreases relative to an increase of the cross-section of the material. Reason: simply, more atoms within that given area, and, for a fixed input of electric current, there are more atoms to receive and interact efficiently with the gyroparticles making up the electric current.

Again the same is true for resistors designed for deliberately producing heat. Such resistors are not materials which are considered good conductors of electric current. It is stated and shown in great detail in the Disclosure Document that the electromagnetic spin orientation of the atoms of a non-conductor are different from that of conductor atoms, and therefore different results will occur from the same inputs of electromagnetic energy.

This is easily seen by the fact that, in a resistor, for a given amount of electric current input, the heat release increases as the diameter increases. What that means is that the property of resistance has decreased. On a conductor it is just the opposite. If the diameter is increased the resistance is decreased, but so is heat release. Again, this is an indication that the gyroparticles in the electric current movement interact with each atom of the

material. This same effect shows up again in conventional electrical induction from a conductor interacting with a magnetic field. Experiments by the inventor have indicated that the property of conventional induction is the result of the same property of resistance.

If one increases the diameter of a conductor, lengths staying the same, one decreases the amount of electric current produced relative to the total number of atoms within the conductors under consideration. Or, if one takes a given number of wires of the same diameter and length, and moves a magnet across them, the current produced will be considerably less, than if one takes the same diameter wire, but only one wire, and increases its length considerably and then forms it into a coil forming the same number of wires on any one side and then moves the same magnet across only one side of that coil, the electric current generated will then be considerably greater. Reason: the property of resistance. This is the mechanical effect within the gyroscopic electromagnetic make-up and orientation of the atoms of all materials which have the mechanical ability to perform a given task efficiently up to a point concerning input of additional electromagnetic energy and then mechanically causes varying results once this threshold is exceeded.

This and all the other thoughts and innovations in this and the previous disclosures of the previous applications and the Disclosure Document previously put forth show that there are many different mechanical ways to release a relatively unlimited source of energy from electromagnetic energy which makes up all matter and which results from this invention.

B. Working Prototypes

Fig.5 and **Fig.6** illustrate rough, working prototypes of this aspect of the invention. These embodiments are only relatively inefficient prototypes built by hand for the purpose of demonstrating the invention. It should be self-evident that the prototypes, by various mechanical means and designs, can easily be made extremely efficient and the illustrated embodiments are being presented only for general, representational purposes.

As is illustrated in **Fig.5**, there is provided a combined electrical current generator and an electromagnetic motor comprising a rotatably mounted, permanent magnet **200**, a battery **201**, brushes and commutator **202**, bearings **203** and power, mounting shaft **204**, and a first, primary, magnetic producing coil **205** and a second, secondary electric producing coil **206**. The two coils **205**, **206** are juxtaposed together in parallel disposition with concurrent core centre-lines, with the magnet 200 positioned alongside of coil **205** at or near its core centre-line with the rotational axis of the shaft 204 positioned orthogonally to the centre-line.

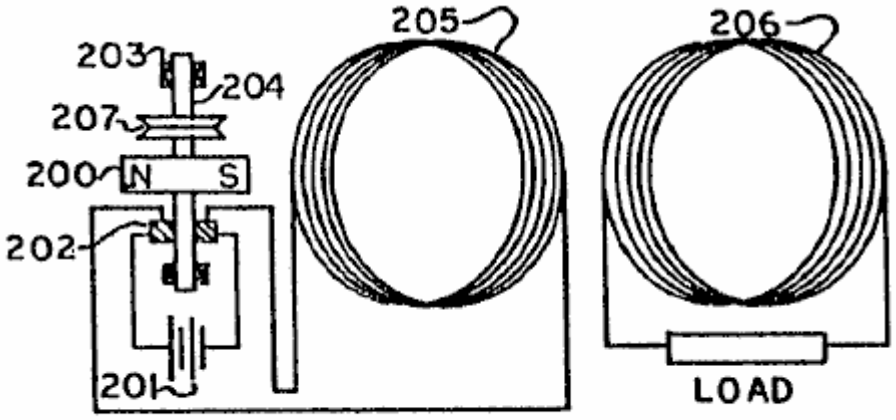

FIG 5

In the prototypes a very small battery **201**, for example, size "N", of 1.5 volts is used. When the circuit is completed, the battery **201** converts an immeasurable amount of its mass into electrical current (gyroscopic particles moving at the speed of light) which goes out through the communicator and brushes **202**, and then enters magnetic producing conductor coil **205** made, for example, from insulated 14-gauge or 15-gauge copper wire, with the total weight of the coil **205** being for example seventy to ninety pounds. This causes the atoms of coil **205** to align extremely fast then releasing some of their electromagnetic make-up (gyroscopic particles) in the form of a magnetic field. This field then interacts with the gyroscopic particles making up the magnetic field coming from the atoms of the material of the permanent magnet **200**.

This causes magnet 200 to attempt to align its magnetic field movement with the magnetic field movement coming from the atoms of coil 205, resulting in rotation of magnet 200 and the shaft 204 to which it is attached. This then changes the position of the commutator and brushes 202 relative to each other's initial positions, which then causes the electric current coming from battery 201 to be going in the opposite direction into coil 205, causing the

atoms of coil 205 to extremely quickly reverse their alignment and the polarity of their magnetic field which they are emitting. The reversed field then interacts again with the magnetic field of permanent magnet **200**, causing it to further rotate.

This process is then continuously repeated, producing continuous rotation of the shaft **204** which can be used as a source of motive power in many different ways. A power belt wheel **207** for example using a continuous "V" belt is illustrated as a general representation of this motive power source for producing useful, obvious work. In a prototype test run with a small 1.5 volt, type "N" battery, the shaft **204** and the magnet **200** - rotated at a high speed for approximately twelve hours before running down. By improving the particular design features of the prototype and by using longer lasting batteries, the rotation time of the shaft **204** can be greatly increased to a theoretical point approaching "perpetual" for all practical purposes. At the same time the alternating magnetic field produced by the coil **205** induces into coil **206** electrical induction, which then causes coil **206** to produce an alternating current across its "load," which current can be made to exceed the conventional output of the battery **201**. The battery source **201** can be replaced when needed.

It is very important to understand that, the longer the length of the conducting wire in coil **205**, the stronger will be the magnetic field produced and the less electric current that will complete the circuit and get back into the battery and destroy the mechanical source of the electrical current. This effect can be increased further by increasing the diameter of the conducting wire in coil **205** and then greatly increasing its length still further in the coil.

Reason: The gyroscopic particles making up the electric current interact with the atoms of coil **205**. The more atoms in coil **205**, relative to it's length, the longer it takes the gyroparticles of the electric current to influence them and exit from the other end of the coil. It is then easily seen that if the direction of the current flowing into coil **205** is then reversed, this then further increases the lag time. Reason: The gyroscopic particles have inertia and are believed to be moving at the speed of light and they are interacting with the gyroscopic particles making up the atoms of the conducting coil **205**. These atoms also have inertia, and when the direction of current in coil **205** is reversed, the incoming current then collides with the current already in coil **205** going in the opposite direction.

This causes a brief hesitation during the time the current already in the coil is being forced to reverse its direction, thereby then reversing the direction of the atoms within coil **205** which have already been influenced to become aligned. This causes a constant force throughout the circuit, but does not allow very much current to get back into the battery **201** to destroy the mechanical means which initiated the release of electric current in the first place.

Therefore, it should be further understood that, the faster the current direction reverses into the coil **205**, the more efficiently the matter of battery **201** is converted into 2 pure electrical energy ($E=MC^2$), without destruction of the mechanical situation that initiates the electrical current release.

It is also important to understand that, the stronger the magnetic field coming from the mass of magnet **200**, the greater will be its rotational speed. Additionally, the greater the magnetic field coming from the mass of coil **205**, the greater will be the rotational speed of magnet **200**, and, up to a point, the greater the electric current input from battery **201**, the greater the rotational speed of magnet **200**.

Reason: the greater the electric current flow into coil **205**, the greater will be the percentage of the atoms making up coil **205** that are aligned. This probably has the same relationship as does achieving atom alignment in conventional magnetic materials. Once complete atom alignment is reached in coil **205**, no amount of current will cause those atoms to increase the strength of the magnetic field emitting from those atoms.

Therefore, it should be clear that, for a given input of electric current from battery **201**, the most efficient design is one in which the most atoms of coil **205** are influenced to atom alignment by that given electric current, which means increasing the diameter and the length of the conducting wire of coil **205** to the point that the strength of the magnetic field produced is sufficient to cause rotation of the magnet **200** to a speed that allows none or at least very little of the electric current which initially comes from the battery **201** to complete the circuit and get back into battery **201** and destroy or reduce the mechanical effect which induced the conversion of the matter of battery **201** in electric current in the first place. Again this desired effect can be increased by increasing the strength of the magnetic field given off by the atoms of the permanent magnet **200**.

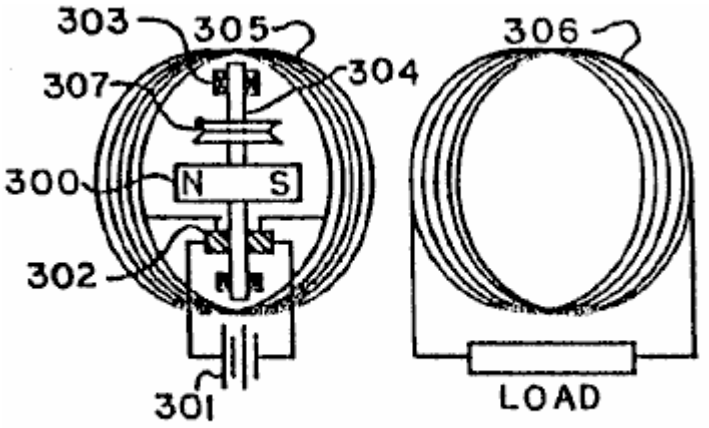

FIG 6

In the second prototype embodiment of **Fig.6**, the structure and operation of the prototype is substantially identical to that of **Fig.5** with the major exception being that the magnet **300**/shaft **304** elements (and related sub-elements **302**, **303** and **307**) are positioned inside of and within the core of the primary coil **305**, as compared to the placement of the magnet **200**/shaft **204** elements next to and along side of the coil **205** of **Fig.5**. Therefore, for brevity, a detailed description of the elements of **Fig.6** will not be repeated, but it is noted that the corresponding and analogous elements and sub-elements are similarly numbered in **Fig.5** and **Fig.6**.

It is also important to again stress the fact that the prototype designs shown are presented simply to prove the correctness of the invention, and it should be clear that the invention can be made extremely more efficient by utilising all of the magnetic field produced by coil **205** and designing the magnet **200** of a shape and strength that efficiently interacts with the majority of the magnetic fields from coil **205**. The illustrated prototypes is relatively highly inefficient in this regard, but even so, the results of the invention itself greatly exceed the prior art as to use of electric current from whatever source and interaction with an electric motor or whatever work was conventionally performed.

The applicant feels it is very important to again stress, in building many varying designs of this invention, consideration must be given to the fact that the Energy in the field of force of any type magnet is the Energy that makes up the Atoms of the material from which it comes! This Energy is a real Entity with, it is believed, a gyroscopic action. It is literally Einstein's Equation of $E=MC^2$ and it is believed that this Energy moves at the speed of light and makes up all Matter. And that this Energy has a constant pressure effect back to the Atoms of the material from which it came, similar to hydraulic pressure. This effect is additionally more fully understood by stating the following results obtained from experimentation by the applicant in the process of this invention.

a) When the system is initially attached to a 1.5 volt size N Battery **201** or **301** and the magnet **200** or **300** and related rotation entities are placed close to or in the centre of coil **205** or **305**, the following results are observed:

If the electric current produced in coil **206** (**306**) is then fed back into coil **205** (**305**) in accordance with proper polarity, the rotation speed of magnet **200** or **300** will then accelerate. If fed back into coil **205** (**305**) in wrong polarity, the rotation speed of magnet **200** (**300**) will slow down.

This proves that the total force from coil **205** (**305**) interacting with the magnet **200** (**300**) is greater when the electrical energy from coil **206**(**306**) is fed back into coil **205** (**305**), then when only the initial electric energy from battery **201** (**301**) is fed into coil **205** (**305**)! When two or three batteries are electrically connected together in series, so as to create for example three or four and a half volts of electrical input, this effect is multiplied. Remember, up to a point, the greater the electrical input, the greater the percentage of atom alignment within coil **205** (**305**).

This further proves that the electric current produced in coil **206** (**306**) is a result of the gyroscopic particles of Energy released from the magnetic fields which came from the Electromagnetic make-up of the atoms of coil **205** (**305**), and is not part of the initial Electrical Energy released from the atoms making up the materials of battery **201** (**301**)! The coil **206** (**306**) can be taken out of the system, or its electrical current fed away from the system, and the rotational speed of the magnet **200** (**300**) will not observably change. However, the rotational speed of magnet **200** (**300**) will noticeably change when the electric current from coil **206** (**306**) is fed back into coil **205** (**305**)!

Now a different result:

b) When the electric current from battery **201** (**301**) becomes weaker to the point that the magnetic field coming from coil **205** (**305**) has weakened and shrunk allowing the magnetic field of the rotating magnet **200** (**300**) to expand and then noticeably induce electric current into coil **206** (**306**) and into coil **205** (**305**), then reverse results are observed. When the magnetic field from the coil **205** (**305**) is large, then the magnetic field from magnet **200** (**300**) is retained! If coil **206** (**306**) is then short circuited, the rotation of magnet **200** (**300**) will noticeably slow down.

If electric current from coil **206** (**306**) is fed back into coil **205** (**305**) in wrong polarity, the rotation of the magnet **200** (**300**) will stop. If fed back into coil **205** (**305**) in correct polarity, the rotation of the magnet **200** (**300**) will slow down. At that point, the rotation of the magnet **200** (**300**) will not accelerate, no matter how connected!

These results show that, at this time, the magnetic field from magnet **200** (**300**) noticeably induces a current in coils **206** (**306**) and **205** (**305**) which opposes the rotation of the magnet **200** (**300**). This effect has already been mechanically explained, and it has been shown that Lenz's Law was simply an observation of that mechanical explanation. These results further demonstrate that the expanding and collapsing magnetic fields from coil **205** (**305**) and **206** (**306**) do not noticeably effect each other detrimentally.

Because the resulting magnetic fields from all the coils are the results of fluctuating atom alignment within the coils! Remember, the gyroscopic energy particles making up the magnetic fields have a hydraulic pressure effect back to the atoms from which they came. Also remember that the atoms making up the material of the permanent magnet **200** (**300**) are stationary as to atom alignment direction! Therefore, the pressure effect resulting from an opposing field which the magnet **200** (**300**) induced, is immediate. As is Hydraulic Pressure.

However, the magnetic field emitted from the atoms of coil **205** (**305**) relative to induction into the atoms of coil **206** (**306**) are fluctuating and out of step, so to speak, and therefore, in harmony with each other. The pressure effect from the induction of coil **205** (**305**) into coil **206** (**306**) is an action and reaction effect which reinforces the flipping action of the atoms of coil **205** (**305**) and back into the atoms of coil **206** (**306**).

This action is again seen when the invention is hooked into one-hundred-fifteen volt alternating current, and battery **201** (**301**) is not used. The magnet **200** (**300**) will not rotate even though the magnetic field from coil **205** (**305**) is strong and is alternating. Reason: The fluctuating magnetic field is so fast, that the inertia mass of magnet **200** (**300**) can not get started in one direction before the magnetic field from coil **205** (**306**) has reversed, thereby, causing magnet **200** (**300**) to vibrate only microscopically at sixty cycles per second. And, if a sixty watt bulb is hooked into the system of coil **205** (**306**), it will only light dimly. And there is a lag time of two to three seconds before it lights even dimly.

If then coil **206** (**306**) is hooked to a meter, there is a reading of forty-nine volts, and if the meter is replaced by another sixty watt bulb it will light only extremely dimly. However, the sixty watt bulb hooked to coil **205** (**305**) will now become noticeably brighter! This again shows that the action and reaction results of the atoms of the coils are not noticeably detrimental to each other. Because of the lag time (out of step, so to speak), resulting in reinforcing the flipping atom alignment of the coils.

From this further explanation of the invention it is seen that desirable results may be obtained by the following:

For example, in **Fig.6** the magnet **300** may be of a design and/or be located at a distance from the inside diameter of coil **305** and coil **306**, whereby the majority of the magnetic field from the magnet **300** does not cut the conducting loops of coil **305** or **306**. Yet the alternating magnetic field produced by coil **305** should efficiently have the majority of its gyroscopic particles interacting with the majority of the gyroscopic particles making up the magnetic field of the permanent magnet **300**, but not directly reacting with the atoms making up coil **305**, or magnet **300**!

When the magnetic lines of force of the magnet **200** (**300**) cross at right angles with the conducting wires of coil **205** (**305**), **206** (**306**), a braking action is incurred. It should be noted that, as the inner diameter of coil **205** (**305**) increases, the percentage of time of braking effect decreases.

Along this same line of instruction, the commutator segments **202** (**302**) can be made of a large diameter and the area of brushes made small, whereby, when the brushes cross over the gaps in the commutator segments, there will be no short circuit at any time directly back to the battery **201** (**301**).

By combining the slip rings and brushes (the slip rings can be made of a small diameter) to the side or sides of the brushes and commutator segments **202** (**302**), then battery **201** (**301**) does not have to rotate with magnet **200** (**300**).

The 14-gauge and 15-gauge insulated copper wire weighing seventy and ninety pounds respectively (31.5 kilograms and 40.5 kilograms) used for the motor coil **205** (**305**) and the generator coil **206** (**306**), respectively, in the first hand-made prototypes of the embodiments of **Fig.5** and **Fig.6**, for demonstration purposes only, come in standard buckets of varying weights from wholesale outlets.

It was then wound in coils as shown, and, as taught, the more conducting wire used, the better the results. The magnets **200** and **300** were each initially about a 2.5 inch (6.25 centimetre) cube and can be any size and strength desired.

In a further, rough, hand-built, demonstration, working prototype of the invention of the type illustrated in **Fig.6**, the primary or motor coil **305** was made of 5-gauge copper wire in a single, continuous wire, weighing approximately 4,100 pounds (1,845 kilograms) with a coil loop diameter of 4.5 feet (135 centimetres), while the secondary or generator coil **306** was made of 24-gauge copper wire in a single continuous wire weighing approximately 300 pounds (135 kilograms) with the same, approximate coil loop diameter of 4.5 feet (135 centimetres), with both coils **305**, **306** coincidentally forming a cylinder of approximately 30 inches (75 centimetres) in length. The coils **305**, **306** were built around a cylindrical, fiberglass core body of approximately 200 pounds (90 kilograms) having a vertical, longitudinal centre-line axis.

The rotating magnet **300** was made up of six, separate, parallel cylindrical magnetic columns spaced and disposed about the periphery of a hollow cylindrical fiberglass surface of approximately twenty inch (fifty centimetres) in diameter. Each column was 30 inches 75 cm.) long and was composed of a stack of 70, individual ceramic ring magnets in disc form as made by Jobmaster Magnets of Randallstown, Maryland, 21133, U.S.A. Each disc had a thickness of seven-sixteenths of an inch (1.09375 centimetres), an inner diameter of 1 inch (2.5 cm.) and an outer diameter of 4 inches (10 cm.). The discs were stacked and secured together in 4 inch (10 cm.) diameter fiberglass tubes longitudinally mounted on the inner surface of the twenty inch (fifty cm.) diameter fiberglass cylinder.

The composite magnet **300** had a total weight of approximately 400 pounds (180 kilograms) and a total length of 30 inches (75 cm.) and an approximate diameter of 20 inches (50 cm.).

The magnet **300** was mounted for rotation on a horizontal shaft **304** extending across the hollow core of the coils **305**, **306** crossing through the centre point of the longitudinal centre-line of the cylinder and orthogonally to the longitudinal centre-line of the magnet **300** for rotation within the open centre area of the cylindrically disposed coils **305**, **306** with the longitudinal centre-lines of the coils being vertically disposed.

With a D.C. battery source **301** of two 12 volt lantern batteries and seventeen 6 volt lantern batteries all in series (totalling 126 volts), a measured voltage of 126 volts and a measured current of 99 milliamps in the primary coil **305** were noted. Concurrently a voltage reading of 640 volts and an amperage measurement in excess of 20 milliamps were noted in the secondary or generating coil **306**, with the magnet **300** rotating at a speed of 120 revolutions per minute (rpm). Thus the system was outputting and producing in the generating coil **306** usable electrical energy in excess of 102% of that being inputted in the motor coil **305**! This excess useful electrical energy, of course, is in addition to the further useful mechanical energy available at the exemplary drive take-off **307** on the rotating shaft **304**, on which the 400 pound, 30 inch long magnet **300** was rotating at 120 rpm!

Thus the invention, by utilising the energy of the gyroscopic particles in the magnetic field, produces a greater energy output than the energy input into the system, thus producing results beyond presently accepted scientific teachings of the world.

This prototype achieves exactly what has already been described in great detail in applicant's prior patent applications. There was simply used in this prototype a stronger magnet and a larger diameter conducting wire of great length, that has a considerably greater number of atoms aligned when current is put into the system, and used a greater number of atoms in the generator coil of fine diameter conducting wire.

While the results of the energy released from this particular prototype is highly impressive to others, the applicant still has only scratched the surface of the energy that can be released using the principles of the present invention.

Again, as has already been stressed, the most efficient design, is one in which the least amount of input of current causes the greatest amount of atom alignment.

These data do not constitute any departure from applicant's previous work, but is only to further document that which has already been stressed in the prior patent applications.

Varying the D.C. voltage for the battery source **301** shows that obvious efficiency will continue to rise as the voltage input goes up! Also, the leverage factor advantage of the invention, combined with the inertia of the 400 pound magnet **300** rotating at 120 rpm (even while causing the electrical generator to put out over 100% of energy input) proves the invention to be greatly over 100% efficient even at this slow rpm.

It is contemplated that the next prototype will use super-conducting type material for the coil **305** with a magnet **300** having a magnetic field strength comparable to that of crycogenic-type magnet relative to percentage of atom alignment or size. This will result in the size of the device being much smaller and yet with the available work output being much greater than the prototype just described. Reason: The most efficient type design is one whereby the least amount of current input into the motor coil produces the greatest atom alignment of said motor coil and having rotatable magnet also comparable in strength, relative to size.

The invention can be made without using the coil **206** (**306**) and producing just useful mechanical energy.

Coil **206** (**306**) can be merged or wound with coil **205** (**305**).

The magnet **200** (**300**) can be an electromagnet, a permanent magnet, a cryogenic magnet or any magnet.

The design of magnet **200** (**300**) can create a strong but retained magnetic field.

The design of coil **205** (**305**) can be used to further retain the magnetic field of magnet **200** (**300**).

Alternating current (A.C.) can be used in place of the direct current (D.C.) battery **201** (**301**), if the magnet **200** (**300**) is designed accordingly.

The coils **205** (**305**) and **206** (**306**) may be made up of several coils rather than a single coil.

The magnet **200** (**300**) may be made up of several individual magnets rather than from just a single magnet.

From the foregoing it should be understood that, unlike the teachings of the prior art, the following is desired in the design of the coil **205/305** under the principles of the present invention:
a) Current initially flowing into and through the coil should be small compared to the energy output of the system;
b) A relatively large diameter wire or its equivalent is used for the coil;
c) A relatively large number of coil loops or coils is used;
d) A relative long, continuous length of coil wire or its equivalent is used; and
e) The greatest magnetism for a given mass of the magnet **200**/**300** is desired but may be designed so that the magnetic lines of force will not cut the coils at a right angle.

The present invention applies to any mechanical device which is operated by electrical energy. In accordance with the principles of the present invention, the mechanical device should be designed wherein the electric current as much as is feasible cannot get back to its source, but the circuit is completed whereby the "pressure force" is constant throughout the system.

What has been invented, built and disclosed is an invention of immense importance to the well-being of the entire world. There will be many devices built from what has been shown and taught. It should now be known that all matter is made up of electromagnetic energy and that there are many mechanical ways to release this energy, as has been stated throughout the five prior, related patent applications hereof and the Disclosure Document. All of these future developments will be as a result of the present invention which - releases energy above and beyond conventional energy release mechanisms, prior to this invention.

Some of the basic approaches of the invention are outlined below:

I. Any device which utilises a means by which the electric current (electromagnetic energy) is retained within a member or members outside of the source of said original electric current and then, as a result thereof, is capable of producing a continuous electromagnetic motion or current if so desired beyond present scientific teachings.

2. Any device which releases the electromagnetic energy make up of matter to such an impressive degree as does this invention that it defies several of the present accepted laws of physics and electrical engineering as of this time.

3. That the energy release is noticeably higher and in some cases more controllable than the conventional means of energy release of this time.

Because many varying and different embodiments may be made within the scope of the inventive concept taught here, and because many modifications may be made in the embodiments detailed here in accordance with the descriptive requirements of the law, it is to be understood that the details given above are to be interpreted as illustrative and not in any limiting sense.

CLAIMS

1. A usable energy generation system, comprising:

usable energy output means for making available for use the usable energy generated in the system; and
usable energy generation means associated with said output means and designed to take into account the reaction to a force of the gyroscopic type energy particles and to utilise the gyroscopic type energy particles moving in a magnetic field for producing usable energy of an amount greater than the amount of energy input.

2. The system of Claim 1, wherein said generation means includes structural means for placing a force at an angle to the gyroscopic particles causing the particles to follow paths having a net directional effect, producing electric current flow.

3. The system of Claim 2, wherein said structural means comprises magnetic means and a closed housing associated therewith containing a fluid in the magnetic field produced by said magnetic means, said fluid becoming charged as a result of its interaction with the gyroscopic type energy particles making up said magnetic field.

4. The system of Claim 3, wherein said magnetic means is a series of aligned magnets positioned centrally within said housing but electrically insulated therefrom.

5. The system of Claim 3, wherein there is included a further, keeper housing completely surrounding said closed housing and electrically insulated therefrom, said keeper housing tending to keep and concentrate the magnetic field produced by said magnetic fields within it.

6. The system of Claim 3, wherein said output means includes a network of metallic surfaces immersed in said fluid to pick up the electrical charges on said fluid.

7. The system of Claim 2, wherein said structural means comprises a member having its atoms aligned to produce a net magnetic field which is at least substantially contained within the surface boundaries of said member.

8. The system of Claim 7, wherein said member is positioned in operative association to at least one magnet, and said member and said magnet are held static with respect to one another.

9. The system of Claim 1, wherein:
The usable energy generation system comprises an electrical energy generation system; said usable energy output means comprises an electrical power output means; and said usable energy generation means comprises electrical energy generation means.

10. The system of Claim 1, wherein:
the usable energy generation system comprises usable motion generation system; said usable energy output means comprises usable motion output means; and said usable energy generation means comprises usable motion generation means.

11. The system of Claim 1, wherein said generation means includes:
a magnetic device;
a source of electrical energy;
complete electrical circuit means between said magnetic device and said source of electrical energy for producing an alternating electrical current potential; and
current retarding means for retarding the flow of current through said device back to said source to the greatest extent practical, producing a relatively small and preferably negligible current flow through said source.

12. The system of Claim 11, wherein said magnetic device includes at least one relatively large coil of wire having a relatively large number of turns of wire of a relatively large diameter and a relatively great length.

13. The method of producing usable energy utilising a magnetic field system, comprising the following steps:
a. providing a structure interacting with a magnetic field; and

b. arranging said structure to utilise the energy of the gyroscopic type particles in the magnetic field to generate an electrical current in said structure, or usable motion from said system, or both, and results in producing a greater energy output than energy input into the system.

14. The method of Claim 13, wherein there is included in step "b" the further step of arranging said structure to place a force at an angle to the gyroscopic particles cause the particles to follow paths having a net directional effect, producing electric current flow, without any normal, visible movement taking place in the system.

15. The method of increasing the availability of usable electrical energy or usable motion, or both, comprising the steps of:

a. providing a magnetic device for producing usable electrical energy or usable motion, which device includes a material through which electrical current can interact producing a magnetic field which interacts with a separate mass having a magnetic field, and further providing a source of electrical energy such as for example a battery, generator, or any other;

b. providing a complete electrical circuit between said magnetic device and said source of electrical energy and producing from said source to said device an alternating electrical current potential; and

c. retarding the flow of current through said device back to said source to the greatest extent practical, producing a relatively small and preferably negligible current flow through said source and resulting in electrical energy output, or usable motion output, being a greater energy output than energy input into the device.

16. The method of Claim 15, wherein step "c" is achieved at least in part by the step of providing in said device a relatively large coil or coils of wire having a relatively large number of turns of wire of a relatively large diameter and a relatively great length.

17. The method of Claim 15, wherein step "c" is achieved at least in part by the step of utilising a means by which the electric current is retained within at least one member outside of the source of said original electric current and then, as a result thereof, is capable of producing a continuous electromagnetic motion or current.

18. The method of claim 15, wherein there is included the step of providing a separate magnetic source positioned so that its magnetic lines of force avoid significantly cutting the material through which the electrical energy flows avoiding a braking effect which would retard the desired motion of said magnetic source.

19. The method of Claim 15, wherein step "a" is achieved by said material being a super conducting material and said separate magnetic mass is at least equivalent to a cryogenic magnet.

20. The method of Claim 15, wherein step "a" is achieved by the step of having said material a conducting material and said separate magnetic mass of any desired configuration or strength or type.

21. The method of increasing the availability of usable electrical energy, or usable motion, or both, comprising the steps of:

a. providing a magnetic device which has a material mass into which an electrical current is introduced, by any desired means, which results in causing pertinent atom alignment, within said material mass, thereby releasing some of the electromagnetic energy making up the atoms of said material mass, in the form of a magnetic field, which then causes the gyroscopic type energy particles of said magnetic field to then interact with the gyroscopic type energy particles making up a magnetic field coming from the atoms of a different material mass; and

b. having the magnetic device then cause a release of electrical current or usable motion or both through at least one power outlet and resulting in producing a greater energy output than energy input into the device.

22. The method of Claim 21, wherein the material mass or masses are made of a material or substance that allows for extremely fast atom alignment, without the delay, or conventional degree of hysteresis losses normally associated with conventional iron atom alignment.

23. A device which increases the availability of usable electrical energy or usable motion, or both, by causing the atoms of a material or materials to release some of their magnetic energy makeup in the form of a magnetic field, consisting of gyroscopic type energy particles which make up the atoms of the material from which the magnetic field comes; and

a properly designed mechanism, or power output arrangement being place to utilise the energy of said gyroscopic type energy particles, causing a release of energy output greater than energy input without producing radioactive material.

24. A device which increases the availability of usable electrical energy or usable motion, or both, from a given mass or masses by a device causing a controlled release of, or reaction to, the gyroscopic type energy

particles making up or coming from the atoms of the mass or masses, which in turn, by any properly designed system, causes an energy output greater than the energy input.

25. A system including an energy generator, motor, etc.

of any design or mechanism that takes into account- the reaction to a force of the gyroscopic type energy particles moving in a magnetic field at tremendous speeds which releases greater output than energy input.

26. The system of Claim 25, wherein a small input of electrical current into the mechanism causes extremely quick and high atom alignment, resulting from using a super conducting material, thereby creating a powerful magnetic field, whereby its gyroscopic type energy particles then interact with the gyroscopic type energy particles coming from a second powerful magnetic field and results in producing a greater output of energy than input of energy into the mechanism.

27. The system of Claim 25, wherein a structure is arranged, whereby, there is, or will be, a pressure, or force, exerted on or in said structure, thereby causing the atoms of said structure to react to said pressure or force, and as a result take a pertinent atom alignment direction that results in said atoms of said structure then causing the gyroscopic type energy particles moving in the magnetic field to be generally deflected in the same direction through said structure, which results in usable electric current flow, producing a greater energy output, than energy input into the system.

28. The system of Claim 25, wherein a rotary magnetic mass is designed to react to a reversing magnetic field of another mass, and said reversing magnetic field can not reverse any faster than the atoms of said other mass can flip and realign; said rotary magnet mass being made as long as is practical to adjust to this requirement, wherein the distance of the arc of circle travelled by the ends of said rotary magnet mass is great; great leverage from said reversible magnetic field of other mass being applied to said rotary magnet, and in addition the increased distance of arc travelled by the ends of rotary magnet before the magnetic field of said other mass reverses, greatly increasing the time in which a maximum force is exerted by the gyroscopic type energy particles moving in the magnetic field coming from the maximum number of atoms aligned in said other mass, thereby causing a longer time of acceleration of said rotatable magnet mass before the atoms of said other mass are required to reverse.

29. The method of producing usable energy, comprising the following steps:

a. imputing energy into a device from an external source;

b. having electrical current flow within said device; and

c. utilising the internal electromagnetic energy of at least some of the matter in the device to add to the energy being imputed into the device from the external source to produce useful energy for use outside of the device having an amount greater than the energy being imputed to the device.

Patent US 4,041,465 **27th September 1977** **Inventor: Philip S. Brody**

Assignee: The Unites States of America as represented by the Secretary of the Army

FERROELECTRIC CERAMIC DEVICES

This version of the patent has been re-worded in an attempt to make it easier to read and understand. The original can be examined at www.freepatentsonline.com and downloaded without charge. This patent covers several different applications, namely; a high-voltage very high-efficiency solar electric device, a photovoltaic memory device, an optical display device and a high-voltage battery, to name just a few. It should be noted that this patent is assigned to the US Army. In my opinion, that lends weight and credibility to this patent. It is claimed that a one centimetre square piece of this material can produce 1,500 volts as opposed to less than one volt using conventional solar cell materials.

ABSTRACT

A method and apparatus is disclosed by which high voltage and current can produced by a polycrystalline ferroelectric ceramic material in response to incident light. Numerous applications of the ferroelectric ceramic material taking advantage of such properties thereof are further disclosed. The polycrystalline ferroelectric ceramic material is initially poled by the application of a pulse of voltage of predetermined magnitude and direction. After being poled in such fashion, light shining on the various surfaces of the ferroelectric ceramic material will generate a consistent high voltage between the surfaces of the ferroelectric ceramic material. If electrodes are attached to the material, then a current will be generated and a load can then be powered by it. Importantly, the magnitude of the voltage produced by the light is directly proportional to the remanent polarisation of the ferroelectric ceramic material, and is further directly proportional to the length of the material, the polarity of the high voltage being dependent upon the polarity of the remanent polarisation and being capable of being reversed when the remanent polarisation is reversed. The open circuit voltages produced by the ferroelectric ceramic material are orders of magnitude higher than those which typically have been produced in the prior-art through the utilisation of standard photovoltaic materials.

DESCRIPTION

BACKGROUND OF THE INVENTION

This invention generally relates to solid state devices exhibiting photovoltaic effects and is particularly directed to the provision of a device consisting of a class of polycrystalline ferroelectric ceramic materials which have been discovered to produce voltages upon the application of light. These voltages are many orders of magnitude higher than voltages typically produced by conventional photovoltaic materials.

Initially, and as background, the instant inventive apparatus and techniques to be discussed below are to be clearly distinguished from the photovoltaic effect now know in the prior-art in that the mechanism for the effect to be discussed herein appears to be unique and different from photovoltaic mechanisms previously described.

SUMMARY OF THE INVENTION

It is the primary objective of the instant invention to provide a device and technique by which extremely high voltage can be generated utilising a solid state polycrystalline class of materials upon the application to such materials of incident light, the voltage generated exhibiting properties entirely unlike the well-known photovoltaic effect of the prior art and of orders of magnitude higher than voltages previously obtainable.

Another equally important objective of the instant invention is the provision of apparatus utilising ferroelectric ceramic materials of the type to be described below, such apparatus taking advantage of the unique properties as discovered to be existent in the class of materials to which the instant invention relates.

These broad objectives, as well as others which will become apparent as the following description proceeds, are implemented by the subject invention which utilises at its heart a class of materials known as ferroelectric

ceramics, and which take advantage of the unique photovoltaic properties discovered to be existent in such class of materials.

Specifically, by illuminating the surfaces of these materials, a steady voltage results across conducting electrodes placed in contact therewith. Currents can then be drawn through loads placed across these electrodes. It has been discovered that an arrangement of an initially polarised ceramic material with electrodes attached thereto as is shown in **Fig.1** of the application drawings produces steady high voltages from a steady illuminating source such as the sun, an incandescent bulb, a fluorescent tube, etc. and that the magnitude of these voltages is high and directly proportional to the length, **l** of the sheet of material provided. In **Fig.1**, the shaded area represents an electrode, and $\mathbf{P_r}$ is the remanent polarisation. In another basic arrangement of the invention, light enters through transparent electrodes and the material is poled in the direction of the light, and the photo-emf up to a certain limiting thickness is proportional to the thickness of the slab.

It has further been discovered that the magnitude of the photo-voltages produced is directly proportional to the remanent polarisation of the material. The polarity of the photo-voltage is dependent on the polarity of the remanent polarisation and reverses when the remanent polarisation is reversed. The magnitude of the voltages that are produced can also be varied by varying the sizes of the grains of which the ceramic is composed, the voltage having a generally proportional relation to the number of grains per unit length. Grain size can be controlled by well-known fabrication techniques involving compositional additives and firing rates, which techniques do not form a part of the present disclosure.

When illuminated at intensity levels such as that produced by direct sunlight or at lesser levels such as that produced by a fluorescent lamp, the materials will behave as voltage sources in series with a high output resistance. The output resistance will decrease an the intensity of illumination increases and also varies with wavelength.

The open circuit voltages produced by the materials of the invention are much higher than those that are typical of other photovoltaic materials. These high open circuit photo-voltages have been observed to some extent in virtually all materials examined which can generally be described or classified by the term ferroelectric ceramic, provided that the material was characterised by a net remanent polarisation. Such high photo-voltages are to be expected in virtually all polarised ferroelectric ceramic materials properly doped, the class including thousands of different known materials of this kind with numerous variations possible in each kind. Such variations are produced by additives, varying grain size, and by changing compositional blends, in those formed from mixtures. Any of these are expected to have application as photovoltaic materials.

From the viewpoint of application, the novel photovoltaic effect seen in ferroelectrics in accordance with the teachings herein differs in two important respects from the well known junction photovoltaic effect which is the mechanism in prior-art devices such as solar cells, and photo-diodes.

First, the prior-art junction photo-emf is independent of the length or thickness of the unit and is low, less than one volt. To obtain high voltages, many cells have to be connected in series. The photovoltaic effect in ferroelectrics, on the other hand, can be used to directly produce high voltages. The photo-emf is proportional to length, and the photo-emf per unit length can be very high. For example, the composition $Pb(Zr_{65}Ti_{35})O_3$ with 7% of the lead substituted by lanthanum, when composed of 2-4 microns grains produces, when illuminated as shown in **Fig.1**, 1500 volts for every centimetre of length between the electrodes. A single one cm square unit thus directly produces 1500 volts.

In this case, it is also clear that the voltage per unit length will be further increased by the development of a composition in which the average grain size is further decreased.

These voltages are so high that applications have been contemplated which are alternatives to the devices presently used for the generation of extremely high DC voltages at low currents -- such as belt machines (the Van de Graaf), in which high voltages are produced by mechanically moving electric charges.

Second, and perhaps even more important, is the fact that the direction of the photo-current and photo-voltage can be reversed simply by reversing the direction of its remanent polarisation. The magnitude of these quantities can be changed by changing that of the remanent polarisation, which in turn can be done (for example) by applying the proper polarity electrical voltage (poling voltage) to the same terminals across which the photo-voltages appear. The reversibility and control provided make immediately possible applications to use in computer memories of a new type -- in which information is stored as remanent polarisation and read out as the polarity and magnitude of a photo-current or photo-emf, such typical applications are disclosed here.

Application to the generation of electrical power from solar radiation, for example, to solar battery type devices and to electrical power generating stations operating on the basis of solar to electrical energy conversion also is

possible and contemplated but would require, to be practical, (except in special cases) considerably larger conversion efficiency than has been observed so far in the materials examined. A calculation of theoretical maximum efficiency, however, yields results which are large enough to suggest eventual practical use in this manner. A conversion system based on these high voltage materials would have the particular advantage of producing its electricity directly at high voltage which is advantageous for power transmission purposes.

The mechanism for the discovered effect appears to be unique and different from photovoltaic mechanisms previously described. Description will be provided explaining the mechanism and developing a theory for it. From this, it will be clear that the entire class of polycrystalline ferroelectrics are expected to exhibit high photo-emf's to at least some extent.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention itself will be better understood and further features and advantages of it will become apparent from the following detailed description which makes reference to the drawings, where:

Fig.1 is a schematic diagram illustrating the basic arrangement by which photovoltaic voltages are generated by the application of light to a ferroelectric ceramic material as shown by this invention;

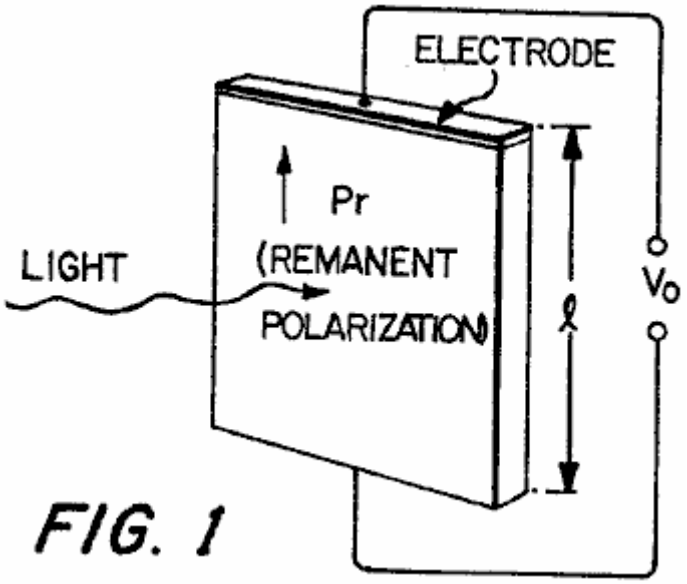

FIG. 1

Fig.2 is an electrical schematic diagram depicting an equivalent circuit to the basic apparatus of **Fig.1**, where $\mathbf{C_0}$ is the capacitance of the sample measured utilising a capacitance meter connected between the electrodes and $\mathbf{C_1}$ is the parallel capacitance of a load coupled to the electrodes, and $\mathbf{R_1}$ is the resistive value of that load;

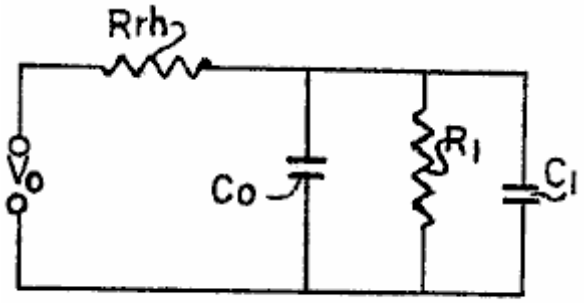

FIG. 2

Fig.3 is a graphical illustration of current vs. applied voltage to an illuminated ferroelectric wafer of the basic form depicted in **Fig.1**;

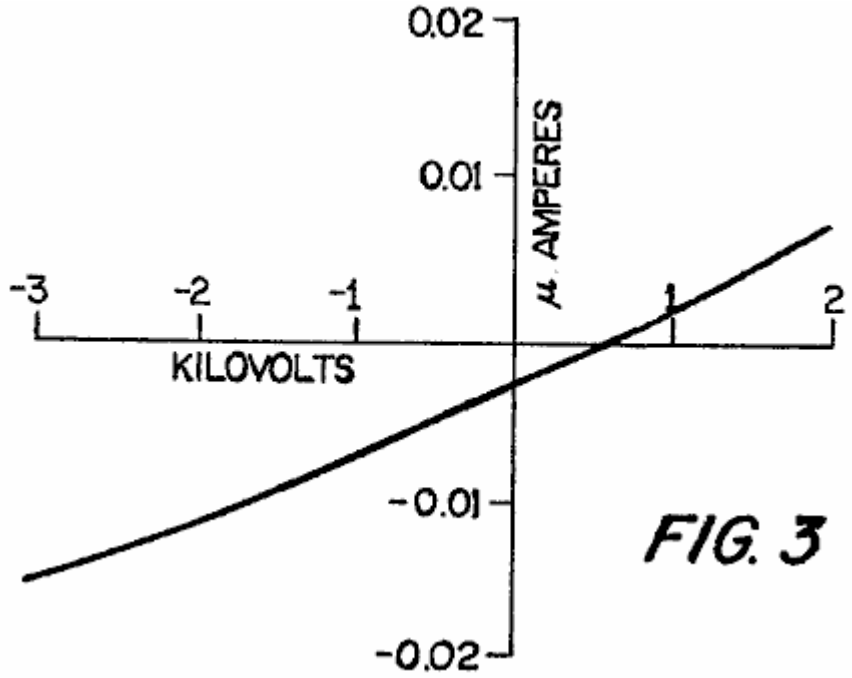

FIG. 3

Fig.4 is a graphical illustration of the photo-emf and photo-current as a function of intensity of illumination, with the particular graphical results being for a solid solution $Pb(Zr_{0.53}Ti_{0.47})0_3$ with about 1% by weight of Nb_20_5 added;

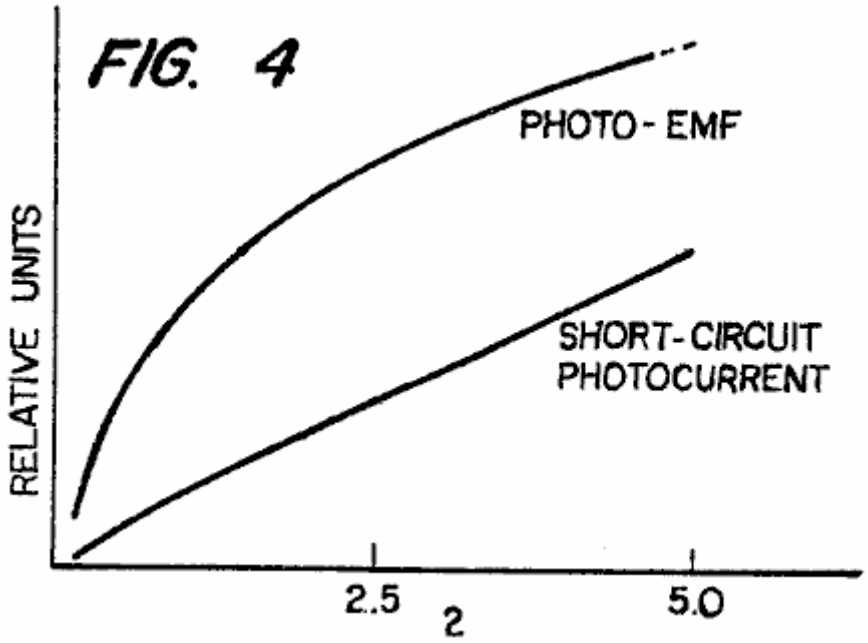

Fig.5 is a graphical illustration of photo-emf vs. grains per unit length (inverse median grain size) for two different materials;

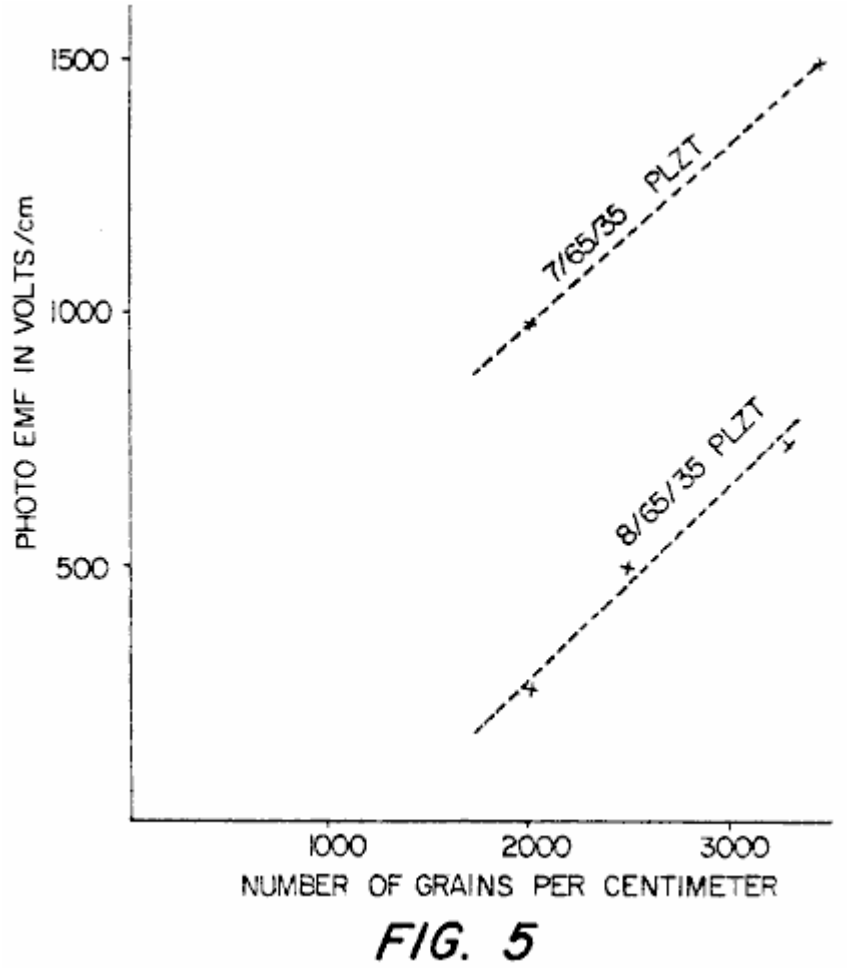

FIG. 5

Fig.6 is a graphical illustration of photo-voltage vs. remanent polarisation for ceramic $BaTi0_3$ + 5% by weight of $CaTi0_3$;

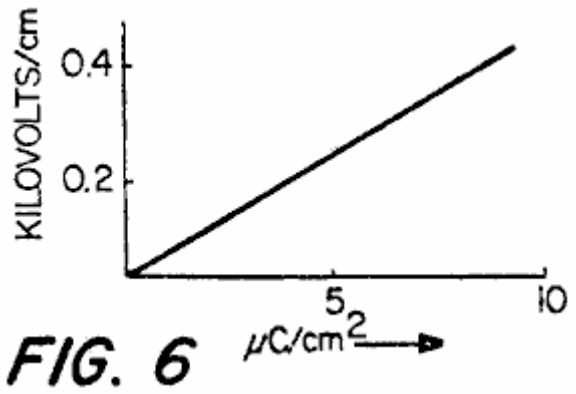

FIG. 6

Fig.7 is a diagram illustrating the short-circuit photo-current as a function of wavelength for the solid solution $Pb(Zr_{0.53}Ti_{0.47})0_3$;

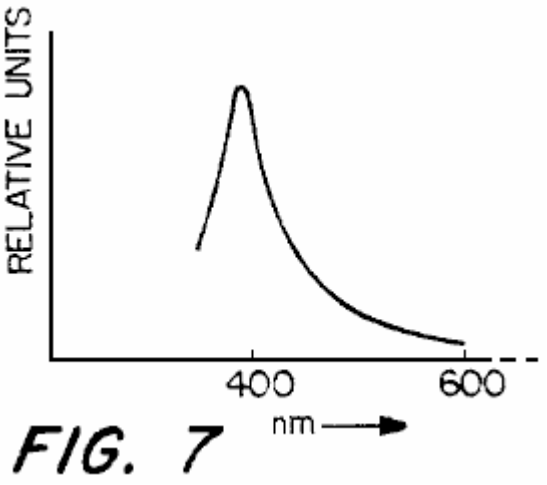

FIG. 7

Fig.8 is a diagram illustrating the short circuit photo-current as a function of wave length for ceramic $BaTi0_3$ + 5% by weight of $CaTi0_3$;

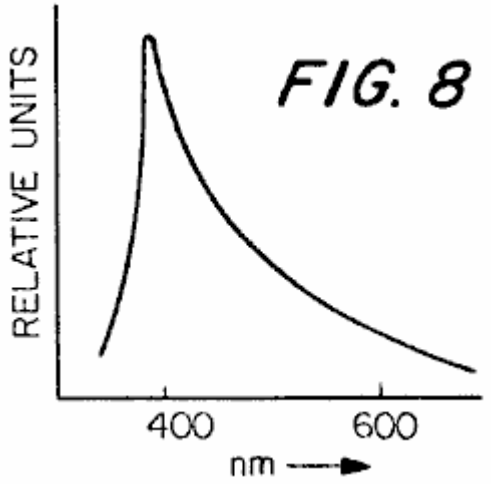

FIG. 8

Fig.9 is a diagram illustrating the short-circuit photo-current as a function of wavelength for the solid solution $Pb(Zr_{0.65}\ Ti_{.0.35})0_3$ with 7% of the lead substituted for by lanthanum;

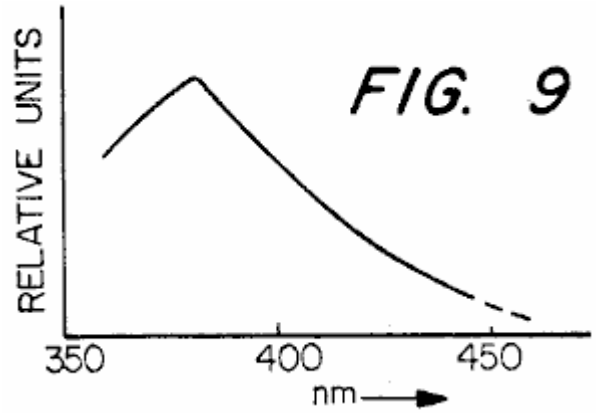

FIG. 9

Fig.10 is a diagram illustrating the photo-emf vs. wavelength for the solid solution $Pb(Zr_{.0.35}Ti_{0.47}0_3$ with 1% by weight of Nb_20_5 added;

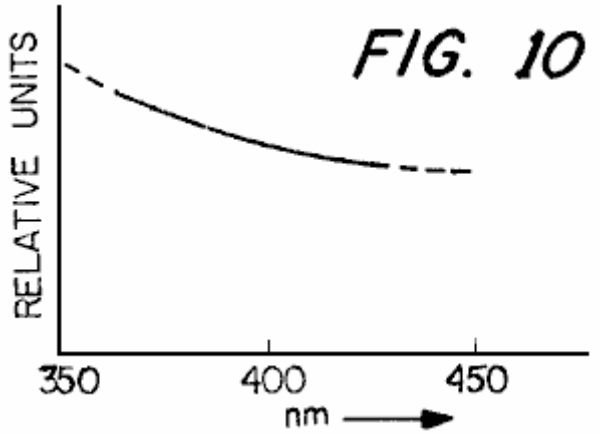

FIG. 10

Fig.11 is a diagram illustrating the photo-current divided by intensity vs. cut-off wave length of long wave length cut-off dichroic filters, with the materials being $Pb(Zr_{0.53}\ Ti_{.0.47})0_3$ with 1% by weight of Nb_20_5 added and utilising a high-pressure mercury arc as the illumination source;

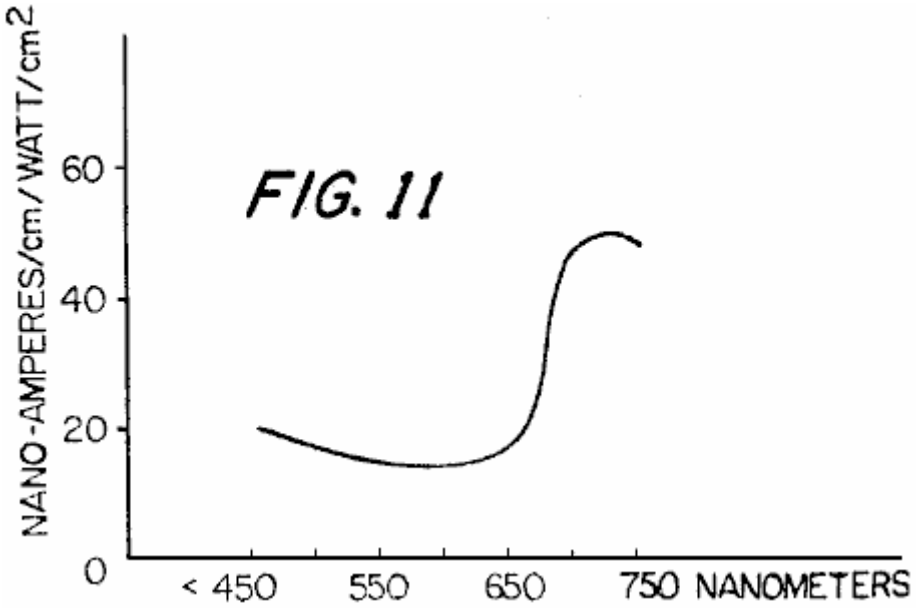

FIG. 11

Fig.12 is a diagram illustrating the photo-current divided by intensity vs. cut-off wavelength of short wave length cut-off filters, with the material being $Pb(Zr_{0.53}\ Ti_{.0.47})0_3$ with 1% by weight of Nb_20_5 added;

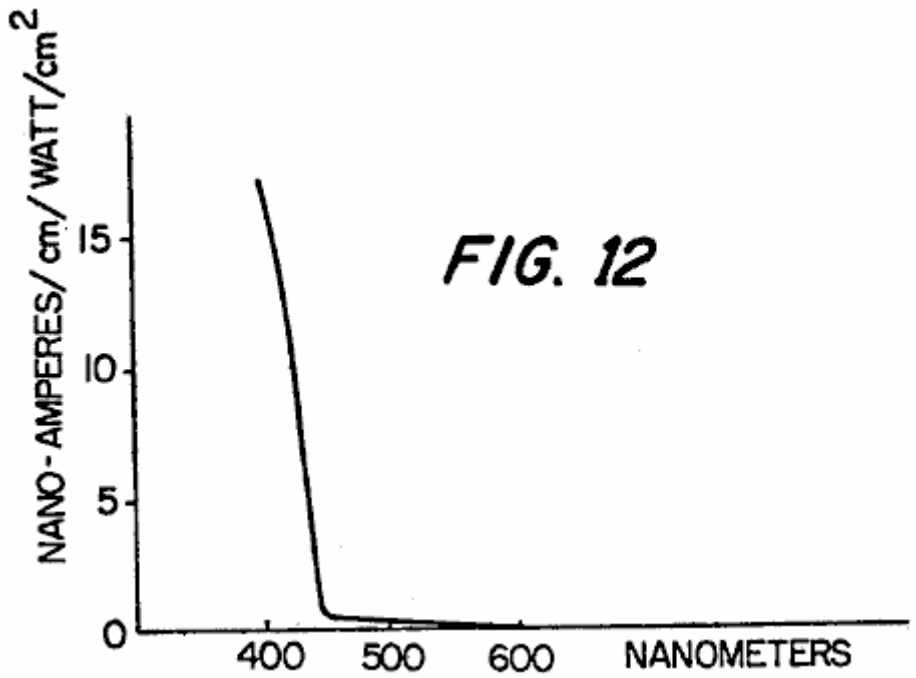

FIG. 12

Fig.13, is diagram illustrating the photo-emf vs. wave length of short wavelength cut-off filters, with the material being $Pb(Zr_{0.53}\ Ti_{.0.47})0_3$ with 1% by weight of Nb_20_5 added;

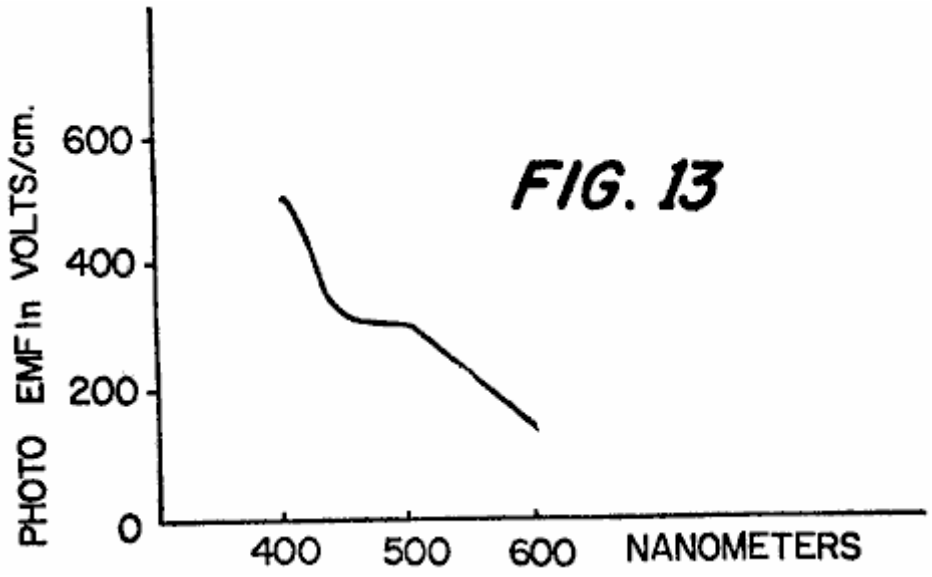

FIG. 13

Fig.14 is a pictorial illustration of the manner in which a single crystal produces a photo-emf, with the polarisation $\mathbf{P_s}$ being normal to the electrodes, which electrodes are illustrated by the shaded area;

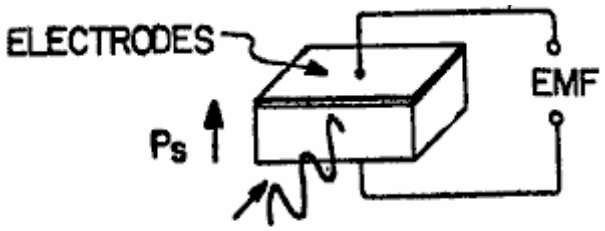

FIG. 14

Fig.15 is a diagram illustrating photo-current vs. wave length of the single crystal $BaTi0_3$;

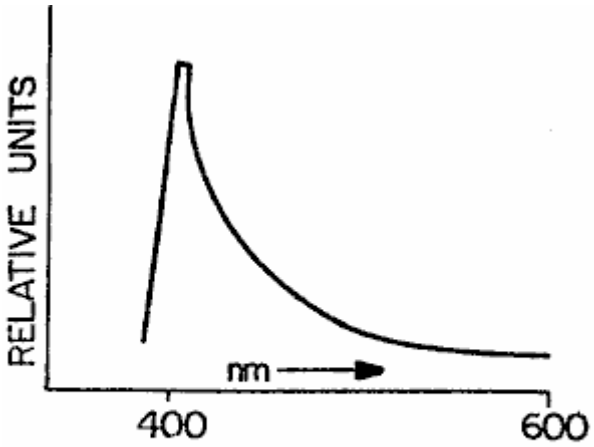

FIG. 15

Fig.16 is a diagram illustrating the photo-voltage vs. temperature for $BaTi0_3$ +5% by weight of $CaTi0_3$;

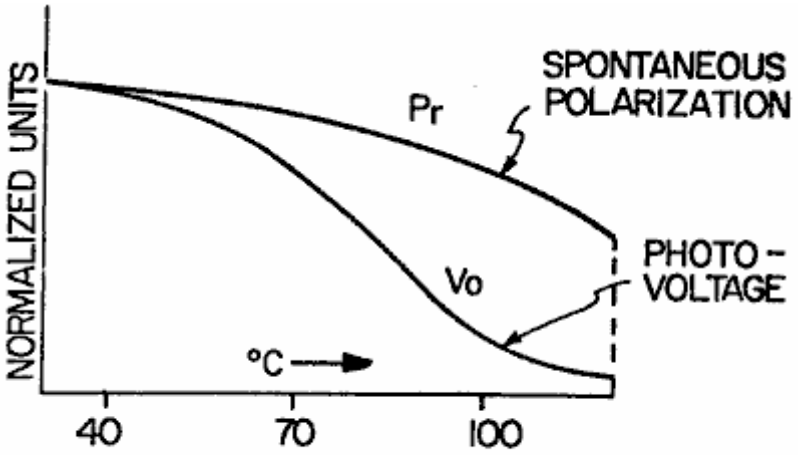

FIG. 16

Fig.17 is a diagram illustrating the photo-voltage vs. temperature of single crystal $BaTi0_3$;

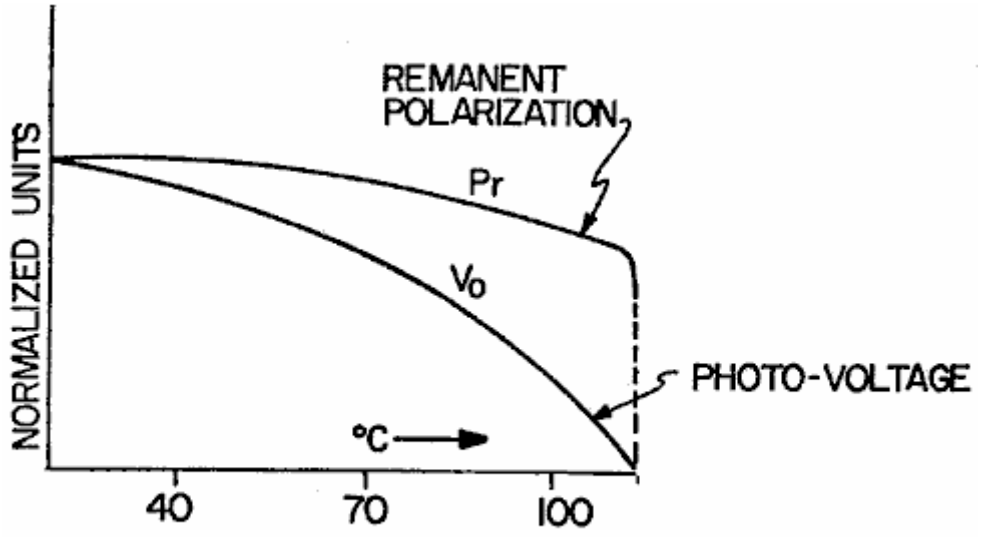

FIG. 17

Fig.18 is a diagram illustrating photo-current vs. temperature for $BaTi0_3$ + 5% by weight of $CaTi0_3$;

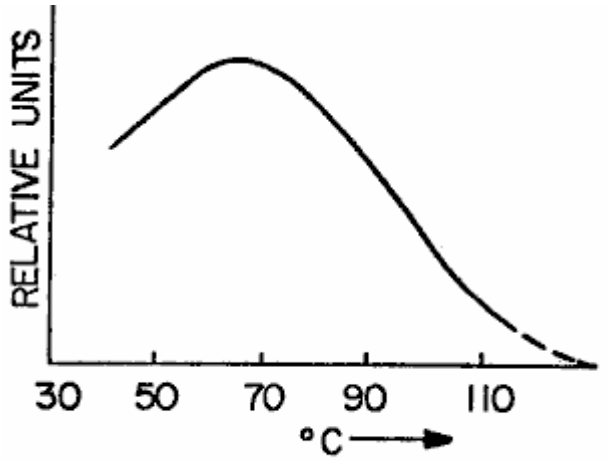

FIG. 18

Fig.19 is a cross-sectional, elevational view schematically depicting the ceramic slab of **Fig.1**, with the photo-emf appearing across the electrodes on the edge, and with most of the photo-current flow being found in the shaded region near the surface;

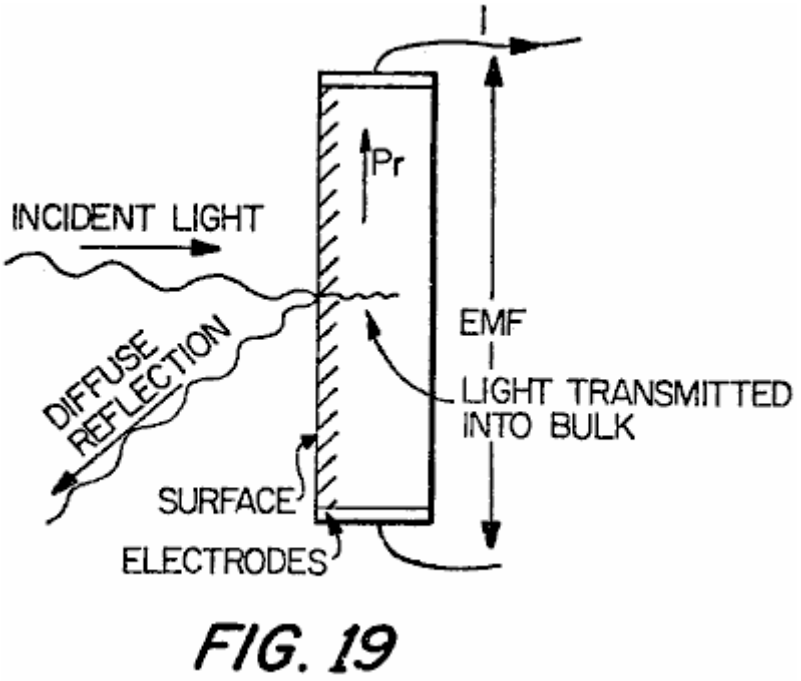

FIG. 19

Fig.20 is a cross-sectional, elevational view of a slab of ferroelectric ceramic material utilising transparent electrodes and depicting light incident through the transparent electrodes into the slab with the slab being polarised in the thickness direction;

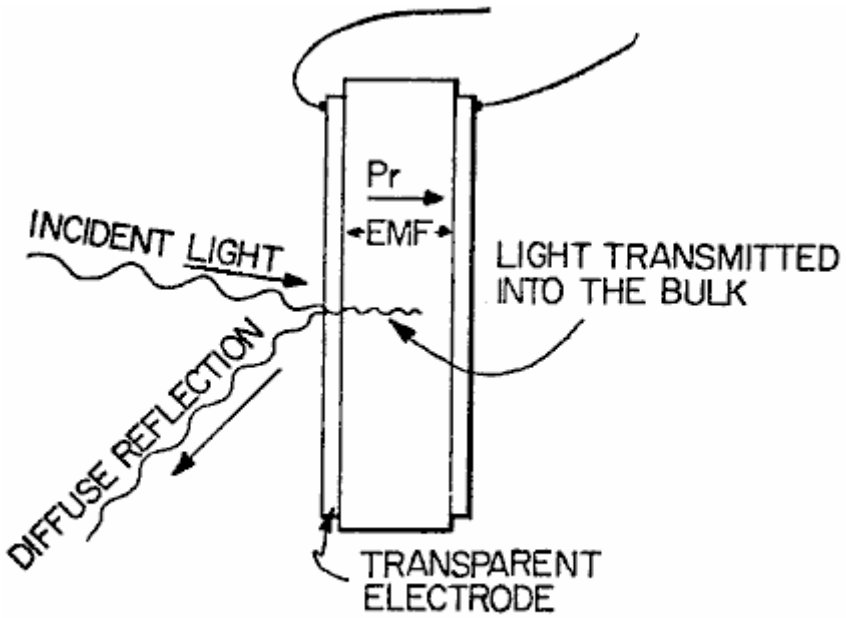

FIG. 20

Fig.21 is a cross-sectional diagrammatic illustration of a single layer of grains depicting the manner in which photo-emf's are produced across the grains in an additive fashion to produce a length dependent effect in the ceramic material, the illumination being incident from the left-hand portion of the drawing and being typically quickly absorbed as it penetrates the material;

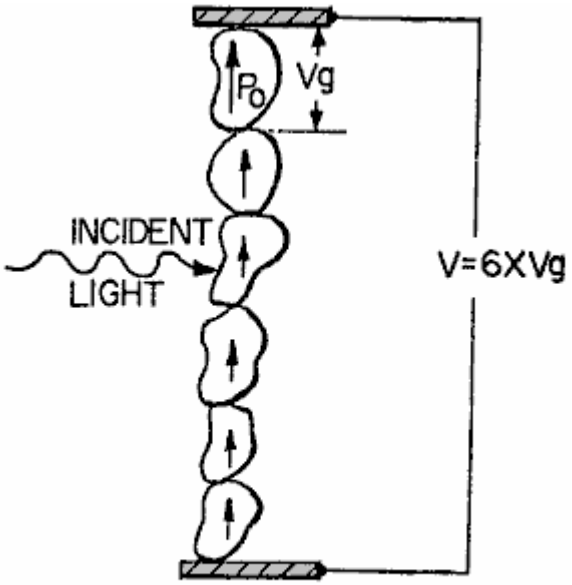

FIG. 21

Fig.22 is a diagram illustrating idealised two dimensional crystals of length **l** with spontaneous polarisation $\mathbf{P_s}$, dielectric constant Epsilon $_b$ compensating surface charge per unit area of Sigma = P_s ;

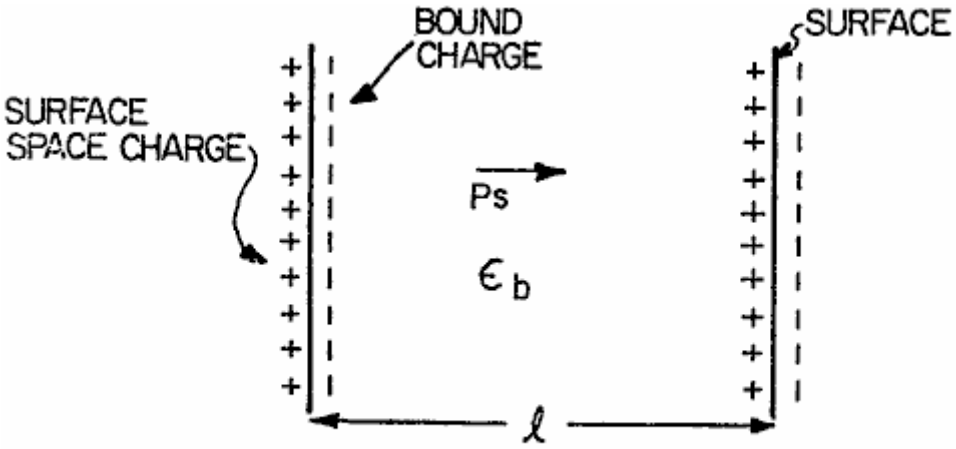

FIG. 22

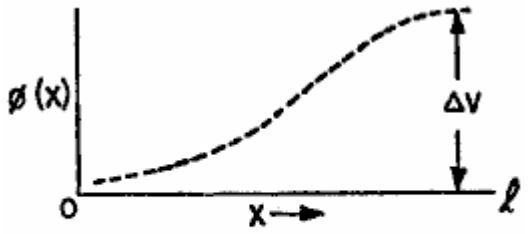

FIG. 25

Fig.26 is a schematic representation of the instant inventive ferroelectric ceramic substrate utilised as a photovoltaic memory device with optical scanning;

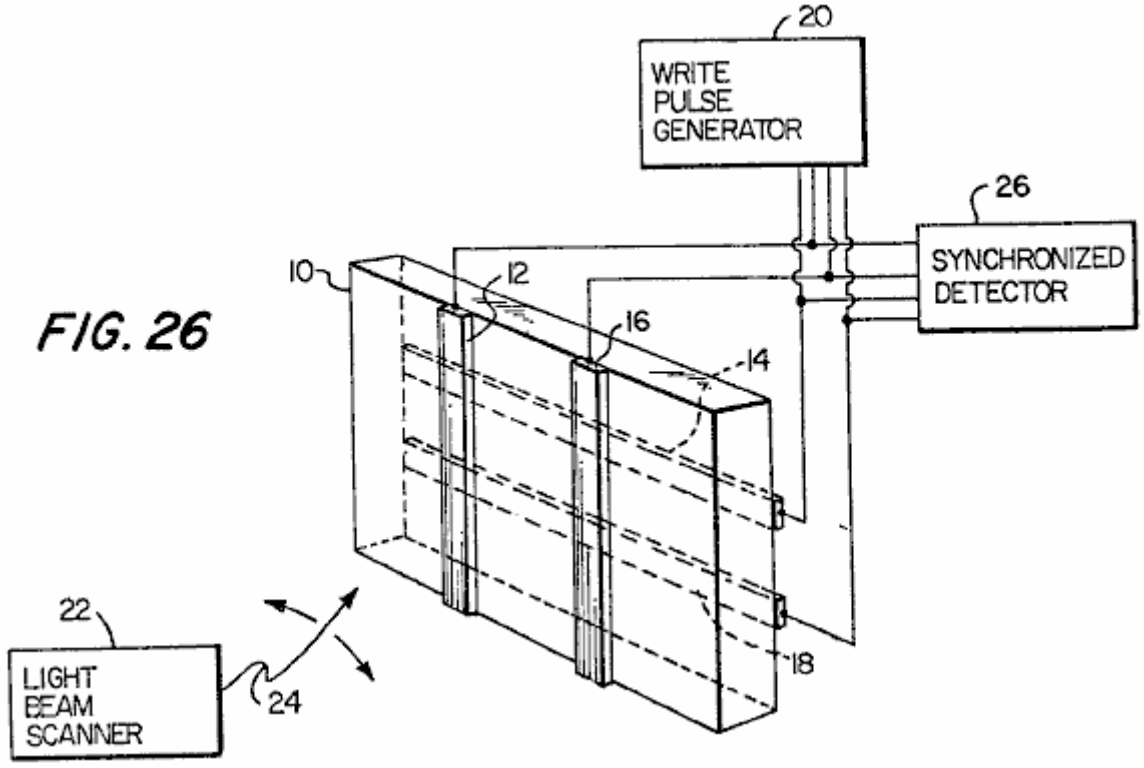

FIG. 26

Fig.27 is a schematic illustration of an optical display apparatus utilising a ferroeletric ceramic material in accordance with the general teachings of the instant invention;

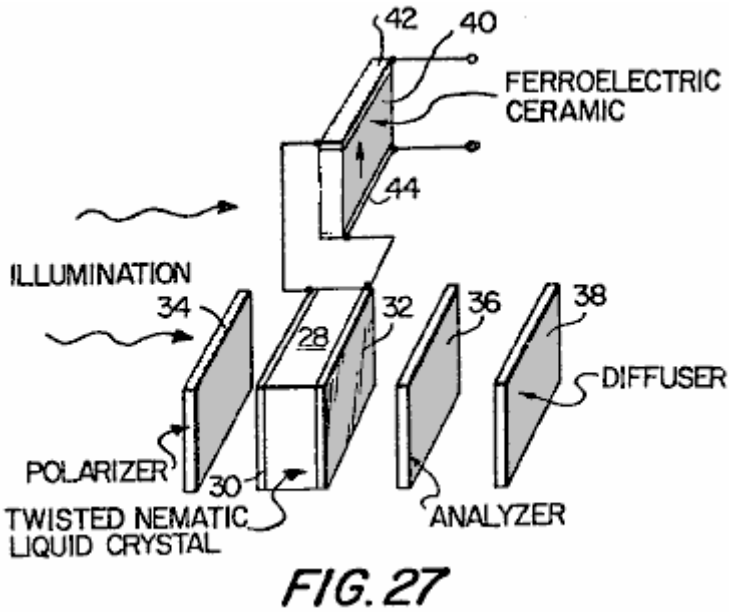

FIG. 27

Fig.28 is a schematic illustration depicting an optical display apparatus constructed in accordance with the teachings of the instant invention in monolithic form utilising a colour switching liquid crystal;

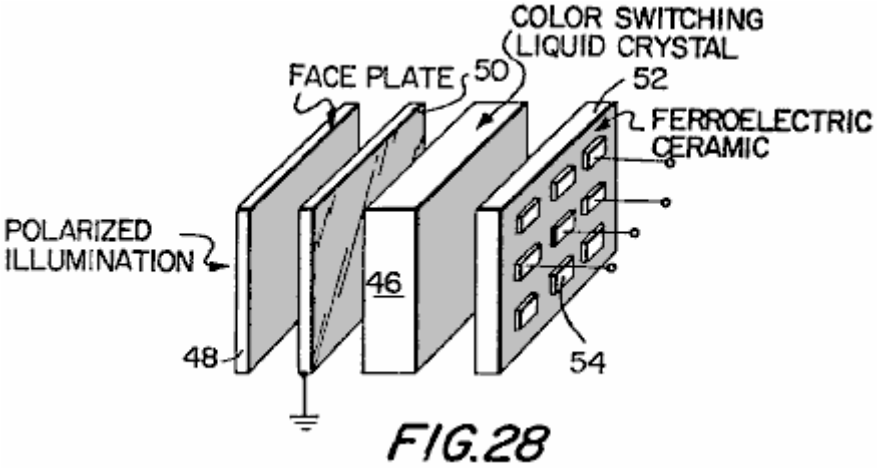

FIG.28

Fig.29 is a schematic illustration of the display apparatus of **Fig.28**, modified to make utilisation of a twisted nematic liquid crystal;

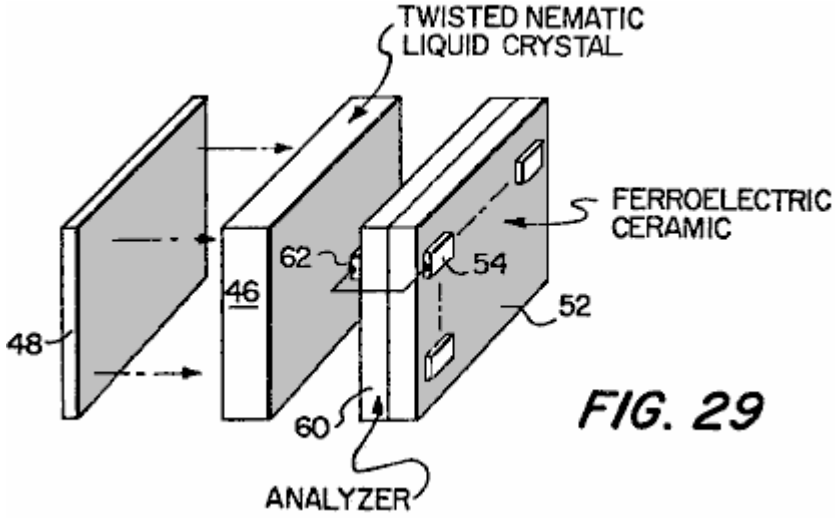

FIG. 29

Fig.30 is a cross-sectional elevational view depicting an optical display apparatus utilising a colour switching liquid crystal in conjunction with a ferroelectric ceramic substrate of the instant invention, and which display apparatus exhibits permanent memory capabilities;

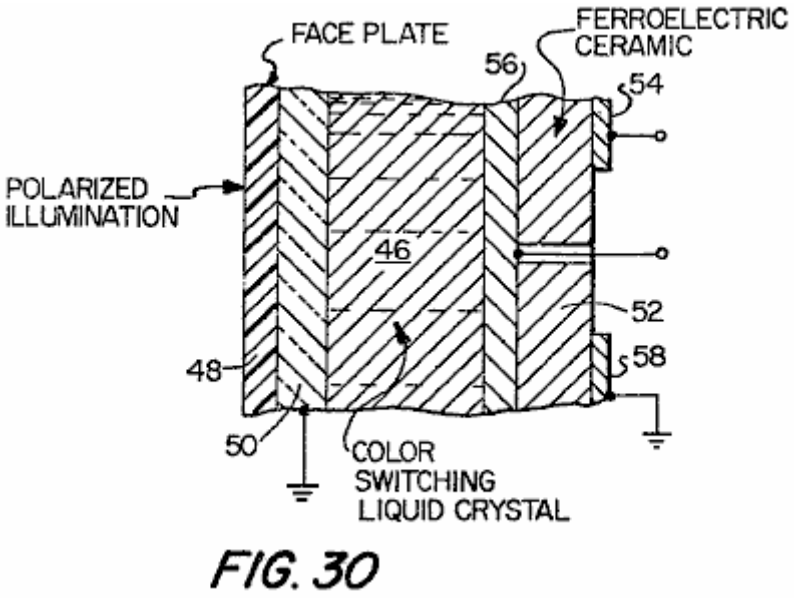

FIG. 30

Fig.31 is a cross-sectional elevational view of a further form of an optical display apparatus constructed in accordance with the teachings of the instant invention, said apparatus utilising a colour switching liquid crystal and further utilising length-wise polarisation of the ceramic substrate;

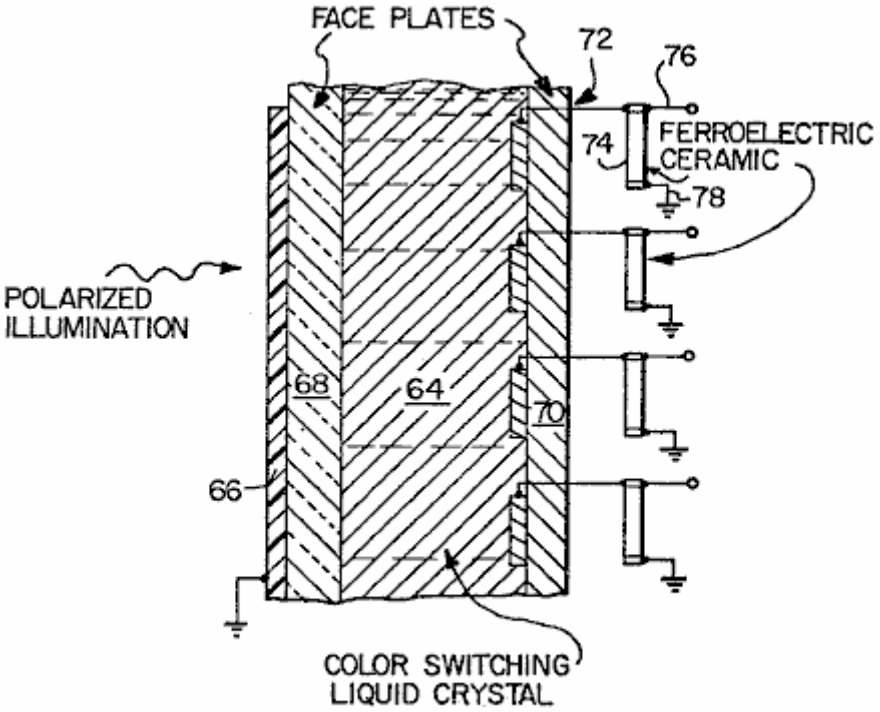

FIG. 31

Fig.32 is an elevational view, in section, of a further form of an optical display apparatus constructed in accordance with the teachings of the instant invention, this apparatus being similar to that depicted in **Fig.31** of the application drawings but utilising a liquid crystal of the twisted nematic type; and

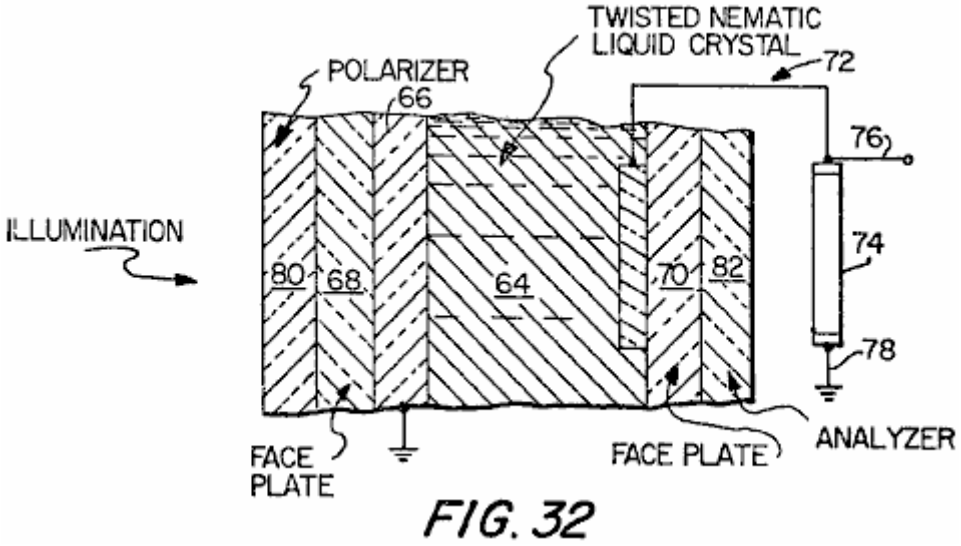

FIG. 32

Fig.33 is a schematic illustration of a further form of optical display and storage utilising the photoconductive as well as photovoltaic properties of the ferroelectric ceramics.

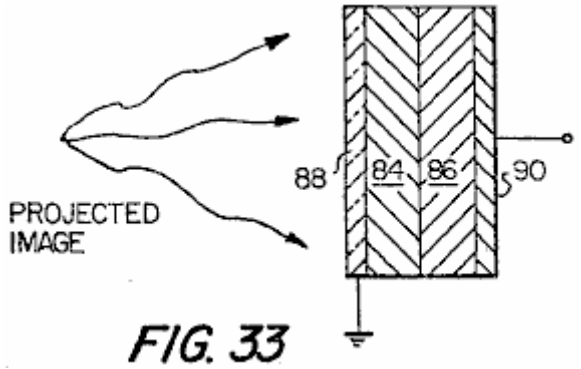

FIG. 33

Fig.34 illustrates how the image stored in a substrate is displayed.

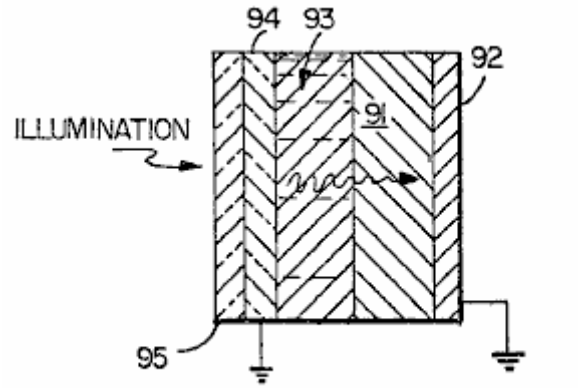

FIG. 34

DETAILED DESCRIPTION OF THE PREFERRED INVENTIVE EMBODIMENTS

With reference now initially to **Fig.1** of the application drawings, a discussion of the novel phenomena of the instant invention will ensue. Upon the application of incident illumination to the ferroelectric ceramic, a steady voltage is produced which is proportional to the length **l** between the electrodes. By dividing the sample into two equal segments along a line perpendicular to the direction of the remanent polarisation and by placing new electrodes on the cut edges, new samples would result each producing photo-emf's which is one half the original photo-emf.

An arrangement such as that shown in **Fig.1** can be described roughly by the equivalent circuit as shown in **Fig.2**. This has a saturation photo-emf **Vo**, in series with the photo resistance of the illuminated sample. **Fig.3** is a current-voltage characteristic of a typical illuminated ferroelectric slab, and has the form expected from the equivalent circuit in **Fig.2** except for the slight tendency towards saturation in the lower left quadrant. As a function of intensity, the photo-emf saturates at relatively low levels of illumination. The short circuit photo-current is, however, linear with light intensity. Results for the material $Pb(Zr_{0.53}Ti_{0.47})0_3$ with 1% by weight of Nb_20_5 are shown in **Fig.4**. The implication of these results and the equivalent circuit in **Fig.2** is that the photo-resistance R_{ph} is inversely proportional to intensity.

A saturation photo-emf and a short circuit current proportional to intensity has been measured in several poled ferroelectric materials. These are shown in Table I:

Table I

Photovoltaic outputs at room temperature for several ceramic compositions. The wafers were fully poled, to their maximum remanent polarization. Filtered illumination had a half bandwidth of about 10 nm. The photo-emf is a saturation value reached at relatively low value of intensity.

Sample	Illumination Wave length (nm)	Saturation Photo-emf (Volts/cm)	Short Circuit Photocurrent ($\frac{\mu Amperes/cm}{watts/cm^2}$)
$Pb(Zr_{.53}Ti_{.47})O_3$ +1 wt% Nb_2O_5	373	610	.31
$BaTiO_3$ + 5 wt% $CaTiO_3$	403	360	.020
$Pb(Zr_{.65}Ti_{.35})O_3$ with 7% lanthanum-lead substitution	382	1500	.030
$Pb(Zr_{.65}Ti_{.35})O_3$ with 8% lanthanum-lead substitution	382	750	.015
$BaTiO_3$ + 5wt% $CaTiO_3$	403	355	.02
$Pb(Zr_{.53}Ti_{.47})O_3$ + 1wt% Nb_2O_3 with polished surfaces	382	610	~.61

For a given composition the photo-emf is also a function of grain size. These results are shown in Table II.

Table II

Photo-emf for different grain size and percent lanthanum substituted for lead. The materials are $Pb(Zr_{.65}Ti_{.35})O_3$ with 7% lanthanum substitution for lead and the same material with an 8% lanthanum substitution for lead.

Grain Size (microns)	Percent Lanthanum-Lead Substitution (percent)	Saturation Photo-emf (Volts/cm)
2-4	7	1500
4-6	7	980
greater than 6	7	560
2-4	8	750
3-5	8	510
4-6	8	330
greater than 6	8	250

the photo-voltage v. number of grains per unit length is plotted in **Fig.5** for two different compositions. The plot clearly shows a relationship between the two quantities.

The fact that the photo-emf of a particular sample depends on the remanent polarisation is shown by the results for a typical ferroelectric material, barium titanate + 5% by weight of $CaTi0_3$,as plotted in **Fig.6**.

The short circuit photo-current depends strongly on the wave length of the impinging illumination. It is a maximum at a wavelength resulting in a photon energy equal to the band gap energy of the material. Other wavelengths can, however, contribute strongly to the current.

Results for typical materials are shown in **Fig.7**, **Fig.8**, and **Fig.9**. The current (ordinate) is that produced by illumination contained in a small band, of about +10 nm about a wavelength indicated on the abscissa. A mercury source and notch type dichroic filters were used. The total intensity within each band was only roughly constant.

The current that has been plotted has been therefore normalised to constant intensity by assuming the linear relation between the two.

The photo-emf is less strongly dependent on wave length. Results for a particular material, using notch dichroic filters is shown in **Fig.10**. These values are saturation values, roughly independent of intensity.

An important additional phenomena shows a dependence of current produced in the red and infrared regions in the presence of simultaneous blue band gap radiation. These results are shown in **Fig.11** and **Fig.12**. The ordinate (**Fig.11**) is the current produced by the light from a mercury arc shining through dichroic long wavelength cut off filters, the abscissa the wavelengths above which no light illuminates the sample. Note the step at 650 nm. Using short wavelength cut off filters which eliminate the band gap light results in no current until the cut off wavelength is below the band gap. These results are shown in **Fig.12**. The amount of output in the red actually depends on the intensity of simultaneous band gap radiation, thus the energy efficiency of these materials for a broad band source is not simply the intensity weighted average of the efficiencies for individual wavelengths as produced by notch filter. The actual value is larger.

Photo-emf vs. cut-off wavelength for $Pb(Zn_{0.53}Ti_{0.47})0_3$ +1% by weight of Nb_20_3 is shown in **Fig.13**. A substantial photo-emf appears at long wavelengths but no current can flow. In other words, the internal resistance R_{ph} is extremely high unless band gap is incident.

Single Crystal Results

The ceramic results imply a small photo-emf from a single crystal illuminated as shown in **Fig.14**. Such emf = 0.55V at room temperature was indeed observed.

The short circuit current is, as for the ceramic material, a strong function of wavelength. These results are shown in **Fig.15**.

Temperature Dependence

Ceramic photo-emf is a function of temperature. Results for barium titanate ceramic with 5% by weight of $CaTi0_3$ are shown in **Fig.16**. For both $Pb(Zn_{0.53}Ti_{0.47})0_3$ with 1% by weight of Nb_20_5 added and barium titanate the photo-emf decreases with increasing temperature. In these measurements, the temperature ranged to the transition temperature, the photo-emf vanishing at the temperature at which the remanent polarisation also vanishes. The remanent polarisation vs. temperature for this material is also shown in **Fig.16**. Similar results for single crystal barium titanate are shown in **Fig.17**. The single crystal photo-emf are, of course, much smaller. Short circuit was measured as a function of temperature. Results for barium titanate +5% by weight of $CaTi0_3$ are shown in **Fig.18**. Similar results over the same temperature range were obtained for $Pb(Zn_{0.53}Ti_{0.47})0_3$ + 1% by weight of Nb_20_5 material. In that case there was no maximum, the photo-current still increasing with increasing temperature at 130^0 C.

Effects of Optical Properties

In the arrangement shown in **Fig.1**, the direction of polarisation, and consequently the direction of the photo-emf is perpendicular to the direction of incidence of the light which is also the direction in which the light is strongly absorbed. The light only enters into a region near the surface of the material. The rapidity of the absorption depends strongly on the wavelength of the light, the light becoming fully absorbed in a region closer and closer to the surface as one decreases the wavelength of the light and approaches the band gap wavelength. For shorter wavelengths, the light no longer enters the material and thus for these wave lengths the light-induced effects decrease rapidly with decreasing wavelength.

Ceramic materials which exhibit these photo-emf's can appear transparent, translucent, and apparently opaque when viewed with white light. Light, however, obviously enters even the opaque materials to produce the photo-emf's. The apparent opacity is produced by diffuse reflection at granular boundaries. It is of course desirable to minimise the degree to which diffuse reflectivity prevents light from entering the material. Nevertheless, the largest photo-currents and greatest photovoltaic efficiency has been originally observed in a material which appears opaque in thickness more than a few thousandths of an inch. The cross sectional drawing **Fig.19** depicts the way light enters the material with the arrangement as originally shown in **Fig.1**.

When a circuit connects the electrodes, the maximum density of current occurs near the surface, the current density decreasing in regions deeper within the thickness.

Polishing the surfaces of these materials, however, increases the transparency and, as expected, the magnitude of the photo-current and the photovoltaic conversion efficiency. An emf will also be produced by the arrangement shown in **Fig.20** provided, of course, that the electrodes are of a nature to allow light to enter the material. Normal thick metal electrodes are opaque to light. When metal electrodes are thin enough, they permit light to be transmitted and yet are sufficiently conductive to function as electrodes. Other conducting transparent electrodes include indium oxide. The emf now will be seen to appear across the thickness of the material, in the direction of the remanent polarisation.

In this arrangement the high dark resistance of any un-illuminated bulk portion of the material is in series with the circuit connecting the electrodes. The current that can be drawn is limited. Maximum currents can be drawn when the thickness between the electrodes is equal to or less than the absorption depth of the radiation. However, since the saturation photo-emf is not a strong function of intensity, vanishing only for extremely low intensities, the full photo-emf per unit length v_o can usually be observed for this samples.

Proposed Mechanism for the High Voltage Photovoltaic Effect in Ferroelectrics

Briefly, it is proposed that the photo-emf results from the action of an internal field within the bulk of an individual ceramic grain on non-equilibrium carriers generated by illumination. These carriers move to screen the internal field. The photo-emf that appears is the open circuit result of such screening. A change in charge distribution upon illumination changes the voltage across a grain from an initial value of zero to the photo-voltages which are observed.

These photo-emf's appears across individual ceramic grains. What is observed as a length dependent high photo-voltage is the series sum of the photo-emf's appearing across grains, each of which is characterised by saturation remanent polarisation P_o. The situation is shown schematically in **Fig.21**. Individual grains typically are small, of the order of 10 microns in diameter. To produce a high photo-voltage per unit length in the ceramic the voltage across an individual grain need not be large. For example the results in **Table II** for $Pb(Zn_{0.65}Ti_{0.47})0_3$ with 7% Lator Pb can be explained by individual grain photo-voltage of only about 0.5 volts per grain. The clear implication of the experimental results (**Table II** and **Fig.5**) is that for the range of grain sizes investigated, the photo-emf across a grain is more or less independent of the size of the grain. This is supported also by the single crystal results.

Ferroelectric crystals are characterised by large spontaneous polarisation which would be expected to produce large emf's even in the dark. Such emf's are not observed even across highly insulating materials. This is presumed to be the result of space charge within the volume or on the surface of a ferroelectric crystal (which, in ceramics, are the individual grains or crystallites). The space charge produces a potential across a crystal cancelling the potential produced by the net polarisation within they crystal. It is obvious that as long as there are sufficient charges within the crystal which are free to move, any potential produced by an internal polarisation will eventually vanish.

This dark zero potential state is the initial state of a crystal crystallite, grain, and of the ceramic body composed of these grains. The absence of a net potential in the dark does not however mean the absence of internal fields. Internal fields can be expected to exist and are the consequence of the spatial distribution of the charges which bring the net potentials across grains to zero. These spatial distributions can not be arbitrarily assigned, but are subjected to constraints of a basic physical nature.

In the idealised two dimensional crystal shown in **Fig.22**, the surface charge density Upsilon = P_s reduces the potential between the surfaces to zero. If the surface charge density (in actuality this does not occur) is completely juxtaposed upon the bound polarisation surface charge, which has a value P_s, then there are no internal fields. Were there no charge, the crystal would show an internal field P_s/ϵ_b and a potential between the surfaces of $P_s l / \epsilon b$.

Such a field would be well above the dielectric breakdown strength of a real dielectric. For a single domain typical ferroelectric barium titanate $P_s = 26 \times 10^{-2}$ C/m, and the relative dielectric constant $Epsilon_r$ in the direction of polarisation is 137. The field that would have to exist in the absence of compensation charge is over 2×10^6 volts/cm which is well above the dielectric strengths typical of these materials. If such a field could momentarily exist within a ferroelectric crystal it would not exist for long but be reduced from its maximum value to some value below the dielectric strength of the material. The strong field would break down the material and a charge flow would produce a space charge distribution resulting in a new lower value for the internal fields within the crystal.

Such a space charge distribution must exist in an actual crystal. The space charge serves to reduce the potential across a crystal to zero. Such charges have limited mobility and the materials continue to behave as insulators for ordinary strength applied fields.

Such a space charge cannot occupy a delta function-like region as in the idealised situation shown in **Fig.22**, but must occupy instead a finite volume. If these are localised near the surface of the crystal, then an internal field $Epsilon_b$ exists within the bulk of the material and additional fields E_s exist within the space charge regions near the surface.

It is hypothesised that these space charge regions are near the surface of real crystals with the charge distributed within a surface layer thickness **s**. The reasons for same are as follows:

(1) The surface regions of ferroelectric crystals are characterised by regions whose dielectric, ferroelectric, and thermodynamic properties differ markedly from that of the bulk. These differences are best explained by the existence of strong fields in this region that would be produced by space charge. There is a considerable body of information in the literature supporting the existence and delineating the properties of these layers;

(2) The interplay of space charge and the very non-linear dielectric constant of ferroelectric would be expected to localise space charge in a low dielectric constant layer near the surface. In ferroelectrics, unusually high, low field relative dielectric constants (of the order of 1000) can be expected to reduce in value with increasing field strength. Thus charge in a region reduces the dielectric constant of that region increasing the field strength of that region. This feedback mechanism can be shown to localise charge within a layer.

The experimental results supporting the existence of surface layers will not be reviewed here, nor the calculations which support the localisation of charge into layers as a result of a non-linear (saturable) dielectric constant. These may be reviewed by referring to the literature.

A schematic description of a typical grain, i.e. crystallite, with space charge regions of thickness **s**, and a bulk region of thickness **l**, is shown in **Fig.23**. The internal fields (in the two dimensional model) of such a charge distribution superimposed on that produced by the bound polarisation charge will be calculated and also the effect of these fields on carriers within the bulk produced as the result of an internal photo effect (photo-ionisation). Formulae for the photo emf that will be derived will have the correct sign, a linear dependence on remanent polarisation, and the kind of temperature dependence that has actually been observed. In addition there will result an estimate of a size independent grain photo-emf for a typical ferroelectric, barium titanate, which is consistent with that implied from the observed ceramic emf, and single grain emf. The grain has as shown in **Fig.23**:

(1) A bulk region with dielectric constant $Epsilon_b$ and uniform polarisation (at zero applied field) P_o ;

(2) Surface layers of dielectric constant $Epsilon_s$, considerably less than that of the bulk. There are also polarisation in the surface regions P_s (x) which exist at zero applied field. These will generally be parallel to the bulk polarisation at one end and anti-parallel at the other end;

(3) Space charges in these surface layers which serves to remove any potential across the grain. It is the space charge layers which produce high fields which reduce the highly non-linear dielectric constant of the bulk to the lesser value in the surface layers, and also produce the remanent polarisation, P_s (x) with the surfaces.

Such a structure also has an internal bulk field, and surface fields which can be calculated. For the purposes of this calculation we assume a simple two dimensional model shown in **Fig.24**.

The polarisation with the various regions are assumed only for simplicity to be uniform within these regions. Again, only for simplicity those in the surface layers and the bulk are assumed equal in magnitude (i.e. P_s (x) = P_o). The space charge densities .+-.n_oe are also assumed uniform and equal in magnitude. The polarisations are equivalent to four bound surface charge densities,

$$\sigma_1 = \vec{P}_o \quad \sigma_2 = -2\vec{P}_o$$

$$\sigma_3 = o \quad \sigma_4 - \vec{P}_o$$

There are, using Gauss's law, electric fields as shown in **Fig.24**.

$$E_1 = \frac{1}{\epsilon_s}[P_o + m_o ex]$$

$$E_2 = \frac{1}{\epsilon_b}[-P_o + m_o es]$$

$$E_3 = \frac{1}{\epsilon_s}[-P_o + n_o e(s-x)]$$

It has been assumed that the voltage across the crystal vanishes,

$$\int_0^{l+2s} E(x)dx = O$$

n_o and s, from this and the three preceding equations, must be related by the expression

$$m_o es = \frac{P_o}{1 + \frac{\epsilon_b}{\epsilon_s}\frac{s}{l}}$$

and the bulk field

$$E_2 = \frac{-P_o}{\epsilon_b}\left[\frac{\frac{s}{e}\frac{\epsilon_b}{\epsilon_s}}{1 + \frac{s}{l}\frac{\epsilon_b}{\epsilon_s}}\right]$$

Surface layers in barium titanate ceramic grains have been estimated at 10^{-6} cm (see for example Jona and Shirane Ferroelectric Crystals, Pergammon Press, 1962). The remanent polarisation typical of the ceramic material is about 8 x 10^{-2} C/m^2, the relative dielectric constant of the poled ceramic about 1300. The high field dielectric constant will be estimated at roughly 0.5 the bulk dielectric constant. These numbers yield a bulk field, for a typical 10^{-3} cm grain of,

E_2 = 350 volts/cm

The potential across the bulk would thus be approximately -0.35 volts. The remaining potential across the grain would be that across the surface layers. Illumination has the effect of producing charges which screen the internal field, E_2 causing it to vanish.

The negative voltage vanishes and a positive potential appears across the sample. The light makes the sample look more positive. This is exactly what happens as the result of a thermally-induced decrease in polarisation. Thus the pyro-electric voltage is in the same direction as the photo-voltage as is experimentally observed.

In the fully screened case, the photo-emf is also the emf across the two surface layers

$$\Delta V = \left[\frac{P_o}{\epsilon_s}\frac{1}{1 + \frac{\epsilon_b}{\epsilon_s}\frac{s}{l}}\right] S \simeq .35 \text{ volts}$$

The light generated free electrons sets up a counter field which tends to cancel the bulk field E_2 ; thus, the observed voltage drop is less than it would be in a perfectly insulating medium. This is what is meant by the term ‘screening’. The counter field approaches -E_2. Assuming the shielding occurs only in the bulk, the total voltage across the grain is now the sum of the voltages across the surface layers.

The photo-emf is in the opposite direction to the bulk polarisation. This fact predicted in the theory is what is always observed experimentally. The complete screening of the bulk field thus would, in barium titanate, be expected to result in a photo-emf of +0.35 volts per grain or 350 V/cm and about 0.35 volts across a macroscopic single crystal. These are roughly the values actually observed as seen in **Table I**, and with the single crystal results. The linear relation between remanent polarisation and saturation photo-emf as shown in **Fig.6** is also predicted by these equations. The dependence on temperature of the photo-emf as shown in **Fig.16** and **Fig.17** is predicted by the fact that as one approaches the curie temperature, not only is P_o decreasing but the dielectric .epsilon..sub.s is increasing. The bulk internal field, E_2, should therefore decrease with temperature more rapidly than the remanent polarisation.

Screening

Solving the general problem of screening in a ferroelectric is difficult. Many of the principles involved can be demonstrated by solving a special case. The special case is meant to be particularly applicable to the $Pb(Zr_{0.53}, Ti_{0.47})0_3$ + 1% by weight of Nb_2O_5 material.

Utilised, only for simplicity, is a two dimensional model, with photo-produced carriers limited to those of a single sign. It will be assumed that these are electrons generated from deep trapping levels midway in the band gap, and that the illumination empties all the traps leaving fixed positive charges to replace the original traps. The complete emptying of a deep trapping level would produce the long wave length photo-voltages and the phenomena of an intensity saturation of the photo-emf typical of the $Pb(Zr_{0.53}, Ti_{0.47})O_3$ + 1% by weight of Nb_2O_5.

Consider a two dimensional illuminated slab of length **l** within which is an internal field **Epsilon** and within which, light generates a uniform density of electrons $\mathbf{n_o}$ (n electrons per unit length). Schematically the situation is shown in **Fig.25**, where **Phi.(x)** is the potential at a point **x**.

The carriers respond to the internal field and occupy a Boltzman distribution

$$M = M_o e^{\vartheta / KT}$$

if the fields due to the electrons could be neglected, then

$$\vartheta(e) = -\mathbf{Ex}$$

This is, of course, too rough an approximation. With n(O) the density of electrons at x=0, and n_o, the density of the immobile donor ions $m(x) = m(0)e^{\vartheta(x)/kt}$ with Phi(x) is given by Poisson's equation,

$$\frac{d^2\vartheta}{dx^2} = \frac{e}{\epsilon}[m(x) - m(0)] = \frac{e}{\epsilon}[m(0)e^{e\vartheta(x)/kT} - mo]$$

Since for Phi = 0 n(0) $=n_o$, and since all traps are emptied, assuming electrical neutrality,

$$\int_0^l mo \int_0^l e^{e\vartheta/kT} dx = m_o l$$

or

$$m_o \int_0^l e^{e\vartheta/kT} dx = m_o l$$

then

$$\int_0^l \frac{d^2\vartheta}{dx^2} dx = \int_0^l \frac{e}{\epsilon}[m(x) - m_o]\, dx = 0$$

or

$$\left.\frac{d\vartheta}{dx}\right|_{x=l} = \left.\frac{d\vartheta}{dx}\right|_{x=o}$$

If the crystal is neutral there must be no electric field at the boundary except the applied field $-E_o$

$$\left.\frac{d\vartheta}{dx}\right|_{x=o} = E_o$$

$$\left.\frac{d\vartheta}{dx}\right|_{x=l} = E_o$$

These two boundary conditions allow the solution of Poisson's equation.

$$\frac{d^2\phi}{dx^2} = \frac{m_e e}{\epsilon}\left[\frac{m(o)}{m_o}\, e^{e\phi/kT} - 1\right]$$

or

$$\frac{d^2\phi}{dx^2}\left[\frac{e\phi}{kT}\right] = \frac{M_e e^2}{\epsilon kT}\left[\frac{M(o)}{M_o}\, e^{e\phi/kT} - 1\right]$$

substituting

$$yo = \ln\frac{M_o}{m(o)} \quad y = \frac{e\phi(x)}{kT}, \quad l_D^2 = \frac{\epsilon kT}{m_e e^2}$$

we obtain,

$$\frac{d^2y}{dx^2} = \frac{1}{l_D^2}\left[e^{y-yo} - 1\right]$$

in this new notation,

$$\left.\frac{dy}{dx}\right|_{x=o} = \left.\frac{dy}{dx}\right|_{x=l} = \frac{eE_o}{kT}$$

let

$$\frac{dy}{dx} = P$$

$$\frac{d^2y}{dx^2} = \frac{dP}{dx} = \frac{dy}{dx}\,\frac{dP}{dy} = P\frac{dP}{dy} = \frac{d}{dy}\left(\frac{1}{2}P^2\right)$$

so

$$\frac{d}{dy}\left(\frac{1}{2}P^2\right) = \frac{1}{l_D^2}\, e^{y-yo} - 1$$

setting $y(o)=0$ since the zero for a potential may be set arbitrarily

$$\frac{1}{2}P^2(l) - \frac{1}{2}P^2(o) = \frac{1}{l_D^2}\int_o^l (e^{y-yo} - 1)\, dy$$

$$= \frac{1}{l_D^2}\left[e^{y(l)-y} - y(l) - e^{-yo}\right]$$

$$y(\infty) = \frac{e\phi(x)}{kT}$$

$$y(l) = \frac{e\Delta v}{kT}$$

$$\left.\frac{dy}{dx}\right|_o = \left.\frac{dy}{dx}\right|_l = P(o) = P(l)$$

so

$$O = \frac{1}{l_D^2} \quad e^{-\mu}[(e^{\Delta} - 1) - \Delta]$$

$$\text{where } \Delta = \frac{e}{kT} \Delta v \quad \text{or} \quad e^{\mu v} = \frac{e^{\Delta} - 1}{\Delta},$$

$$\text{and thus } \frac{Mo}{M(O)} = \frac{e^{\Delta} - 1}{\Delta} = \frac{e^{\frac{e}{kT} \Delta v} - 1}{\frac{e}{kT} \Delta v}$$

substituting

$$\frac{d}{dy} \left(\tfrac{1}{2} p^2\right) = \frac{1}{l_D^2} \left[\frac{\Delta}{e^{\Delta} - 1} e^{y} - 1 \right]$$

so

$$\tfrac{1}{2} p^2(x) - \tfrac{1}{2} p^2(o) = \frac{1}{l_D^2} \left[\frac{\Delta}{e^{\Delta} - 1} (e^{y} - 1) - y \right]$$

$$= \frac{1}{l_D^2} \left[\Delta \frac{e^{y} - 1}{e^{\Delta} - 1} - y \right]$$

Thus

$$\left(\frac{dy}{dx} \right)^2 = \left(\frac{eF_o}{kT} \right)^2 + \frac{2}{l_D^2} \left\{ \Delta \left(\frac{e^{y} - 1}{e^{\Delta} - 1} \right) - y \right\}$$

or

$$\frac{dy}{dx} = \frac{\sqrt{2}}{l_D}\sqrt{\Gamma^2 + \Delta\left(\frac{e^y - 1}{e^\Delta - 1}\right) - y}$$

where

$$\Gamma^2 = \frac{1}{2}\frac{e}{kT}E_o l_p$$

integrating this equation from O to l yield

$$\int_o^{y(l)} \frac{dy}{\sqrt{\Gamma^2 + \Delta\left(\frac{e^y - 1}{e^\Delta - 1}\right) - y}} = \frac{\sqrt{2}}{l_D}\int_o^l dx$$

or,

$$\int_o^\Delta \frac{dy}{\sqrt{\Gamma^2 + \Delta\left(\frac{e^y - 1}{e^\Delta - 1}\right) - y}} = \frac{\sqrt{2}l}{l_D}$$

which is an implicit expression for ΔV in terms of E_o, l, and l_D.

For low n_o and/or large E_o, Γ is large

$$\int_o^\Delta \frac{dy}{\sqrt{\Gamma^2}} = \frac{\sqrt{2}\,l}{l_D}$$

$$\Delta = \sqrt{2}\,l\,\Gamma/l_D$$

or

$$\Delta = \sqrt{2}\,l \times \frac{1}{\sqrt{2}}\left[\frac{e}{KT}E_o l_D\right] l_D$$

$$= \frac{e}{KT}E_o l$$

or

$$\Delta V = E_o l$$

which is the original potential across the bulk of the crystal.

The situation of interest is however large n_o and small l_D and small Γ^2.

It is in this situation that

$$\Delta = \frac{e}{KT}\,\Delta V$$

can be expected to vanish.

Expanding the expression for Δ small, which is always the case, then

$$\Delta\,\frac{e^y - 1}{e^\Delta - 1} - y \simeq \tfrac{1}{2}y^2 - \tfrac{1}{2}y\Delta$$

Keeping only second order terms in y and Δ, then

$$\int_o^\Delta \frac{dy}{\Gamma^2 + \frac{1}{2}(y^2 - y\Delta)} = \frac{l\sqrt{2}}{l_D}$$

Let

$$\xi = y - \frac{\Delta}{2},$$

this becomes

$$\int_{-o/2}^{\Delta/2} \frac{d\xi}{\sqrt{(\Gamma^2 - \frac{1}{8}\Delta^2) + \frac{1}{2}\xi}} = \frac{l\sqrt{2}}{l_D},$$

Setting

$$\xi = \sqrt{2\Gamma^2 - \left(\frac{\Delta}{2}\right)^2}\ ,\ \sin h\ O$$

gives

$$2\sqrt{2}\,\sin h^{-1}\left[\frac{\Delta/2}{\sqrt{2\Gamma^2 - \left(\frac{\Delta}{2}\right)^2}}\right] = \frac{\sqrt{2}\,l}{l_D}$$

or

$$\Delta = 2\sqrt{2}\ \Gamma \tan h \frac{l}{2l_D}$$

or

$$\Delta V = E_o(2l_D) \tan h \frac{l}{2l_D},$$

clearly as

$$l_D \rightarrow O\ \Delta V \rightarrow O$$

This approximation for Δ V is good for all reasonable values of T.

Illumination thus reduces the dark bulk emf = $E_o l$, producing a net photovoltage

$$V_{PHOTO} = E_o l \left[1 - \frac{\tanh \frac{l}{2l_D}}{\frac{l}{2l_D}} \right]$$

where

$$l_D = \sqrt{\frac{EkT}{m_o e^2}}$$

A simplified expression occurs for small

$$\frac{l}{2l_D}$$

where, $\tanh x \simeq x - \frac{1}{3}x^3$

$$V_{PHOTO} = E_o l \left[\frac{1}{2} \left(\frac{l}{2l_D} \right)^2 \right]$$

Here, it is clear that the photovoltage becomes insignificant for

$$\frac{l}{l_D}$$

The implication is therefore that photovoltaic contributions from the bulk will be much larger than that from the surface layers, for surface layers are extremely small white $\mathbf{l_D}$ can be estimated as very roughly equal in the bulk and the surface.

Thus, illumination will result in the vanishing of the internal field within the bulk resulting in a maximum photo-emf. $\Delta V = 0\ E_2 l$ where E_2 is the bulk field.

For small intensities, we can assume n_o small, then

$$V_{PHOTO} = E_o l \frac{1}{4} \frac{n_o e^2}{ekT}$$

i.e., the photo-voltage is proportional to n_o which can be reasonably assumed proportional to intensity which is experimentally observed (see **Fig.4**).

The model just described explains the long wave length photo-emfs, in the material $Pb(_{0.53}Zr,_{0.47}Ti)0_3$ + 1% by weight of Nb_20_5. Such a deep trapping level is probably typical of the lead titanate-lead zirconate materials with characteristic lead vacancies. These bind electrons leaving holes (producing p type dark conductivity). The addition of common dopants -- for example niobium gives rise to free electrons which combine with holes or get trapped by the lead vacancies. The doping can thus be said to provide electrons which fill traps.

It is these trapped electrons which are photo-injected into the conduction band by the long wave length light providing near maximum photo-emfs in material illuminated at 500 nm and even longer wave lengths as shown in the results plotted in **Fig.13**. Full saturation, that is the complete shielding of the bulk internal field, requires however band gap carriers which occurs as one approaches the 373 nm band gap wave length. Solving this problem, that of band gap carriers in addition to electrons generated by deep traps, can be accomplished in a manner similar to that which was accomplished for the trapped electrons but is more complex for example because mobile holes are being produced in addition to electrons and one cannot necessarily fix the maximum number of carriers.

The photo-emfs are created by photo-induced carriers shielding the bulk field. Effectively, no photo-current can flow however unless band gap light is present as is clear from the results shown in **Fig.12** and **Fig.13**. Here it is clear the band gap light produces maximum photo-emf and maximum photo-currents, less than band gap light, maximum or almost maximum photo-emf but no photo-currents and that the output resistance under these circumstances appears extremely high. Addition of band gap light allows current to flow.

The tentative explanation is that the surface layers from high resistance barriers, the magnitude of which lowers with band gap light. The surface layers thus act as intrinsic photoconductors in series with an emf. This picture not only explains the rather unique dependence of photo-emf and short circuit photo-current on wave length as shown in **Fig.12** and **Fig.13** but also the equivalent circuit which is typical of all these materials as described in **Fig.2** and as indicated by the current-voltage results in **Fig.3**.

A possible explanation for the high resistance of the surface layers is that they include quantities of charged ions which have been localised there. These are immobile under normal applied voltages moving only under the action of high fields such as produced by the reversal of the remanent polarisation. Those ions not only will occupy trapping levels, eliminating the need for easily ionised trapped electrons and thus reducing the intrinsic conductivity but also form centres for coulomb scattering of conduction electrons which should contribute markedly to the resistivity.

Efficiency

Some insight into the possible maximum efficiency of the process can be obtained by considering carriers generated by band gap light. with potential energy

$$U = 2\int_o^L e\,\phi(x)\delta M_2 dx$$

with $\phi(x) < Ex$
so that a maximum value of energy

$$U = 2e\int_o^L E\delta m x dx$$

$$= e\delta m_o EL^2$$

The energy required to produce δm_o electron hole pairs

$$\epsilon = \delta M_o L\, E_g$$

where Eg is the band gap energy.
The power into the crystal is

$$P_m = LEg\frac{\delta M_o}{\delta t}$$

while the power out (the rate of increase in internal potential energy) is

$$P_{out} = eEL^2 \frac{\delta M_2}{\delta T}$$

The efficiency

$$= \frac{eEL}{Eg}$$

For $Pb(Zr_{.53}\ Ti_{.47})O_3 + 1$ wt% Nb_2O_5 added E is roughly 600 v/cm and the grain size roughly 5 microns. The emf across a grain is thus about .3 volts. The band gap is about 3 eV. Thus the efficiency is

$$\simeq \frac{.3}{3} \simeq 10\%,$$

Which compares with an observed band gap efficiency of about 0.06%. The calculation, of course, depends on idealising assumptions, some of which may be practically obtainable**.**

PHOTOVOLTAIC MEMORY DEVICE

With the above background and general teachings of the unique discovery of the invention now firmly in mind, numerous and important applications of the properties of the ferroelectric ceramics above-discussed are readily possible as will be evident to those skilled in this art. For example, the device of the instant invention will be shown to exhibit particular utility as a memory apparatus, thus making use of the property of the ferroelectric ceramic defined as remanent polarisation or "memory" as previously explained.

With particular reference now to **Fig.26** of the application drawings, one such photovoltaic memory apparatus is disclosed, the memory apparatus being optically addressed. In this respect, a substrate or sheet of a ferroelectric ceramic material of the type above-discussed is indicated by reference numeral 10 as being "sandwiched" between at least one pair of electrodes such as electrodes **12** and **14** positioned on opposing sides of the substrate.

In the preferred embodiment as shown, an array of electrode pairs, such as pairs **12-14** and **16-18** are disposed on opposing sides of the substrate **10** as to define a matrix configuration. Information is put into the memory and particularly into the region of the substrate **10** lying between electrode pairs by temporarily applying a voltage pulse of a predetermined polarity between the electrode pairs, such pulse being provided by the Write Pulse Generator **20** coupled to the various electrodes and of typical construction. Specifically, if a positive voltage pulse was provided by the Write Pulse Generator **20** between electrode pairs **12-14**, with electrode **12** being presumed to be the positive electrode in this example, a remanent ferroelectric polarisation will take place in the region of substrate **10** lying between the crossed electrode pair, this remanent polarisation being in a direction and of a polarity dependent upon the polarity of the write pulse.

Similarly, if a negative voltage pulse was applied between electrode 16 on the one hand, and electrode 18 on the other hand, with electrode **16** in this instance being presumed to have the negative polarity, a remanent polarisation within the ferroelectric ceramic **10** will take place in the region disposed between the intersecting or crossed electrodes **16** and **18**. In a similar fashion, predetermined remanent polarisation can be produced individually in all of the regions of the ferroelectric ceramic **10** that are disposed between crossed electrode pairs of the matrix array in direct dependence upon the polarity of the write pulse voltage applied, this remanent ferroelectric polarisation constituting stored information in that such polarisation within the ceramic will remain until removed by the application of a write voltage pulse of opposing polarity.

In accordance with the teachings of the instant invention, these stored "bits" of information in the form of remanent ferroelectric polarisation within the various regions of the substrate **10** can be extracted or "read" by selectively illuminating the poled regions of the substrate with a beam of light, as preferably can be provided by a laser, for example. Upon illumination, the polarised regions of the ferroelectric ceramic will produce a photovoltaic current and voltage at an associated electrode pair, with the polarity of the photo-current and photo-voltage being

dependent upon the "stored" remanent ferroelectric polarisation or "information" within the particular region of the substrate.

In the preferred embodiment of the device wherein a so-called matrix configuration of the electrode pairs are provided, the entire ferroelectric ceramic substrate can be scanned by the illuminating beam which is contemplated to be continuously swept in the fashion of a "light pencil" by a light beam scanner of conventional construction as is designated by reference numeral **22**, for example, light beam scanner **22** providing the sweeping illuminating beam designated by reference numeral **24**. Further, and in this particular embodiment, the illumination from the light beam **24** would be transmitted into the associated poled regions of the ferroelectric ceramic **10** by passing through electrodes **12**, **16** etc. disposed on the surface of the ceramic facing the illuminating beam, electrodes **12**, **16**, etc. being constructed so as to be transparent.

The generated photovoltaic currents and voltages at the electrode array would be detected by a synchronised detector designated by reference numeral **26** coupled to each of the electrode pairs, detector **26** being of conventional construction and serving to monitor the polarity of the photovoltaic currents and voltages developed in time synchronism with the light beam scanner **22**. Such synchronism can be effected through a direct coupling of the detector **26** to the light beam scanner **22** in typical fashion, or through the utilisation of an external computer clock, all in accordance with standardised matrix memory addressing techniques.

Optical Display Apparatus

The discovered properties of the ferroelectric ceramic substrate of the instant invention can further be applied in conjunction with liquid crystals to fabricate a novel display apparatus and, in this respect, attention is generally directed to **Fig.27** to **Fig.32** of the appended application drawings.

The operational principle associated with the fabrication of such optical displays relies upon the utilisation of the photovoltaic currents and voltages generated by substrates of a ferroelectric ceramic material to effect switching of the opacity state of a liquid crystal operating in the field - effect mode. This generalised combination will be seen to provide a write-in read-out memory and optical display. Both the liquid crystal and the ferroelectric ceramic effectively function as a memory, either in a binary or bi-stable mode having two possible states designated as an "on" state or an "off" state wherein the liquid crystal is switched from a substantially transparent condition to a substantially opaque condition, or in a multi-state mode by which the transmission characteristics of the liquid crystal are varied through many states to effect a so-called gray scale display.

With particular reference to **Fig.27** of the application drawings, a typical optical display device following the general teachings of the instant invention is shown, such display device providing so-called dark spot display capabilities. As depicted in **Fig.27**, a twisted nematic liquid crystal is designated by reference numeral **28**, such crystal being sandwiched between two transparent electrodes **30** and **32**.

As is known, the twisted nematic liquid crystal **28** will vary its transmission characteristic to incident light dependent upon the polarity and magnitude of a voltage applied across electrodes **30** and **32**. Specifically, the twisted nematic liquid crystal **28** serves to transmit illumination through it as long as there is no voltage across electrodes **30** and **32**. In conjunction with the twisted nematic liquid crystal **28**, a linear polariser **34** is provided, as is an analyser **36** of conventional construction. The linear polariser **34** and the analyser **36** are crossed so that no light passes through the combination to a diffuse reflector **38** except for the fact that the twisted nematic liquid crystal cell interposed between them rotates the polarisation of the incident illumination by 90^0 so as to allow passage of light. Application of a voltage across the cell electrodes **30** and **32** destroys the ability of the liquid crystal cell **28** to rotate the plane of the polarisation of the illumination and the illumination is consequently absorbed in the analyser **36** rather than transmitted and reflected off the diffuse reflector **38**.

Accordingly, when voltage is applied across electrodes **30** and **32**, a dark colour of the liquid cell would be displayed in so-called dark spot display. The magnitude of the display is dependent upon the magnitude of the applied voltage, such that a voltage applied across cell electrode **30** and **32** less than a characteristic amount necessary to effect full plane rotation will only partially reduce the rotating ability of the liquid crystal **28** thereby resulting in only a partial extinction of illumination and the generation of a gray-scale display. The above discussion of the operation of a so-called twisted nematic liquid crystal is entirely conventional.

To obtain the switching voltage for application to the cell electrodes **30** and **32**, a substrate of a ferroelectric ceramic designated by reference numeral **40** it utilised, the substrate **40** being sandwiched between electrodes **42** and **44** as shown, ceramic substrate **40** being disposed such that the illustrated illumination impinges not only on the liquid crystal **28**, but also on the ceramic substrate. As illustrated, electrodes **42** and **44** of the ceramic substrate **40** are respectively coupled to the transparent electrodes **30** and **32** of the twisted nematic liquid crystal cell **28**.

Initially, a polarisation voltage is applied to the ferroelectric ceramic substrate **40** across the associated electrodes **42** and **44**, such voltage being in the form of a pulse and serving to produce a remanent polarisation in the direction of the arrow shown within the substrate. Subsequently, and in accordance with the teachings of the invention, when the substrate **40** is illuminated, a current will flow in a circuit connecting terminal **42** to terminal **30** of the liquid crystal cell **28**, through the cell **28** to electrodes **32**, and then to terminals **44** of the ceramic substrate **40**, this current being a photovoltaic current proportional to the magnitude of the remanent polarisation effected within the ferroelectric ceramic by the initial application of the polarisation voltage pulse.

The magnitude of the photovoltaic current can be varied in accordance with the generalised teachings of the instant invention discussed at the outset by simply varying the magnitude of the initial polarising pulse. The so-called gray-scale display capability of the light transmission characteristics of the liquid crystal **28** is provided simply through a pre-selection of the magnitude of the remanent polarisation produced and, of course, assuming a constant intensity illumination. The memory characteristics of the ferroelectric ceramic **40** are inherently brought about in that the value of the photovoltaic current can be changed only through the application of another polarising pulse. Thus, the generalised apparatus of **Fig.27** functionally constitutes an apparatus which effects an optical display of the state of the memory within ferroelectric ceramic substrate **40**.

In the embodiment as described in **Fig.27**, a so-called "dark spot display" was effected. In the event that a so-called "bright spot" is desired to appear during the "on" state of the liquid crystal in transmission or reflection, polariser **34** and analyser **36** would be disposed in a parallel relationship with respect to one another, rather than crossed. Further, and although the basic embodiment above-discussed refers to the utilisation of liquid crystals of the twisted nematic type, similar results can be obtained with so-called colour switching crystals which, in like fashion, alter their light transmission characteristics to incident polarised light in response to the application of a voltage across them.

In accordance with the generalised teachings of **Fig.27**, various other forms of optical displays can be constructed. For example, and with particular reference to **Fig.28** of the application drawings, a different form of combined memory and optical display apparatus is illustrated, this apparatus making use of a colour switching liquid crystal 46 instead of the twisted nematic liquid crystal **28** of **Fig.27**. As was explained above, the colour switching liquid crystal such as crystal **46** serves to alter its light transmission characteristics to incident polarised light, and it is for this reason that the light source illustrated in **Fig.28** is defined as being polarised illumination, although it is to be understood that in this embodiment, as well as in the following embodiments to be discussed which use colour switching liquid crystals, a non-polarised light source can be provided if a linear polariser is disposed within the apparatus on the side of the liquid crystal nearest the incoming illumination.

The display apparatus of **Fig.28** defines a so-called monolithic structure as opposed to the exemplary structure of **Fig.27** wherein the liquid crystal was physically spaced from the energising ferroelectric ceramic. In **Fig.28**, a "sandwich" construction is provided comprising a face plate **48**, a transparent electrode **50** coupled to ground, the colour switching liquid crystal **46**, a slab or substrate of a ferroelectric ceramic **52**, and a plurality of electrodes such as electrodes **54** coupled to the ferroelectric ceramic **52** in an array.

When a short voltage pulse is initially applied between the ground electrode **50** and one of the polarity of rear electrodes **54**, the region of the liquid crystal **46** immediately in front of the rear electrode **54** will become transparent resulting in a potential appearing between the semi-transparent ground electrode **50** and the rear electrode **54** due to the incident illumination. In this instance, the ferroelectric ceramic material **52** would preferably be a transparent ceramic, such as 0.020 inch disk of 8.5/65/35 PLZT with a grain size of 6 microns, polarised in the thickness direction and producing a photo-emf of about 30 volts and a short circuit current of 10^{-7} amperes/cm.sup.2 per watt per cm.sup.2 input at 388 nm, for example. Further, the rear electrodes **54** are contemplated to be of a transparent variety, such as indium oxide 50 that a display can be provided in transmission.

A further variant of the operation of the device of **Fig.28** is possible, eliminating the necessity for the initial application of a short voltage pulse between the ground electrode **50** and one of the plurality of rear electrodes **54** to commence the process of clearing of the liquid crystal **46**. In this respect, and in addition to the normally provided uniform polarised illumination, an additional intense source of light providing a thin beam such as a laser would be provided, the laser constituting a so-called "light pencil". Upon application of the intense pencil beam of light of the apparatus of **Fig.28**, such intense light would penetrate the liquid crystal even in its nominally closed state thus illuminating the ferroelectric ceramic **52**, such illumination causing a photo-voltage to be generated as above-discussed which would then appear across the liquid crystal in the region of the intense light beam causing that region to become transparent and allowing the uniform polarised illumination to penetrate into that region, such uniform illumination further clearing the crystal in a regenerative process. This would result in a clear region which looked bright under reflected light, and a current flowing from the associated rear electrode **54** to ground, for example, through a non-illustrated resistor that would be provided. With this modification, the intense beam of

light constituting the "light pencil" can be utilised to actually enter a line drawing into the display, with a point by point read-out being provided.

As opposed to obtaining a point-by-point electrical read-out, the image written-in by the "light pencil" can be externally projected. In this respect, and as explained, the "image" constitutes transparent sections of the liquid crystal. If a light source such as a tungsten-halogen lamp normally associated with projectors was additionally provided to illuminate the display apparatus from the "rear" thereof in a direction opposing the direction of the incident polarised illumination, such auxiliary light source would pass through the display apparatus at the transparent regions, much in the same manner as a photographic slide is projected, the projection image being displayed on a suitable screen. In this instance, of course, a ferroelectric ceramic material that is transparent would be required, such as the material known as PLZT 7/65/35.

As can further be appreciated, the memory characteristics of the optical display of **Fig.28** are not permanent. If domain switching and a permanent memory capability is desired, an alternative electrode configuration would be required in the fashion illustrated in **Fig.30** of the application drawings, components of the apparatus of **Fig.30** that are the same as those of **Fig.28** being represented by the same reference numerals. Specifically, an additional transparent electrode **56** would be disposed between the colour switching liquid crystal **46** and the ferroelectric ceramic **52** polarisation within the ferroelectric ceramic **52** being effected by the application of a voltage pulse across electrodes **54** and **56**, and with an additional grounding electrode **52** being provided on the ceramic **52** as is shown so as to couple one end of the ferroelectric ceramic **52** to the transparent electrode **50**.

If a twisted nematic liquid crystal were desired to be utilised in the generalised configuration of the optical display of **Fig.28**, a still further modification of the electrode arrangement would be needed and, in this respect, attention is directed to **Fig.29** of the application drawings. Like parts in this figure are again represented by the same reference numerals.

Initially, since a twisted nematic liquid crystals alters its light transmissions characteristics by rotating the plane of the polarisation of the illumination, a further polariser such as analyser **60** is required to be disposed between the ferroelectric ceramic **52** and the liquid crystal **46**, the crystal **46** thereby being properly responsive to incoming polarised illumination either provided directly by a polarised source, or provided through the utilisation of a non-polarised illumination source in conjunction with a polariser such as polariser **34** of the embodiment of **Fig.27**. Additionally, a light transmitting electrode **62** would be disposed on the surface of the analyser **60** immediately adjacent the liquid crystal **46**, transparent electrode 62 being coupled through the analyser and the ferroelectric ceramic substrate **52** to an associated rear electrode 54. Each of the rear electrodes **54** of the array would have associated therewith an additional transparent electrode **62** in similar manner.

If the analyser **60** was constructed to be crossed with the incoming polarised illumination, the liquid crystal **46** would normally transmit light through it and, upon the application of a voltage between electrode **54** and the front transparent electrode **50**, would cause the apparatus to provide a so-called "dark spot display." Alternatively, if the incoming polarised light has a plane of polarisation parallel to the polarisation plane of analyser **60**, a so-called "bright spot display" would result. It should further be appreciated that the embodiment of **Fig.29** can be utilised with a "light pencil" to provide a functional operation similar to that discussed with respect to **Fig.28**.

Attention is now directed to **Fig.31** of the application drawings wherein an illustration is provided of an optical display array utilising a liquid crystal **64** of the colour switching type. Each of the units shown is contemplated to represent one of the horizontal row in an overall array. The structure illustrates is in monolithic form and, as shown, constitutes a polarity of superposed layers. Specifically, a transparent electrode **66** is provided, behind which is the liquid crystal **64** disposed between two face plates **68** and **70**. A transparent electrode structure **72** is provided imbedded at one end with the liquid crystal **64** and coupled at the other end to one end of the ferroelectric ceramic substrate **74** as is shown. The other end of each ferroelectric ceramic slab **74** is commonly coupled to ground along with the front transparent electrode 66 as was discussed.

With the embodiment of **Fig.31**, each ferroelectric ceramic substrate **74** would be initially polarised by the application of a polarising voltage pulse between the representative terminals or electrodes **76** and **78**, for example. Now, upon the application of illumination to the ferroelectric ceramic, a photovoltaic voltage will be generated which appears between the front transparent electrode **66** and the rear transparent electrode **72** causing the liquid crystal **64** between these electrodes to become transparent.

Liquid crystal **64** would normally be in a nominally opaque state. However, sufficient light would be transmitted through the liquid crystal material so as to produce the photo-voltage in the ferroelectric ceramic **74**, which photo-voltage applied to the electrodes **66** and **72** in a positive feed-back arrangement serves to increase the transparency of the colour switching liquid crystal **64** in the region between the electrodes. This increased transparency, in turn, increases the voltage output of the ferroelectric material **74** which further increases the transparency of the liquid crystal **64** such that a transparent region would be formed appearing as a bright spot

with reflected light. The surface of the ferroelectric ceramic **74** would in this instance serve itself as a diffuse reflector which would be required by a display function in the reflection mode.

Further, it should be appreciated that a certain threshold light transmission of the liquid crystal **64** would be required to begin this process of creating a transparent region. If the liquid crystal is sufficiently thick, the transmitted light through the crystal in its normally opaque state would be insufficient to commence this clearing process and an applied voltage would be initially necessary across the crystal to commence the process, this voltage being used as a "read" signal.

As can be appreciated, the remanent polarisation of the ferroelectric ceramic material **74** in the embodiment depicted in **Fig.31** is along the length of the ceramic substrate. An alternate arrangement is possible wherein the memory writing is accomplished by altering the remanent polarisation of the ferroelectric ceramic in the thickness direction. In this respect, reference is once again made to **Fig.30** of the application drawings illustrating the disposition of a ferroelectric ceramic **52** in conjunction with the colour switching liquid crystal **46** such that the remanent polarisation of the ceramic is achieved in the thickness direction, and such that permanent memory characteristics are imparted. With this arrangement, the incident illumination would be quickly absorbed in the surface of the ferroelectric ceramic material but would still penetrate sufficiently so as to produce relatively large photovoltaic voltages.

Finally, the optical display device of **Fig.31** can be constructed with a twisted nematic liquid crystal as opposed to the colour switching liquid crystal of **Fig.31** and attention is herein directed to **Fig.32** of the application drawings. Again, components of the apparatus of **Fig.32** which are similar to those in **Fig.31** are represented by the same reference numeral.

In this embodiment, a polariser **80** would initially be provided so as to polarise the incoming illumination. In a fashion similar to the generalised embodiment of **Fig.27**, an analyser **82** would likewise be provided, polariser **80** and analyser **82** being assumed to be parallelly disposed. Incoming polarised light will not impinge on the ferroelectric ceramic material **74** because the twisted nematic crystal **64** would rotate the plane of the polarisation of the illumination by 90^0 and such illumination would thus be absorbed in analyser **82**. The display unit, accordingly, would initially be in an "off" or dark state and no voltage would exist across the terminals or electrodes **76** and **78** of the ferroelectric ceramic.

The "on" of the display apparatus would be bright under reflected illumination and would be indicated by the appearance of a DC voltage across terminals **76** and **78**. The unit would be switched to the "on" stage through the application of an initial polarising voltage pulse between electrodes **76** and **78**. The twisted nematic liquid crystal would now lose its ability to rotate the plane of polarisation of the illumination and light would fall on the surface of the now-polarised ferroelectric ceramic material **74** such that the ceramic would generate a steady, high photovoltaic voltage which would appear across the electrodes of the liquid crystal. This photovoltaic voltage would prevent the liquid crystal from returning to the twisted phase and the liquid crystal would thus remain transparent and a voltage potential would be maintained across the electrodes for the duration of the illumination.

The display apparatus can be returned to its dark state simply by shorting across terminals **76** and **78** and the crystal cell would return to its opaque condition with no voltage appearing across the electrodes. A new external voltage pulse would be required across electrodes **76** and **78** to again switch the unit on. It should be appreciated that only a momentary voltage pulse is required to turn the display unit on, and only a momentary short circuit is needed to turn the unit off.

If the incident illumination were interrupted, the display unit would likewise be put into an "off" state. The memory characteristics of the display apparatus thus are volatile in the sense that a removal of illumination will put the display unit into an "off" state. Permanent memory characteristics can be obtained by depoling the ferroelectric ceramic **74** with additional circuitry and the illumination could then be interrupted. When illumination is restored, a voltage pulse would switch "on" only those units of the array which were in an "on" state at the time of interruption of illumination, since only the polarised ferroelectric ceramic units will produce a photo-voltage. The depoled units can then be repoled without switching them "on", utilising a suitable circuit to apply a polarising voltage to the ceramic but not to the liquid cell to therefore retain the liquid crystal cell in its dark state as it was at the time the illumination was removed.

Many other different embodiments combining a liquid crystal display with the ferroelectric ceramic substrate of the instant invention can be fabricated along the generalised teachings referred to above. From the standpoint of materials selection, PLZT is desired when a transparent ferroelectric ceramic is required, and other ferroelectric ceramics such as $Pb(Zr_{0.53}Ti_{0.47})O_3$ + 1% by weight of Nb_2O_5 (i.e. PZT-5), a solid solution of lead titanate, and lead zirconate can be utilised when relatively cheap "opaque" materials are acceptable. With the display devices as above-discussed, typical thickness of the ferroelectric ceramic material are on the order of 0.020 inches. In accordance with the generalised teachings appearing at the outset of this specification, it is to be appreciated that

the photovoltaic output of the ferroelectric ceramic material is proportional to the material length and, the higher the photovoltaic output, the faster the switching time of the associated liquid crystal.

A further form of optical display apparatus is contemplated herein by which the previously discussed photoconductive properties of ferroelectric ceramic materials are utilised in the formation of display apparatus. As will be recalled and appreciated, the resistivity of typical ferroelectric ceramic materials varies as a function of the illumination incident thereon and thus, the voltage drop across illuminated regions of a ferroelectric ceramic substrate that has a polarising voltage applied thereto would be less than the voltage drop across non-illuminated or dark regions of the ceramic. Attention in this respect is directed to **Fig.33** of the application drawings.

The display device depicted in **Fig.33** is such that a photograph in the form of a projected image can be stored in a ferroelectric ceramic sheet or substrate **84** as a pattern of poled ferroelectric regions where the remanent polarisation of such regions is simply related to the intensity of the projected image at that point. The pattern of poled regions can be produced by the already discussed technique of a photoconductive ferroelectric sandwich, or by utilising the photoconductive properties of ferroelectric materials directly.

In the embodiment of **Fig.33**, an image is projected onto a ferroelectric-photoconductive substrate **84**, which substrate is backed by a sheet of resistive material **86** such as evaporated carbon, semiconductor material or the like. A transparent front electrode **88** forming a ground plane covers the surface of the ferroelectric material **84**, which material is of the type which would exhibit a sizable polarisation dependent photovoltaic effect. A further electrode **90**, covers the rear surface of the resistive material **86**, and a polarising voltage would be applied to the apparatus between electrodes **90** and **83**.

With such an arrangement the voltage drop will be seen to exist across those regions of the ferroelectric substrate **84** which are illuminated will be less than the voltage drop apparent across the non-illuminated or dark regions. As such the lower remanent polarisation within the ferroelectric material will be effected than in those regions of the ferroelectric material that are not illuminated by the projected image. Accordingly a "negative" of the projected image would thus be stored in the ferroelectric substrate or sheet **84** as regions of varying remanent polarisation. In that the ferroelectric **84** is photovoltaic having polarisation dependent photo-voltages as discussed this stored image is now read out electrically utilising the techniques already described with respect to the embodiments of the invention illustrated in **Fig.26** of the application drawings or **Fig.28** et. seq. of the application drawings. It is displayed by applying the photo-voltages from regions of polarisation in which the image is effectively stored to liquid crystal electrodes as for example is illustrated in **Fig.34** of the application drawings where illumination sufficiently strong penetrates the dark liquid crystal **93**, to in a regenerative fashion, apply the photo-voltage from polarised region **91**, to the liquid crystal region immediately adjacent varying in intensity depending on the value of the polarisation. A negative image is produced in reflection.

High Voltage Battery

The teaching in this patent may be applied toward the provision of a novel high voltage battery serving to convert radiation such as X-radiation in this instance, directly into electrical energy. In this respect, a block or substrate of ferroelectric ceramic material would again be provided to which electrodes are attached in the identical fashion as was discussed with respect to the basic physical configuration of the invention illustrated in **Fig.1** of the application drawings. An example of the constituent material of the ferroelectric ceramic in this instance is solid solution PZT-5A consisting of 53 mole percent $ZrTiO_3$ and 47 mole $PbTiO_3$ with 1 percent by weight of niobium added such as Nb_2O_5. This ferroelectric ceramic material would be poled in the usual fashion by the application of a high voltage applied across the electrodes.

To function as a battery, the ceramic material can contain a radioactive component and this can be all or a portion of any of the above-discussed constituent elements. For example, the material may be fabricated with a radioactive isotope of Zr,TiO, Nb, etc., or a radioactive additive can be added to the composition. Alternatively, the composition may be placed next to a strong radioactive source and, for example, could actually be coated with a radioactive material. The primary requirement is that a flux of gamma rays or X-rays within the material be produced, which radiation has the effect of ionising the ferroelectric ceramic material so as to produce non-equilibrium carriers.

Thus, in the instance of the application of a poled ferroelectric ceramic material as a high voltage battery, an external light source would not be required as the ionising source in that the non-equilibrium carriers would be produced by the internal ionisation of the ferroelectric ceramic material effected by the radiation and would result in an emf which would appear across the electrodes.

Accordingly, an open circuit voltage proportional to the length of the ferroelectric ceramic material between the electrodes and inversely proportional to average grain size, and the like as was discussed at the outset of this

specification would be produced by the gamma or X-radiation. Similarly, a short circuit current proportional to the electrode area and the net (steady state) increment of excess carriers introduced into the conduction band would likewise be produced, this being related to the intensity of the ionising radiation.

As can be appreciated, the emf would persist as long as the ionising radiation persisted and, extrapolating from the detailed photo-effect results, the emf produced by this high voltage battery would be relatively independent of the intensity of the radiation and thus not strongly dependent on the half-life of the radioactive material.

While there has been shown and described several preferred embodiments and applications of the basic invention hereof, those skilled in the art should appreciate that such embodiments are exemplary and not limiting and are to be construed within the scope of the following claims:

CLAIMS

1. A photovoltaic memory apparatus comprising: a substrate of a ferroelectric ceramic; means for selectively applying a voltage pulse of a predetermined polarity across a region of said substrate to thereby effect a remanent ferroelectric polarisation in said region of said substrate representative of the information to be stored; means for selectively illuminating said poled region of said substrate with a source of radiation, whereby a photovoltaic voltage is produced at said region of a polarity dependent upon said predetermined polarity of said polarising voltage pulse; and means for detecting said photovoltaic voltage whereby the stored information is retrieved.

2. A memory apparatus as defined in claim 1, wherein an array of electrode pairs are disposed on opposing sides of said substrate to define a matrix configuration of poled regions, said polarising voltage pulse being applied across selected electrode pairs, and wherein said information reading means scans said matrix configuration in accordance with a desired pattern, said detecting means being coupled to said array of electrode pairs and being synchronised with said information reading means.

3. A memory apparatus as defined in claim 1, wherein said substrate is sandwiched between at least one electrode pair and one electrode of said electrode pair is transparent such that said illumination from said information reading means passes through it into said respective poled region of said substrate.

4. A method of addressing and storing information utilising a substrate of a ferroelectric ceramic as a memory core, said method comprising the steps of initially effecting a remanent electrical polarisation in regions of the ferroelectric ceramic by the application of a voltage pulse across the regions of the substrate, the voltage pulse having at least one of a polarity and magnitude representative of the information to be stored; addressing the memory core while illuminating the polarised regions of the ferroelectric ceramic substrate with a source of radiation; and detecting at least one of the polarity and magnitude of the photovoltaic current and voltage produced by such illumination upon the polarised regions, the polarity and magnitude being dependent upon the polarity and magnitude of the initial polarising voltage pulse whereby the stored information is recovered.

5. An optical apparatus comprising in combination: an electro-optic means providing variable light transmission characteristics in response to the magnitude and polarity of an applied voltage; a substrate of a ferroelectric ceramic; means for applying a polarising voltage pulse of a predetermined magnitude and polarity across said substrate to effect a remanent electrical polarisation within said substrate; means for illuminating said electro-optic means and said ceramic substrate, illumination impinging upon said substrate effecting the generation by said substrate of a photovoltaic current and voltage having a polarity dependent upon the polarity of said polarising voltage pulse; and means for applying said generated photovoltaic voltage to said electro-optic means, whereby the transmission characteristics of said electro-optic means to the illumination impinging thereon is varied to effect a visual display.

6. A display apparatus as defined in claim 5, wherein the light transmission characteristics of said electro-optic means is switched from a relatively low opacity to a relatively high opacity upon application thereto of said generated photovoltaic voltage.

7. A display apparatus as defined in claim 5, wherein the light transmission characteristics of said electro-optic means is switched from a relatively high opacity to a relatively low opacity upon application thereto of said generated photovoltaic voltage.

8. A display apparatus as defined in claim 6, wherein said relatively low opacity is of a value such that said electro-optic means is substantially transparent, said relatively high opacity being of a value such that said electro-optic means is substantially opaque.

9. A display apparatus as defined in claim 7, wherein said relatively low opacity is of a value such that said electro-optic means is substantially transparent, said relatively high opacity being of a value such that said electro-optic means is substantially opaque.

10. A display apparatus as defined in claim 5, wherein the magnitude of said polarising voltage is selected such that the light transmission characteristics of said electro-optic means is switched between varying opacities to define a gray scale.

11. A display apparatus as defined in claim 33, wherein said electro-optic means is a liquid crystal of the twisted nematic type.

12. A display apparatus as defined in claim 5, wherein said electro-optic means is a liquid crystal of the colour switching type.

13. A display apparatus as defined in claim 11, wherein said liquid crystal is sandwiched between a light polariser and a light analyser.

14. A display apparatus as defined in claim 5, wherein said electro-optic means and said ferroelectric ceramic substrate are disposed in superposition to define a monolithic structure.

15. A display apparatus as defined in claim 14, wherein said electro-optic means is a colour switching liquid crystal disposed in superposition with said ceramic substrate to define a monolithic structure, and wherein said means for applying a polarising voltage to said substrate and said means for applying said photovoltaic voltage to said liquid crystal comprises a plurality of electrodes disposed on opposite faces of said structure with said structure being sandwiched between them, at least one electrode pair being in contact with said liquid crystal and with said ceramic substrate, respectively; said electrode of said pair which is in contact with said liquid crystal being transparent.

16. A display apparatus as defined in claim 14, wherein said monolithic structure constitutes a plurality of stacked superposed layers comprising a first transparent electrode, an electro-optic means, a second transparent electrode, said substrate of a ferroelectric ceramic, and a third electrode, said third electrode being coupled to said first electrode, said means for applying said polarising voltage being defined by said second and third electrodes, said means for applying said generated photovoltaic voltage being defined by said first and second electrodes, and wherein said means for illuminating said electro-optic means and said substrate comprises a light beam directed to impinge upon said first transparent electrode.

17. A display apparatus as defined in claim 16, wherein said electro-optic means is a liquid crystal of the colour switching type.

18. A display apparatus as defined in claim 16, wherein said plurality of stacked layers further includes a polariser disposed over said first transparent electrode, and an analyser disposed between said second transparent electrode and said ceramic substrate, said electro-optic means being a liquid crystal of the twisted nematic type.

19. A display apparatus as defined in claim 16, wherein said illumination means comprises a source of polarised light, said plurality of stacked layers including an analyser disposed between said second transparent electrode and said ceramic substrate, said electro-optic means being a liquid crystal of the twisted nematic type.

20. A display apparatus as defined in claim 19, wherein said analyser is disposed in a direction parallel to the plane of polarisation of the incident illumination.

21. A display apparatus as defined in claim 19, wherein said analyser is disposed so as to be crossed with respect to the plane of polarisation of the incident illumination.

22. A method of electrically storing optical information comprising the steps of: projecting an image constituting the optical information onto a sandwich of a ferroelectric ceramic backed by a layer of resistive material to form an illumination pattern thereon; applying a voltage pulse across the sandwich whereby varying remanent polarisations within the ferroelectric ceramic are produced in dependence upon the illumination pattern.

23. The method of claim 22, further including the step of reading out the remanent polarisations to thereby extract the stored optical information.

24. A display apparatus as defined in claim 5, wherein said variation of the transmission characteristics of the electro-optic means ensures that illumination continues to impinge upon said substrate to latch said electro-optical means and maintain said transmission variation thereof.

25. A method of electrically storing optical information comprising the steps of: projecting an image constituting the optical information onto a ferroelectric ceramic layer to form an illumination pattern thereon and thereby alter the resistivity of the ceramic layer in accordance with said pattern; applying a voltage pulse across the ceramic whereby varying remanent polarisations within the ferroelectric ceramic are produced in dependence upon the illumination pattern.

Patent US 6,246,561 **12th June 2001** **Inventor: Charles J. Flynn**

METHODS FOR CONTROLLING THE PATH OF MAGNETIC FLUX FROM A PERMANENT MAGNET AND DEVICES INCORPORATING THE SAME

This patent covers a device which is claimed to have a greater output power than the input power required to run it.

ABSTRACT

A permanent magnet device includes a permanent magnet having north and south pole faces with a first pole piece positioned adjacent one pole face thereof and a second pole piece positioned adjacent the other pole face thereof so as to create at least two potential magnetic flux paths. A first control coil is positioned along one flux path and a second control coil is positioned along the other flux path, each coil being connected to a control circuit for controlling the energisation thereof. The control coils may be energised in a variety of ways to achieved desirable motive and static devices, including linear reciprocating devices, linear motion devices, rotary motion devices and power conversion.

DESCRIPTION

FIELD OF THE INVENTION

This invention relates generally to permanent magnet devices and more particularly, to a permanent magnet control component in which the flow of flux from a permanent magnet is controlled between two or more flux paths by utilising timed delivery of electrical signals through one or more coils placed along at least one of the flux paths. Such permanent magnet control components may take on a variety of configurations facilitating use of such components in a variety of applications including applications involving the production of reciprocating, linear, and rotary motion and power conversion. Several novel permanent magnet rotary motion devices of motor constructions which operate by controlling the path of magnetic flux from one or more permanent magnets are described, such permanent magnet rotary motor constructions having increased efficiency and more desirable torque characteristics as compared to many currently used motors.

BACKGROUND OF THE INVENTION

Magnetic force of attraction is commonly used in a variety of types of permanent magnet devices including both linear and rotary motors. In the field of such permanent magnet devices there is a continuous pursuit of increased efficiency and reduced complexity.

Accordingly, an object of the present invention is to provide a permanent magnet control component in which the path of a given level of permanent magnet flux can be controlled by a lesser level of electromagnetic flux.

Another object of the present invention is to provide a permanent magnet control component in which substantially all of the flux from a permanent magnet can be switched between at least two different flux paths of the permanent magnet control component so as to enable useful work in the form of linear, reciprocating, and rotary motion.

Still another object of the present invention is to provide permanent magnet control components and motor constructions in which flux path control is provided by energising an 10 electromagnet to oppose the magnetic flux of one or more permanent magnets.

Another object of the present invention is to provide permanent magnet control components and motor constructions in which flux path control is provided by energising an electromagnet to aid the magnetic flux of one or more permanent magnets.

Yet another object of the present invention is to provide permanent magnet motor 15 constructions with improved operating characteristics.

SUMMARY OF THE INVENTION

These and other objects of the invention are attained by an apparatus which, in one aspect, is a permanent magnet device, comprising a permanent magnet having north and south pole faces, a first pole piece, a second pole piece, a first control coil, a second control coil, and circuit means, the first pole piece positioned adjacent the north pole face of the permanent magnet and including a first path portion, a second path portion and a third portion, the first path portion extending beyond a perimeter of the north pole face and the second path portion extending beyond the perimeter of the north pole face to define first and second flux paths for magnetic flux emanating from the north pole face of the permanent magnet, the first path portion of the first pole piece connected to the second path portion of the first pole piece by the third portion which extends across the north pole face of the permanent magnet, the second pole piece positioned adjacent the south pole face and including a first path portion and a second path portion, the first path portion extending beyond a perimeter of the south pole face and substantially aligned with the first path portion of the first pole piece, the second path portion extending beyond the perimeter of the south pole face and substantially aligned with the second path portion of the first pole piece, the first control coil positioned around the first path portion of the first pole piece, the second control coil positioned around the second path portion of the first pole piece, the circuit means connected to each of the first control coil and the second control coil to alternately energise the first coil and the second coil in a timed sequential manner.

Another aspect of the present invention provides a method for controlling the path of magnetic flux from a permanent magnet which involves placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face. A second pole piece is placed adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece. A first control coil is placed along and around the first path portion of the first pole piece and a second control coil is placed along and around the second path portion of the first pole piece. The first control coil is repeatedly energised in a permanent magnet magnetic flux opposing manner so as to prevent magnetic flux of the permanent magnet from traversing the first path portion of the first pole piece, and the second control coil is repeatedly energised in a permanent magnet magnetic flux opposing manner so as to prevent magnetic flux of the permanent magnet from traversing the second path portion of the first pole piece.

Yet another aspect of the present invention provides a method for controlling the path of magnetic flux from a permanent magnet by placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face. A second pole piece is placed adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece. A first control coil is placed along and around the first path portion of the first pole piece, and a second control coil is placed along and around the second path portion of the first pole piece. The following steps are alternately performed in a repeated manner:

(i) energising the first control coil in a permanent magnet magnetic flux aiding manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the second path portion of the first pole piece when the first control coil is so energised; and

(ii) energising the second control coil in a permanent magnet magnetic flux opposing manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the first path portion of the first pole piece when the second control coil is so energised.

A further aspect of the present invention provides method for controlling the path of magnetic flux from a permanent magnet by placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face, and placing a second pole piece adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece. A first control coil is placed along and around the first path portion of the first pole piece, and a second control coil is placed along and around the second path portion of the first pole piece. The following steps are alternately performed in a repeated manner:

(i) energising the first control coil in a permanent magnet magnetic flux aiding manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the second path portion of the first pole piece when the first control coil is so energised; and

(ii) energising the second control coil in a permanent magnet magnetic flux opposing manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the first path portion of the first pole piece when the second control coil is so energised.

BRIEF DESCRIPTION OF THE INVENTION

DETAILED DESCRIPTION OF THE DRAWINGS

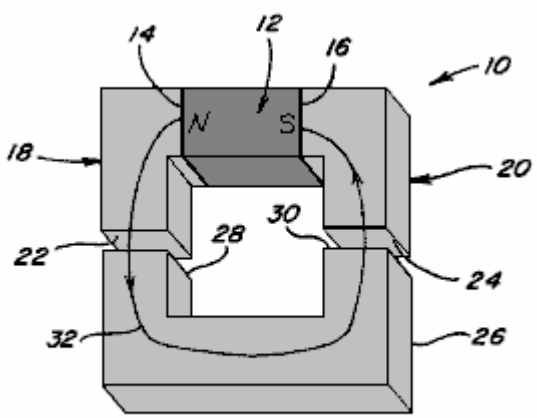

Fig. 1

Referring now to the drawings, Figs.1-4 are provided to facilitate an understanding of various aspects or features of the technology utilised in the present invention. **Fig.1** depicts a device **10** having a magnetic flux producing member **12** which may be a permanent magnet or electromagnet with magnetic poles **14** and **16** as shown. Pole pieces **18** and **20** are positioned adjacent respective poles **14** and **16** to provide a path for the magnetic flux of member **12**. Each pole piece **18** and **20** has a pole piece end face **22** and **24**. As used throughout this specification, it is understood that a pole piece, regardless of its shape or size, is preferably formed of soft iron, steel or some other magnetic material, with the preferred material being one which provides low reluctance, exhibits low hysterisis, and has a high magnetic flux density capability. Accordingly, the various pole pieces disclosed and described herein could likewise be of laminate type construction.

Referring again to **Fig.1** an armature **26**, also formed of magnetic material, is shown with end faces **28** and **30** which are positioned and sized for being placed adjacent pole piece end faces **22** and **24**, such that when so positioned a substantially continuous low reluctance path **32** is provided for magnetic flux from north pole **14**, through pole piece **18**, through armature **26**, through pole piece **16**, and to south pole **16**. The magnetic flux travelling along such path **32** results in a force which tends to hold armature **26** in position aligned with pole piece end faces **22** and **24**. The resulting magnetic coupling or holding force F provided between adjacent pole piece end face **22** and armature end face **28**, and between adjacent pole piece end face **24** and armature end face **30**, can be approximated by the following equation:

$$F=B^2A/2\mu_0,$$

where **B** is the magnetic flux density passing through the adjacent end faces and **A** is the surface area of the adjacent end faces. Assuming that if **B** is uniform throughout flux path **32** and that the area **A** of all end faces **22**, **24**, **28**, and **30** is the same, then the total holding force $\mathbf{F_{T26}}$ of armature **26** against pole pieces **18** and **20** will be:

$$F_{T26}=B^2A/\mu_0,$$

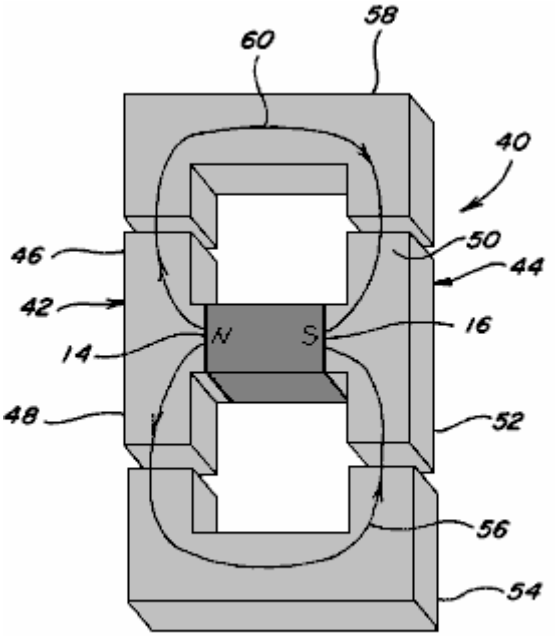

Fig. 2

In **Fig.2** a device **40** having the same magnetic flux producing member **12** with magnetic poles **14** and **16** is shown. Pole pieces **42** and **44** are positioned adjacent respective pole faces **14** and **16** to provide two paths, as opposed to one above, for the magnetic flux of member **12**. In particular, pole piece **42** includes a first path portion **46** extending beyond a perimeter of north pole face **14** in one direction and a second path portion **48** extending beyond the perimeter of north pole face **14** in another direction. Similarly, pole piece **44** includes a first path portion **50** extending beyond the perimeter of south pole face **16** in one direction and a second path portion **52** extending beyond the perimeter of south pole face **16** in another direction. Each pole piece path portion **46**, **48**, **50**, **52** includes a respective end face. A first armature **54** which can be positioned adjacent to the end faces of pole piece path components **48** and **52** provides a first magnetic flux path **56** and a second armature **58** is which can be positioned adjacent the end faces of pole piece path components **46** and **50** provides a second magnetic flux path **60**. If the flux carrying area along flux paths **56** and **60** is the same as the flux carrying area along flux path **32** of **Fig.1**, the magnetic flux density along each flux path **56** and **60** will be one-half the magnetic flux density along flux path **32** of **Fig.1** because the same amount of flux is split between two like paths. The effect of dividing a given amount of magnetic flux along two like flux paths instead of it passing along just one flux path can be seen by examining the holding force on armature **54** as compared to the holding force on armature **26** of **Fig.1**. As already noted the magnetic flux density along path **56** will be one-half that along flux path **32** and thus the total holding force F_{T54} can be determined as:

$$F_{T54}=(B/2)2A/,\mu_0=B^2A/4\mu_0=F_{T26}/4.$$

It is therefore seen that dividing the same amount of magnetic flux along two flux paths rather than along one flux path reduces the magnetic holding or coupling force on an armature to one-fourth rather than one-half as might have been expected. This unexpected magnetic holding or coupling force differential, resulting from multiple flux paths, can provide advantageous properties in linear, reciprocating, and rotary motion devices.

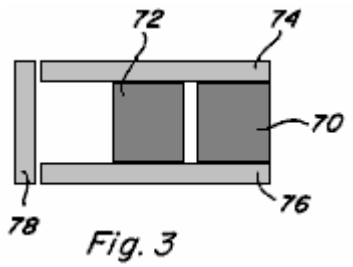

Fig. 3

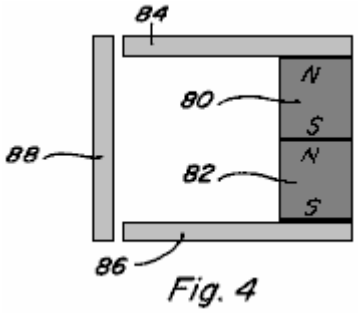

Fig. 4

Referring now to **Fig.3** and **Fig.4**, the behaviour of multiple magnetic flux sources arranged in parallel and series is described as compared to a single flux source. When identical flux sources or magnetic flux producing members **70** and **72** are positioned in parallel as shown in **Fig.3** with pole pieces **74** and **76** positioned adjacent the poles thereof to provide a flux path through armature **78**, the flux density B through armature **78** is double what the flux density would be if only one magnetic flux producing member were present. However, the field intensity H resulting from the two members **70** and **72** remains unchanged. This result holds true regardless of whether members **70** and **72** are both permanent magnets, are both electromagnets, or are a combination of one permanent magnet and one electromagnet. On the other hand, the properties resulting from magnetic flux producing members **80** and **82** arranged pole-to-pole in series between pole pieces **84** and **86**, with armature **88**, as shown in **Fig.4**, will vary depending on the nature of the members **80** and **82**.

In a first case, if both members **80** and **82** are permanent magnets, the magnetic field intensity H resulting from the two permanent magnets will be double that of one permanent magnet and the flux density B through armature **88** will be the same as what the flux density would be if only one permanent magnet type member were present.

In a second case, if both members **80** and **82** are electromagnets, the field intensity H again doubles and the flux density B increases according to the B/H curve or relationship of the pole piece **84**, **86** and armature **88** materials.

In a third case, if member **80** is a permanent magnet and member **82** is an electromagnet, the field intensity H again doubles, but, since the permanent magnet is near flux density saturation B_r the flux density can only be increased from B_r to B_{max} of the permanent magnet. At the point where electromagnet-type member **82** contacts permanent magnet-type member **80** the flux from the electromagnet-type member **82** couples with the flux of the permanent magnet-type member **82** until the flux density through permanent magnet-type member **80** reaches B_{max}. At that point additional flux from electromagnet-type member **82** does not contribute to the flux density along the flux path unless a bypass path around the permanent magnet-type member is provided. Use of such bypass paths will be described below.

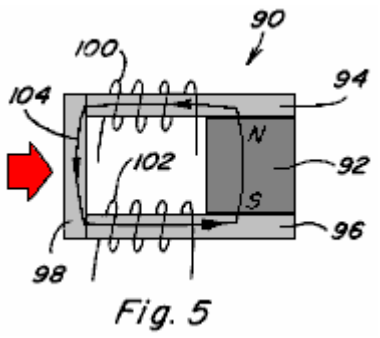

Fig. 5

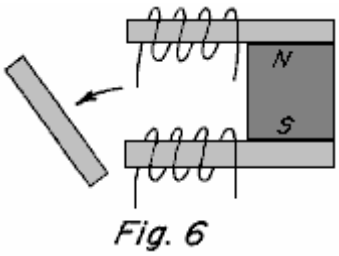

Fig. 6

Controlling the flow of flux along both one and multiple flux paths is best described with reference to **Figs.5-9**. In **Fig.5** and **Fig.6** a permanent magnet device **90** including a permanent magnet **92** having pole pieces **94** and **96** positioned adjacent to it's pole faces, and an armature **98** completing a low reluctance path **104** from pole to pole is shown. Control coils **100**, **102** are positioned along path **104**. When control coils **100**, **102** are not energised, the magnetic flux of permanent magnet **92** follows path **104** as shown and armature **98** is held in place against

pole pieces **94**, **96** due to the resulting magnetic coupling forces. However, if coils **100**, **102** are energised to provide an equal but opposing magnetic flux to that of permanent magnet **92**, the result is that the magnetic flux of permanent magnet **92** is blocked and no magnetic flux traverses the path which includes armature **98** and therefore no magnetic coupling forces act on armature **98** allowing it to fall away as shown in **Fig.6**. The permanent magnet device **90** is useful, although as will become apparent below, it is more advantageous to provide multiple flux paths rather than one.

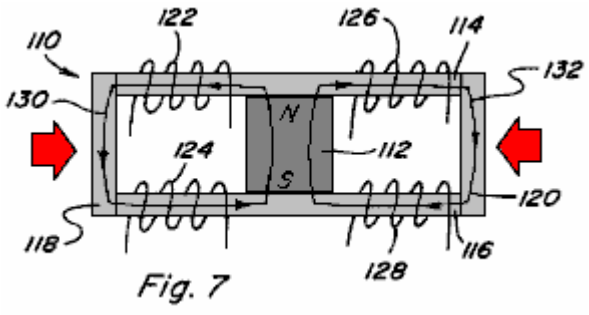

Fig. 7

In this regard, in **Fig.7** a permanent magnet device **110** includes a permanent magnet **112** having pole pieces **114**, **116** positioned adjacent the pole faces of it, with armatures **118**, **120** completing two low-reluctance paths **130**, **132** from pole to pole thereof. Control coils **122**, **124** are positioned along path **130** and control coils **126**, **128** are positioned along path **132**. The two paths provided are assumed to be of equal reluctance. With no coils energised, the magnetic flux of permanent magnet **112** divides equally along flux path **130** and flux path **132** such that both armatures **118**, **120** are subjected to a magnetic coupling force which holds them in place against pole pieces **114**, **116**.

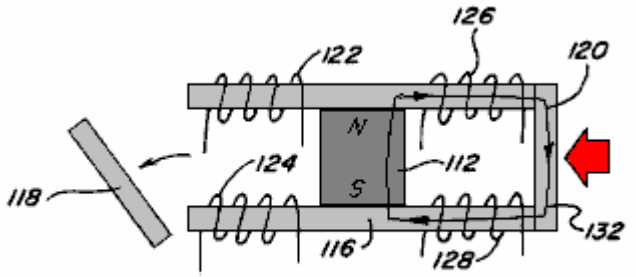

Fig. 8

If coils **122**, **124** are energised to provide a magnetic flux equal to but opposing the magnetic flux which travels along flux path **130** from permanent magnet **112** when no coils are energised, the result is that the magnetic flux of permanent magnet **112** is blocked and no magnetic flux traverses the path which includes armature **118** and therefore no magnetic coupling forces act on armature **118** allowing it to fall away as shown in **Fig.8**. Further, the magnetic flux traversing path **132** will be double that of when no coils are energised and therefore the magnetic coupling force on armature **120** will be about four (4) times that of when no coils are energised. By energising coils **126**, **128** in an opposing manner a similar result would be achieved such that armature **120** would fall away and such that the magnetic coupling force on armature **118** would be increased.

If coils **122**, **124** are energised to provide a magnetic flux equal to and aiding the magnetic flux which travels along flux path **130** when no coils are energised, the result is that the control coils couple completely with the magnetic flux of permanent magnet **112** and no magnetic flux traverses the path which includes armature **120** and therefore no magnetic coupling forces act on armature **120** allowing it to fall away as shown in **Fig.9**. Further, the magnetic flux traversing path **130** will be double that of when no coils are energised and therefore the magnetic coupling force on armature **118** will be about four (4) times that when no coils are energised. By energising coils **126**, **128** in an aiding manner a similar result would be achieved such that armature **118** would fall away and the magnetic coupling force on armature **120** would be increased.

Based on the foregoing, it is seen that the full magnetic coupling force available from the permanent magnet **112,** can be switched from one path to another path by the application of one half the power it would require for a coil alone to produce the same magnetic flux along one path. The ability to switch the full magnetic coupling force easily from one path to another, allows for efficient reciprocating, linear, and rotary motion and power conversion to be achieved.

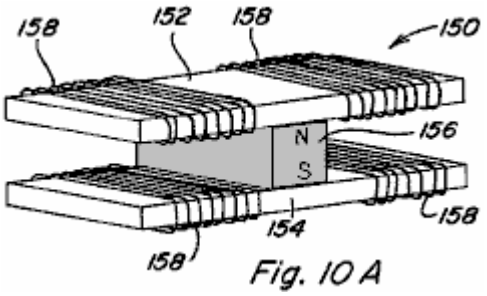

Fig. 10 A

The basic device utilised to achieve permanent magnet flux division and to control such permanent magnet flux division is defined herein as a "permanent magnet control component," various configurations of which are shown by way of example only, and not by way of limitation, in **Figs.10A-10F**. **Fig.10A** depicts a permanent magnet control component **150** in which pole pieces **152** and **154** are positioned adjacent to the pole faces of permanent magnet **156** to provide two magnetic flux paths extending from opposite sides of permanent magnet. Control coils **158** are positioned along each path.

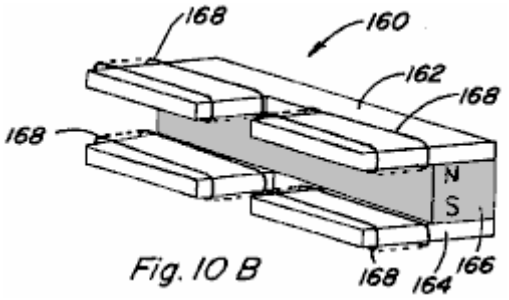

Fig. 10 B

Fig.10B depicts a permanent magnet control component **160** in which pole pieces **162** and **164** are positioned against the pole faces of permanent magnet **166** to provide two spaced, adjacent magnetic flux paths extending from the same side of permanent magnet **166**. Control coils **168** are positioned along each path.

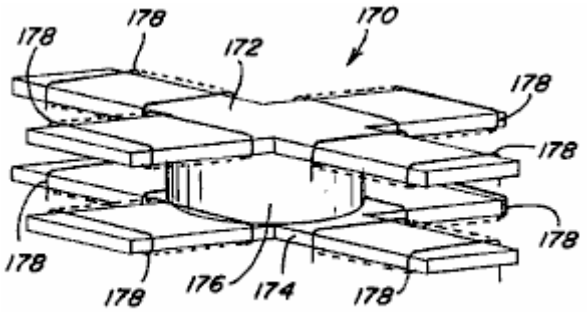

Fig. 10 C

Fig.10C depicts a permanent magnet control component **170** in which pole pieces **172** and **174** are configured so as to be positioned adjacent the pole faces of permanent magnet **176** so as to provide four flux paths, each flux path extending in a respective direction from permanent magnet **176**. Control coils **178** are also positioned along each path.

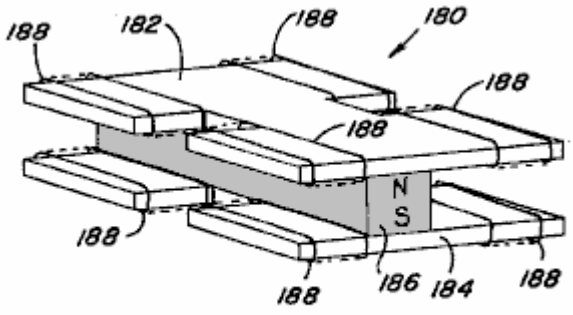

Fig. 10 D

Fig.10D depicts another four-path configuration of a permanent magnet control component **180** in which pole pieces **182**, **184** are configured and positioned to provide four flux paths for permanent magnet **186**, with a pair of spaced, adjacent flux paths extending from each side of permanent magnet **186**. Control coils **188** are positioned along each path.

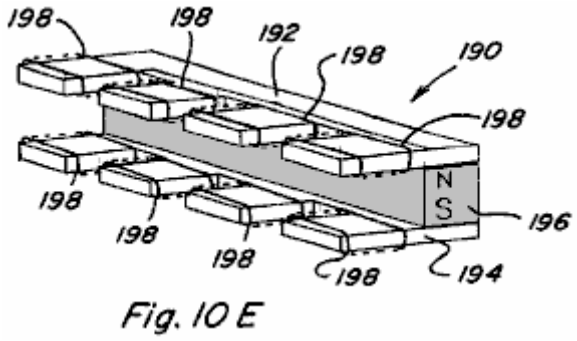

Fig. 10 E

Fig.10E depicts another four-path configuration of a permanent magnet control component **190** in which all four flux paths formed by pole pieces **192**, **194** extend from one side of permanent magnet **196**. Again, control coils **198** are positioned along each flux path.

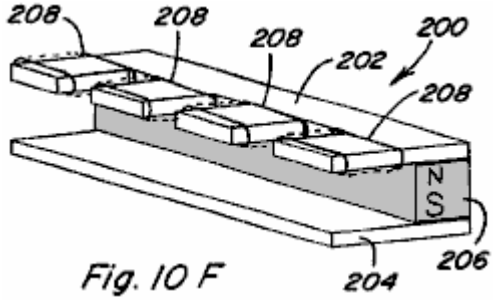

Fig. 10 F

Fig.10F still further depicts a four-path configuration of a permanent magnet control component **200** in which pole pieces **202**, **204** extend to one side of permanent magnet **206**, with pole piece **202** defining four flux paths and with pole piece **204** including a continuous return path. Control coils **208** are positioned along each path of pole piece **202**. Many other variations are possible.

Accordingly, it is seen that a variety of different configurations of permanent magnet control components are possible, in accordance with the present invention. The important considerations for division of permanent magnet flux in such permanent magnet control components include, extending each pole piece to, or beyond, the outer perimeter of the pole face of the permanent magnet in each region where a flux path is intended and assuring that the pole face of the permanent magnet intersects each of the flux paths. It is not necessary for each pole piece to include the same number of path portions extending beyond the perimeter of the respective permanent magnet pole face as noted with reference to permanent magnet control component **200**. Although two control coils are shown along each of the flux paths in **Figs.10A-10E**, it is apparent from component **200** in **Fig.10F** that one control coil positioned along a flux path is generally sufficient for purposes of the present invention. Further, although in the illustrated configurations each pole piece is positioned to contact a respective pole face of the permanent magnet, a small spacing between a pole piece and its adjacent permanent magnet pole face could be provided, particularly in applications where relative movement between the subject pole piece and the permanent magnet will occur.

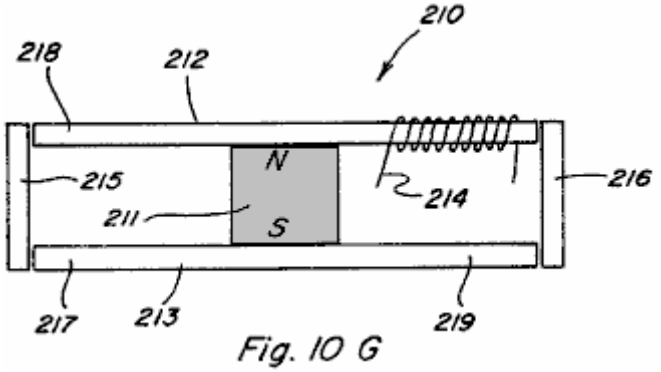

Fig. 10 G

In its simplest form a two path permanent magnet control component only requires one control coil positioned along one of the control paths to permit the magnetic flux of a permanent magnet to be switched between the two paths. In particular, a side view of such a two path component **210** is shown in **Fig.10G** and includes a permanent magnet **211** pole pieces **212** and **213**, and control coil **214** which may be connected to a suitable control circuit. By alternating energising control coil **214** in an opposing manner and an aiding manner the magnetic flux of permanent magnet can be switched between the path including armature **215** and the path including armature **216**. When control coil **214** is energised in an opposing manner the magnetic flux will traverse the path including armature **215** and when control coil **214** is energised in an aiding manner the magnetic flux will traverse the path including armature **216**. Control coil 214 could also be placed at any of the positions **217**, **218**, or **219** to achieve the flux path switching.

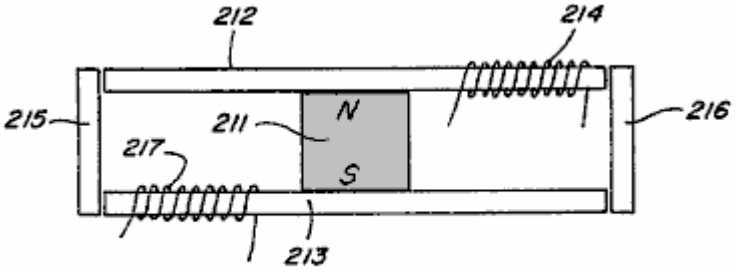

Fig. 10 H

Further, in the two coils embodiment shown in **Fig.10H** control coil **217** is added. In such a device, flux switching can be achieved by simultaneously energising control coil **214** in a flux aiding manner and control coil **217** in a flux opposing manner, and by then simultaneously reversing the energisation of the respective control coils **214** and **217**.

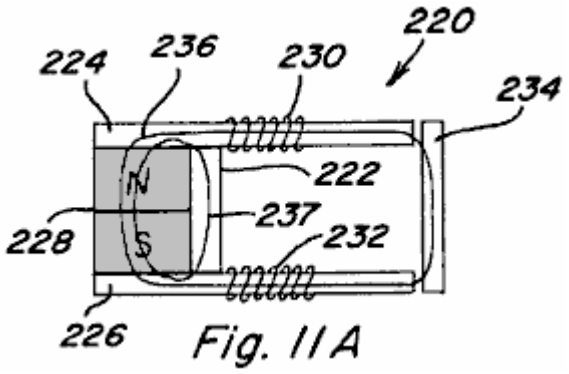

Fig. 11A

Reference is made to **Figs.11A-11F** which depict devices similar to that of **Figs.5-6** except that a bypass, formed of magnetic material, is provided in each case. In device **220** of **Figs.11A-11C** a bypass **222** is provided from pole piece **224** to pole piece **226** and is located between permanent magnet **228** and control coils **230**, **232**, with armature **234** located adjacent the ends of pole pieces **224**, **226**. In **Fig.11A** with no coil energisation, magnet flux components **236** and **237** travel as shown.

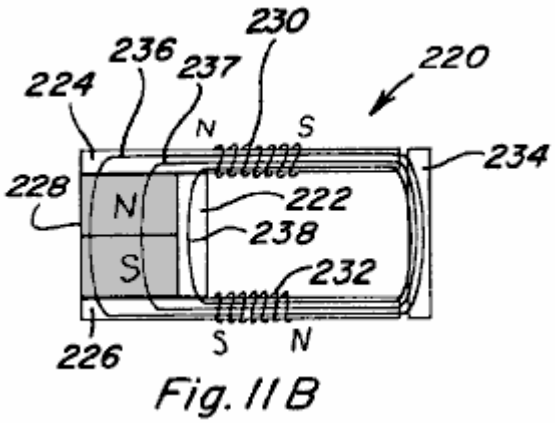

Fig. 11B

When coils **230** and **232** are energised in an aiding or adding manner as in **Fig.11B**, the result is permanent magnet magnetic flux components **236** and **237** travelling as shown, and with the added magnetic flux component

238 from coils **230** and **232** also travelling as shown. Thus, in device **220** energising the coils in an aiding manner results in an increased magnetic coupling force on armature **234**.

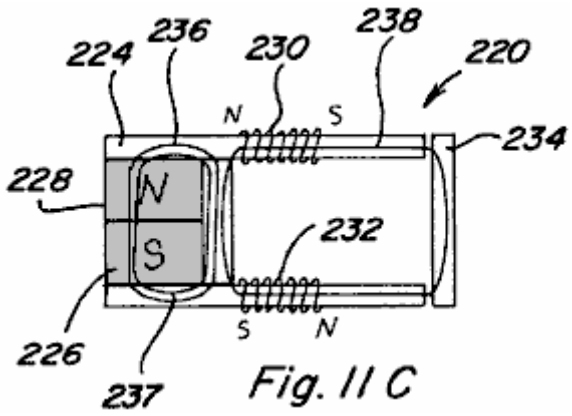

Fig. 11 C

In **Fig.11C** coils **230**, **232** are energised in an opposing exceeding manner which results in permanent magnetic flux components **236** and **237** travelling as shown and excess magnetic flux component **238** travelling as shown. Thus, in device **220** energising the coils in an opposing exceeding manner results in magnetic coupling force on armature **234**, albeit smaller than that in the aiding exceeding case.

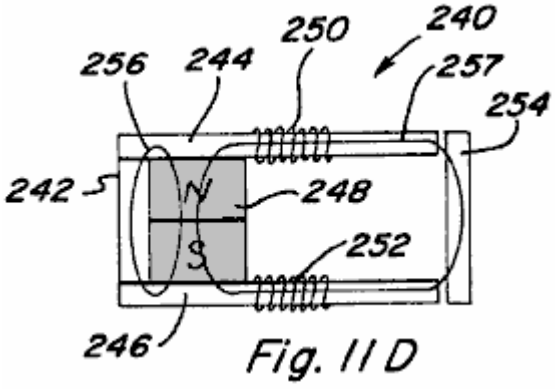

Fig. 11 D

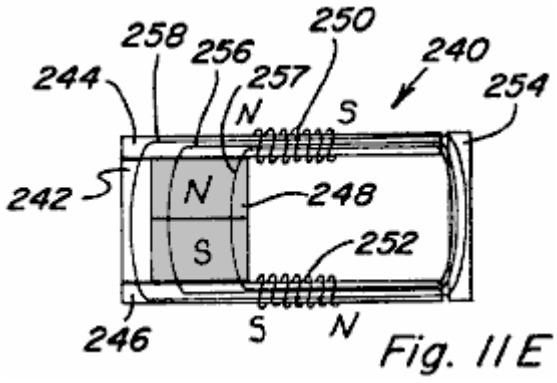

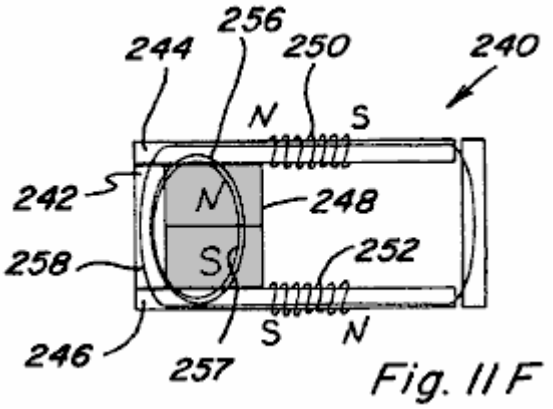

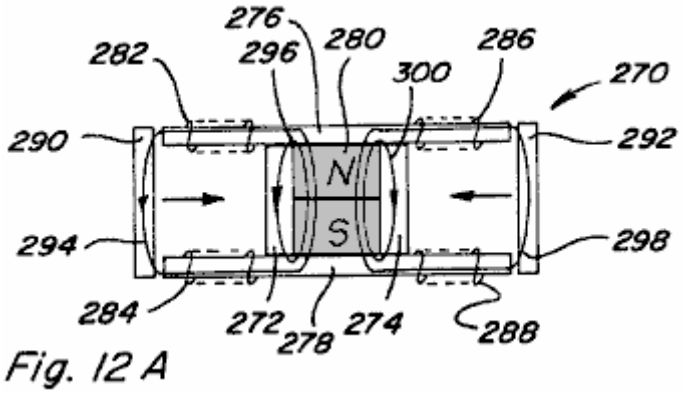

Fig. 11 E

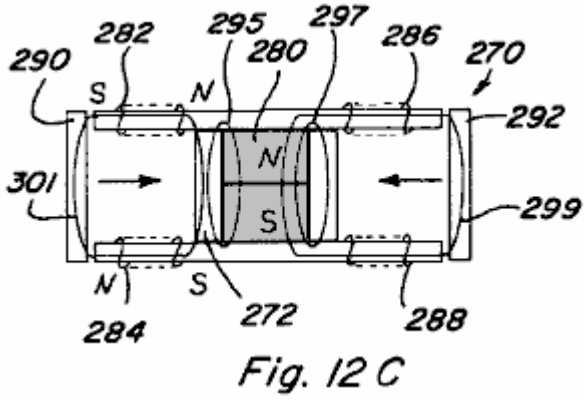

In device **240** of **Figs.11D-11F** a bypass **242** is provided between pole piece **244** and pole piece **246** but is located on an opposite side of permanent magnet **248** as compared to control coils **250**, **252** and armature **254**. Permanent magnet flux components **256** and **257** are shown for no coil energisation in **Fig.11D**. In **Fig.11E** the paths of permanent magnet flux components **256** and **257**, as well as excess coil magnetic flux **258**, are shown when coils **250**, **252** are energised in an aiding exceeding manner.

In **Fig.11F** the path of each magnetic flux component **256**, **257**, and **258** is shown when coils **230**, **232** are energised in an opposed exceeding manner.

Figs.12A-12E depict a device **270** similar to that shown in **Figs.7-9** except that bypasses **272** and **274** are provided from pole piece **276** to pole piece **278**. Bypass **272** is located between permanent magnet **280** and control coils **282**, **284** and bypass **274** is located between permanent magnet 280 and control coils **286**, **288**. Armatures **290** and **292** are also provided. When no coils are energised permanent magnet magnetic flux components **294**, **296**, **298**, and **300** travel as shown in **Fig.12A**.

If coils **282**, **284** are energised in an opposing manner permanent magnet flux components **295**, **297**, and **299** travel as shown, with no flux component traversing the path which includes armature **290** and therefore no magnetic coupling force acting thereon. This would be the case when coils **282**, **284** are energised to the level where the coils magnetic flux just blocks, but does not exceed, the magnetic flux component **294** (**Fig.12A**) from permanent magnet **280**. However, if coils **282**, **284** are energised in an opposed exceeding manner an excess coil magnetic flux component **301** is produced which travels a path including armature **290** and bypass **272** results as shown in **Fig.12C**.

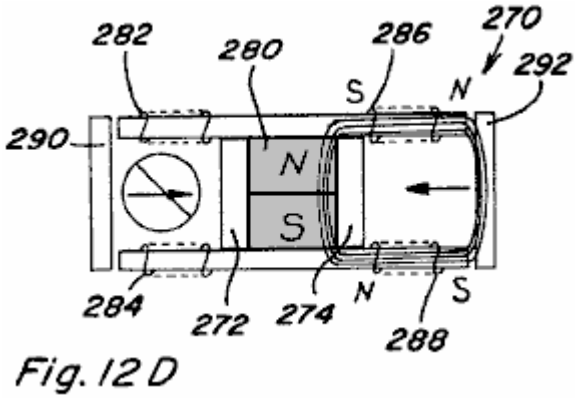

Fig. 12 D

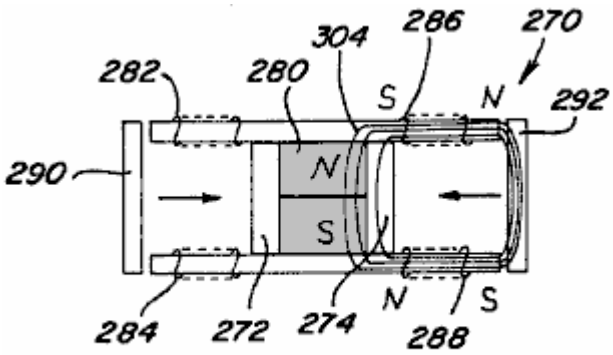

Fig. 12 E

Coils **286**, **288** may be energised in an aiding manner such that all permanent magnet magnetic flux travels along the path which includes armature **292** as shown in **Fig.12D**. If coils **286**, **288** are energised in excess of the level of **Fig.12D** then the excess magnetic flux component **304** traverses the path which includes armature **292** and bypass **274** as shown in **Fig.12E**, thereby increasing the magnetic coupling force on armature **292** as compared to **Fig.12D**. The advantage of incorporating such bypasses into permanent magnet control components in certain applications will become apparent below.

Reciprocating Motion

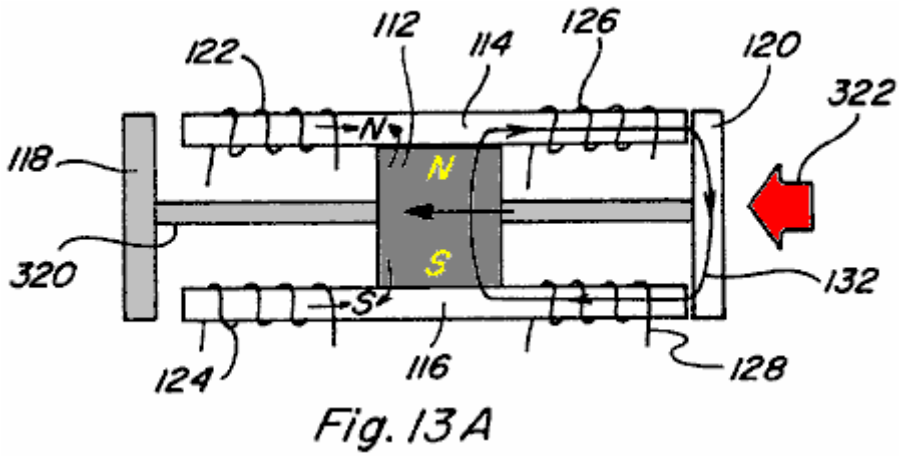

Fig. 13 A

As mentioned above, controlling the path of magnetic flux from a permanent magnet can be useful in a variety of applications such as achieving reciprocating motion. In this regard, if the device **110** of **Figs.7-9** is modified such that armatures **118** and **120** are fixed to a sliding shaft **320** as shown in **Figs.13A-13C**, and if the distance between the armatures is greater than the end to end length of pole pieces **114**, **116**, limited linear motion in two directions (left and right in **Figs.13A-13C**), and therefore linear reciprocating motion, can be achieved by the timed, alternate delivery of electrical signals to control coils **122**, **124** and control coils **126**, **128**. By way of example, **Fig.13A** represents the position of shaft connected armatures **118**, **120** when coils **122**, **124** are energised in an opposing manner to block the flux of permanent magnet **112** such that all magnetic flux traverses path **132** as shown and such that the resulting magnetic coupling force acts to the left as indicated by arrow **322**.

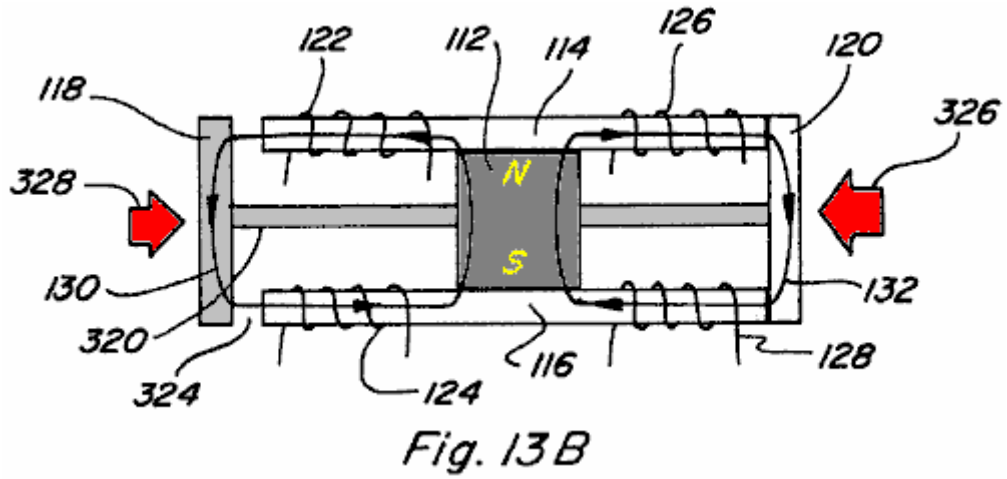

Fig. 13B

As shown in **Fig.13B** when coils **122**, **124** are de-energised the magnetic flux from permanent magnet **112** can again travel along path **130** through armature **118**. However, due to the air gap **324** between armature **118** and pole pieces **114**, **116** the reluctance along path **130** will be significantly greater than the reluctance along path **132**. Accordingly, the amount of magnetic flux which flows along path **130** will be less than the amount of magnetic flux which flows along path **132** such that the magnetic coupling force on armature **118** acting to the right will be significantly less than the magnetic coupling force on armature **120** acting to the left as shown by arrows **326** and **328**, which arrows are sized to represent the strength of the respective directional force.

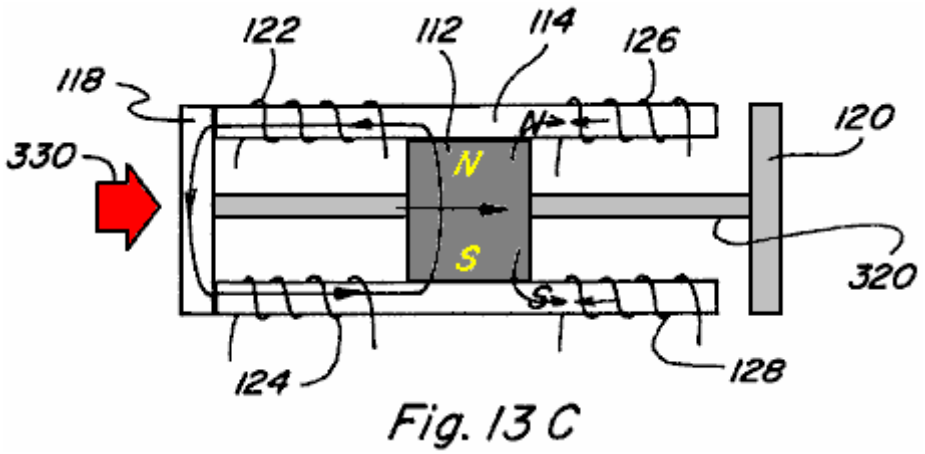

Fig. 13C

Fig.13C represents the position of shaft connected armatures **118**, **120** after coils **126**, **128** are energised in a manner to oppose the flux of permanent magnet **112** such that all flux traverses path **130** and the resulting magnetic coupling force on armature **118**, depicted by arrow **330**, moves the shaft **10** connected armatures **118**, **120** to the right.

Control coils **122**, **124** and **126**, **128** could also be energised in a flux aiding manner to achieve the same result. In such a device, **Fig.13A** would represent coils **126**, **128** energised to aid magnetic flux along path **132**, **Fig.13B** would again represent no coils energised, and **Fig.13C** would represent coils **122**, **124** energised to aid magnetic flux along path **130**.

Thus, by alternately energising and de-energising control coils **122**, **124** and **126**, **128** a linear reciprocating motion of shaft connected armatures **118**, **120** may be achieved. Further, such reciprocating motion may be achieved by energising the coils in either an opposing or aiding manner. The magnetic coupling force exerted on a given armature when **20** the control coils are energised to establish all magnetic flux along a single path which includes that armature is significantly greater than the magnetic coupling force which would be exerted on such armature by an identical energisation of the control coils in the absence of the permanent magnet.

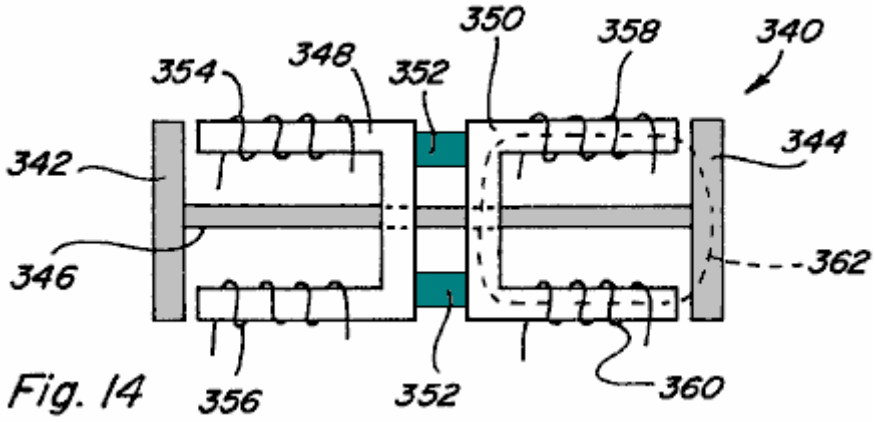

Fig. 14

This is demonstrated with reference to **Fig.14** which depicts a reciprocating device **340** in which only coils or electromagnets are utilised. As shown armatures **342** and **344** are connected by shaft **346**, and each armature **342**, **344** includes a respective U-shaped pole path piece **348**, **350** which pole path pieces are mechanically connected by a non-magnetic material **352**. Each pole path piece **348** and **350** has respective control coils **354**, **356** and **358**, **360** positioned along them. By comparison with the device of **Figs.13A-13C**, if coils **358**, **360** of device **340** are energised to cause magnetic flux flow in either direction, clockwise or counterclockwise, along path **362**, the amount of electrical energy which would be required in order to achieve the same magnetic coupling force on armature **344** as achieved on armature **120** above in **Fig.13A** would be twice that delivered to coils **122**, **124** or **126**, **128** in **Fig.13A**. It is therefore demonstrated, that by controlling or switching the flow of magnetic flux from a permanent magnet between at least two different paths results in greater coupling forces per unit of input electrical energy, and therefore that such control or switching will enable more work to be achieved per unit of input electrical energy.

As described above, if a coil is energised beyond the point where the magnetic flux produced by the coil aiding the amount of the permanent magnet's flux that is either opposed or aided, the extra magnetic flux needs a low reluctance path between the poles of the coil that produces the excess magnetic flux. If a complete low-reluctance path is not provided for the excess magnetic flux, there is little potential for taking advantage of the excess magnetic flux in terms of producing additional magnetic coupling forces. The path for such excess flux cannot be through a permanent magnet member. In assemblies which include an armature on each path, the armature will provide the necessary low-reluctance path.

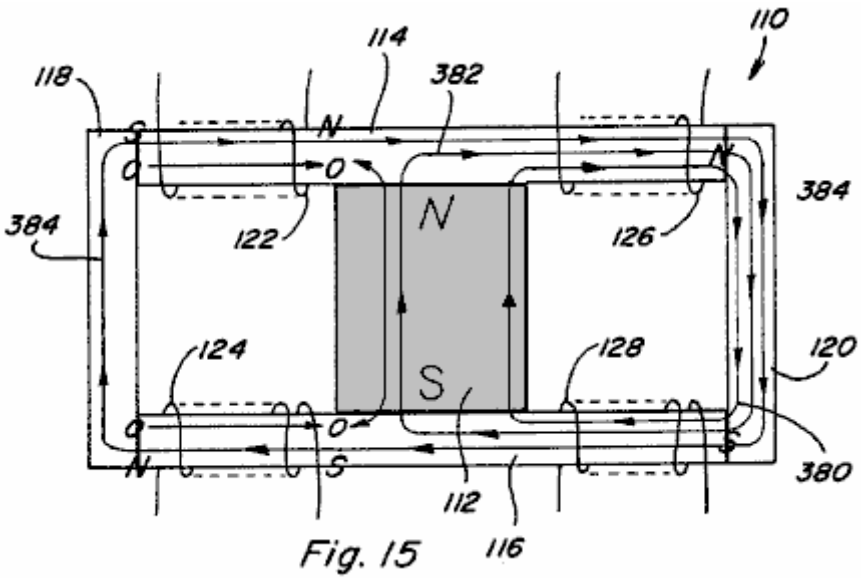

Fig. 15

Referring to **Fig.15**, various components of the magnetic flux in device **110** (**Figs.7-9**) are depicted by numerals **380**, **382**, and **384** for the case when coils **122**, **124** are energised to oppose the magnetic flux of permanent magnet **112** in an amount which exceeds the level of magnetic flux which permanent magnet **112** would cause to flow through armature **118** when no coils are energised. **Fig.15** is likewise representative of the case when coils **126**, **128** are energised to aid the magnetic flux of permanent magnet **112** by an amount which exceeds the level of magnetic flux which permanent magnet **112** would cause to flow through armature **118** when no coils are energised. In particular, magnetic flux component **380** represents the magnetic flux of permanent magnet **112** which normally flows through the path including armature **120**; magnetic flux component **382** represents the magnetic flux of permanent magnet **112** which is diverted by the opposing field of coils **122**, **124** so as to traverse

the path which includes armature **120**; and magnetic flux component **384** represents the magnetic flux produced by coils **122**, **124** which is in excess of the diverted magnetic flux **382**. As shown, the excess magnetic flux **384** produced by coils **122**, **124** traverses the path which includes armature **120** and bypasses permanent magnet **112** so as to also traverse the path which includes armature **118**. Thus, the excess magnetic flux produced by coils **122**, **124** adds to the permanent magnet flux traversing the path which includes armature **120**, thus increasing the magnetic coupling force on armature **120**, while at the same time providing a magnetic coupling force on armature **118**.

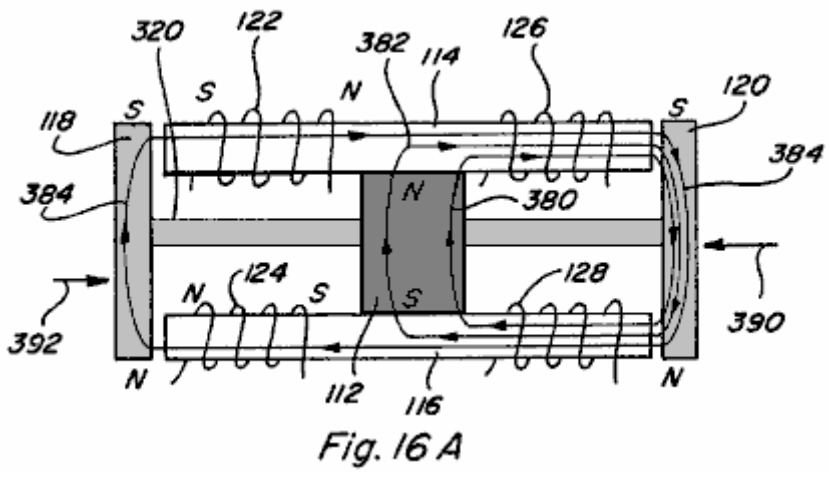

Fig. 16 A

In a reciprocating device where armatures **118** and **120** are connected by shaft **320** as shown in **Figs.13A-13C** and again in **Fig.16A**, excess magnetic flux **384** will increase magnetic coupling force **390** on armature **120** acting to the left. However, because such excess flux **384** also traverses the path which includes armature **118**, such excess magnetic flux **384** also results in a magnetic coupling force **392** on armature **118** which acts to the right. Even though excess magnetic flux **384** traversing the path which includes an armature **118** has an opposite polarity to that which would traverse the path due to permanent magnet **112**, the magnetic coupling force on armature **118** still acts to the right because armature **118** is not polarity sensitive, that is, armature **118** will be attracted regardless of the direction of the magnetic flux traversing the path. The overall effect is that a resultant force which is the difference between force **390** and force **392** will act on the shaft-connected armatures **118**, **120**. However, if armatures **118** and **120** were formed by permanent magnets having polarities as shown at the top and bottom of such armatures, the force acting on each armature would be in the same direction and therefore additive.

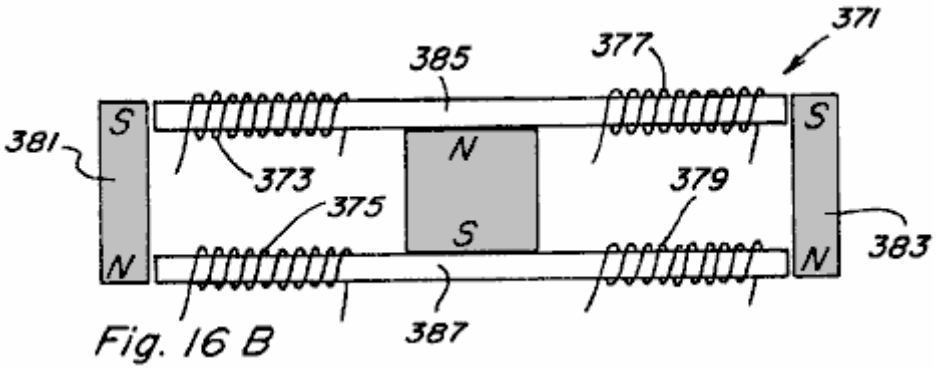

Fig. 16 B

In this regard reference is made to **Fig.16B** in which a two path device **371** having four control coils **373**, **375**, **377** and **379** is shown with the illustrated armatures being formed by permanent magnets **381** and **383** having polarities as shown. With no coils energised both permanent magnet armatures **381** and **383** are attracted to the ends of pole pieces **385** and **387**. With coils **373**, **375** energised in an opposing manner and coils **377**, **379** energised in an aiding manner, the attractive force on permanent magnet armature **383** will generally increase and the attractive force on permanent magnet armature **381** will generally decrease.

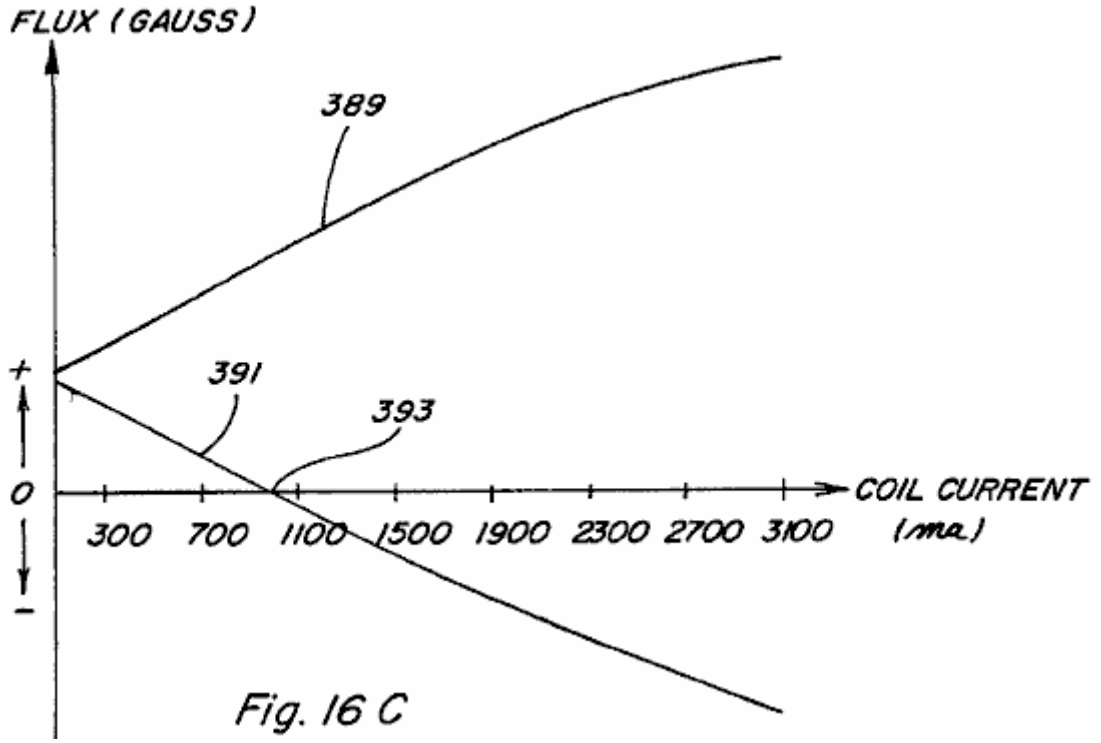

Fig. 16 C

This is demonstrated with reference to the graph of **Fig.16C** which depicts a graph of the current flowing in the control coils on the x-axis verses the magnetic flux in gauss on the y-axis with line **389** representing the flux along the aiding side of device **371** and line **391** representing the flux along the opposing side of device **371**. As shown, the magnetic flux on the coil opposing side decreases as the coil current increases and passes through zero at point **393**. After point **393**, reverse magnetic flux begins to be produced and would result in a repelling force on permanent magnet armature **381**. In some applications, particularly those where permanent magnet armatures and rotors are not utilised, it is critical to recognise point **393** so that reverse magnetic flux is not produced.

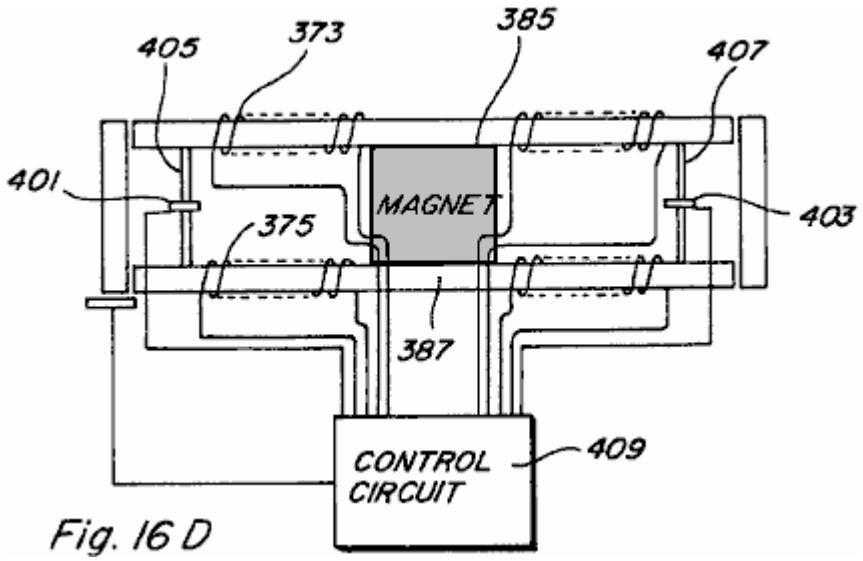

Fig. 16 D

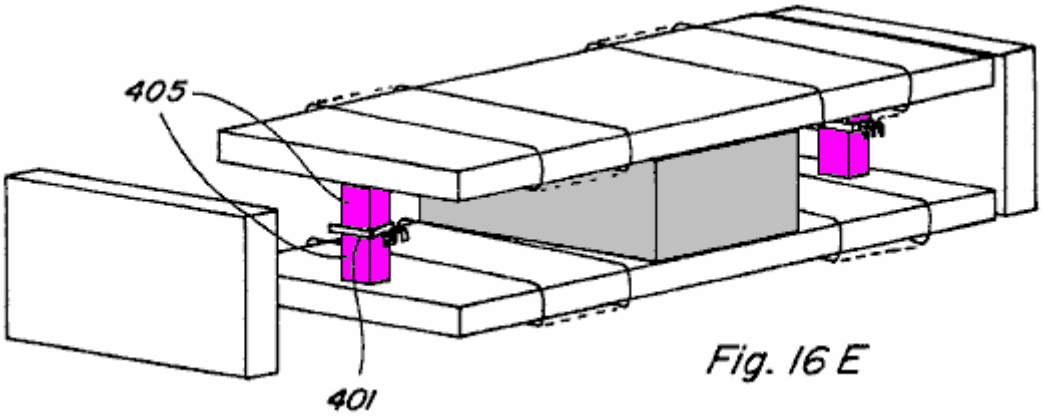

Fig. 16 E

In this regard, reference is made to **Fig.16D** and **Fig.16E**, in which use of Hall Effect switches **401** and **403** is made to enable control of the coil energising current in situations where it is desirable to prevent reverse magnetic flux. As shown, small bypasses **405** and **407** are provided with Hall Effect switches **401** and **403** positioned in gaps along them, the switches being connected to control circuit **409**. As the flux travelling along the bypass path falls to zero, the Hall Effect switch can be utilised to prevent further energisation of the control coils so that no reverse flux is created.

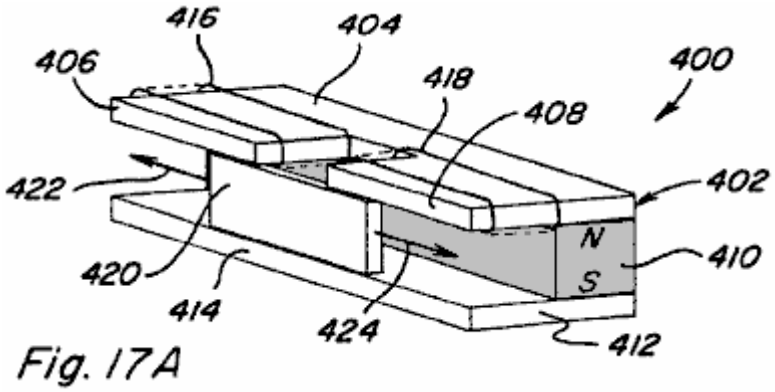

Fig. 17A

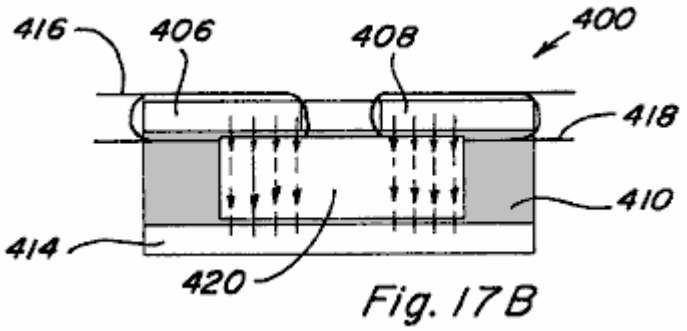

Fig. 17B

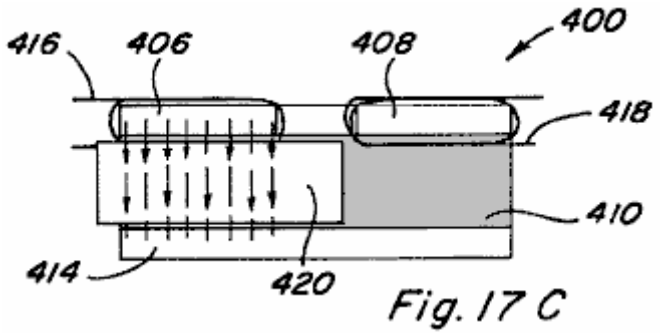

Fig. 17 C

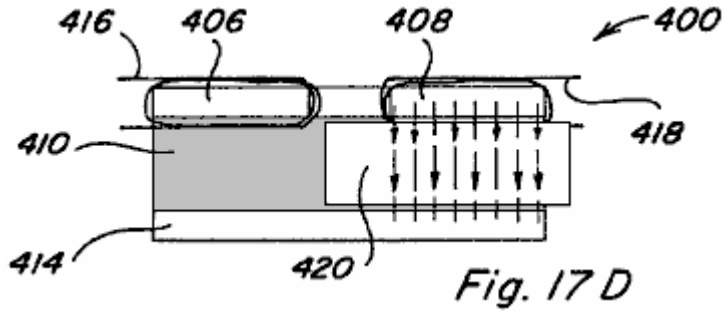

Fig. 17 D

Another embodiment of a device **400** which would provide reciprocating motion is shown in **Figs.17A-17D** in which a permanent magnet control component **402** having two flux paths may is provided. A first pole piece **404**, has two spaced, adjacent path portions **406** and **408** extending beyond the perimeter of the pole face of permanent magnet **410**, and a second pole piece **412** includes only one continuous portion **414** extending beyond the perimeter of the pole face of permanent magnet **410**, each path portion **406** and **408** of pole piece **404** being substantially aligned with at least a part of portion **414** of pole piece **412**. Control coil **416** is positioned along pole piece path portion **406** and control coil **418** is positioned along pole piece portion **408**. An armature **420** is positioned in the region between pole piece path portions **404**, **406** and pole piece portion **414** and is free to slide from side to side as shown by arrows **422** and **424**.

A front view of component device **400** with no coils energised and armature **420** at a mid-point depicts flux flowing from the north pole face of permanent magnet **410**, through each of pole piece path portions **406** and **408**, through armature **420**, and returning to the south pole face through pole piece portion **414**. Thus, the magnetic flux divides equally along two paths. If coil **416** is energised in an aiding manner, or if coil **418** is energised in an opposing manner, all or a majority of the magnetic flux of the permanent magnets can be made to flow through pole piece portion **406** so that a resulting magnetic coupling force on armature **420** causes it to move to the left as shown in **Fig.17C**.

Likewise, if control coil **416** is energised in an opposing manner, or if control coil **418** is energised in an aiding manner, all or a majority of the permanent magnet flux can be made to flow through pole piece path portion **408** such that a resulting magnetic coupling force on armature **420** causes it to move to the right as shown in **Fig.17D**. Accordingly, by alternately energising and de-energising coils **416** and **418** a reciprocating motion of armature **420** may be achieved.

Linear Motion

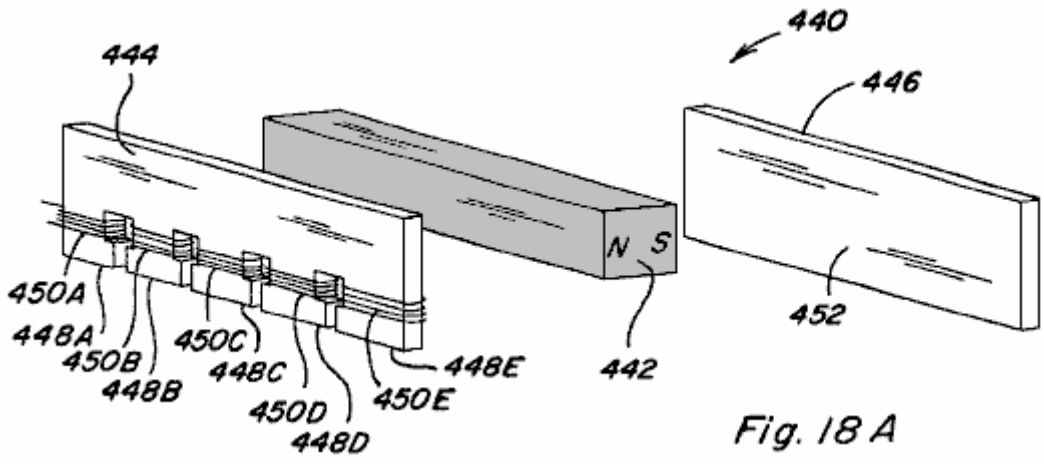

Fig. 18 A

Referring now to **Figs.18A-18E**, linear motion in accordance with the present invention is described. In particular, a permanent magnet control component **440** including a permanent magnet **442** with a pole piece **444** positioned against it's north pole face and a pole piece **446** positioned against it's south pole face is shown in an exploded view in **Fig.18A** and assembled in **Fig.18B**.

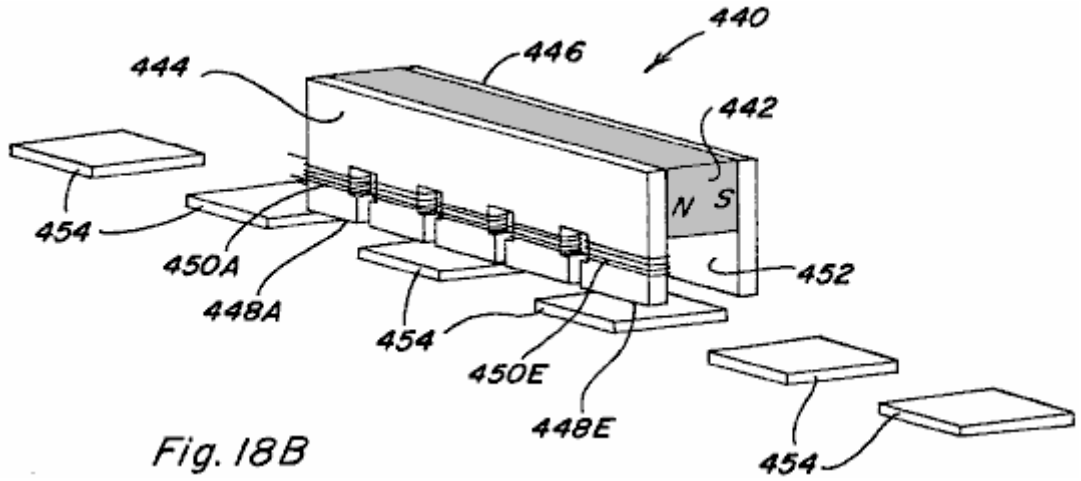

Fig. 18B

Pole piece **444** includes five path portions **448A-448E** which extend beyond the edge of the north pole face of permanent magnet **442** to one side of it and at respective positions along it's length, and it has path portion **448A-448E** each with a control coil **450A-450E** positioned around them. Pole piece **446** includes one portion **452** extending beyond the edge of the south pole face of permanent magnet **442** to the one side of it, and this portion **452** extends along the entire length of permanent magnet **442**. A number of armatures **454** define a path of relative movement between permanent magnet control component **440** and such armatures **454**, and by providing timed energisation of given control coils **450A-450E** such relative movement can be achieved.

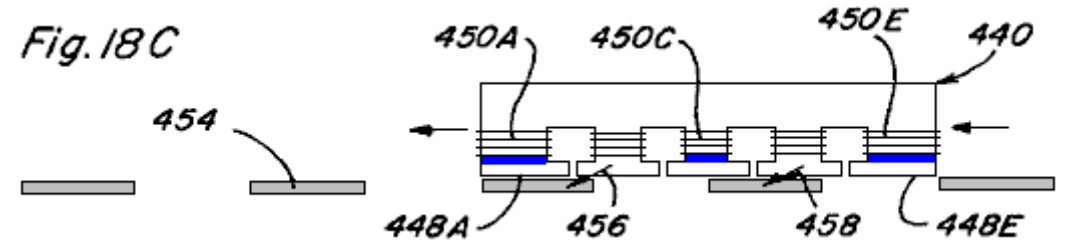

Fig. 18C

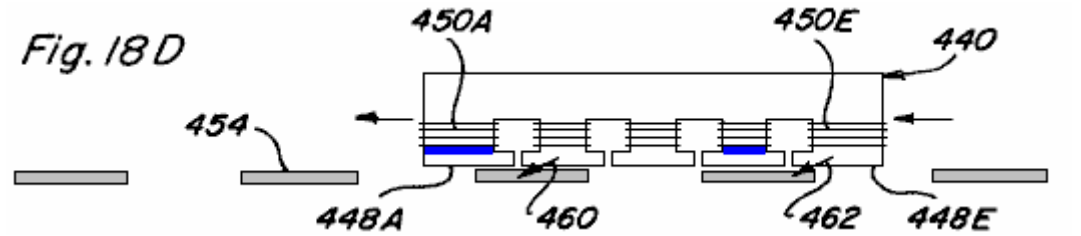

Fig. 18D

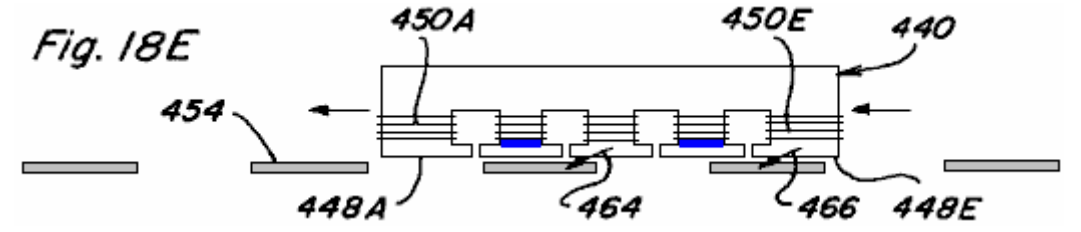

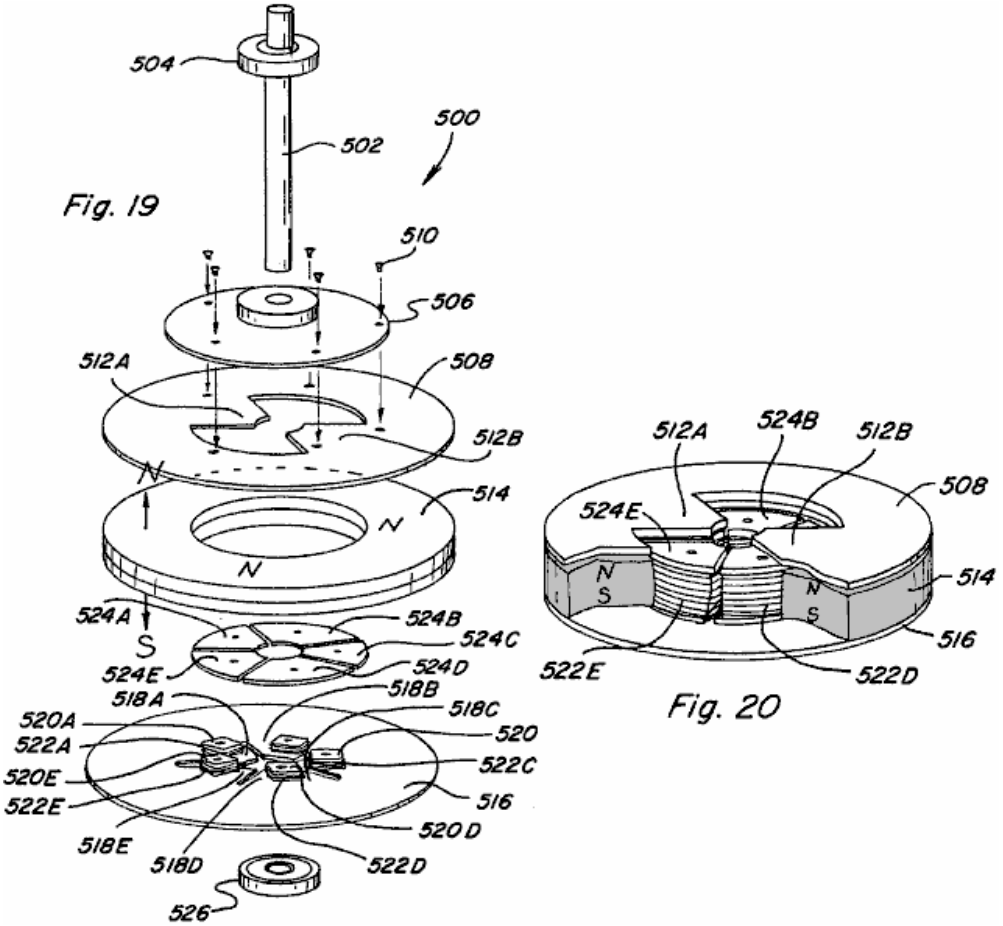

Fig. 18E

The sequence of side views depicted in **Figs.18C-18E** illustrate such relative movement,
with coils **450A**, **450C** and **450E** being **energised** in an opposing manner simultaneously in **Fig.18C**,
with coils **450A** and **450D** being **energised** simultaneously in an opposing manner in **Fig.18D**, and
with coils **450B** and **450D** being **energised** simultaneously in an opposing manner in **Fig.18E**.

In **Fig.18C**, magnetic flux will only flow along path portions **448B** and **448C** of pole piece **444** causing resultant magnetic coupling forces depicted by arrows **456**, **458** which act to move permanent magnet control component **440** to the left, assuming armatures **454** are fixed. Similarly, due to the timing of subsequent coil energisation resultant magnetic forces depicted by arrows **460**, **462** in **Fig.18D** and arrows **464**, **466** in **Fig.18E** act to continue movement of permanent magnet control component **440** to the left. Thus, if permanent magnet control component **440** were fixed to a device or structure, controlled movement of the device or structure along the path defined by armatures **454** could be achieved. Conversely, if permanent magnet control component **440** were fixed and armatures **454** were located on a device or structure, controlled movement of the device or structure

could also be achieved. It is also easily recognised that by varying the coil energisation sequence and timing relative movement in the opposite direction can be achieved. Further, if the permanent magnet was doughnut shaped and the armatures were arranged in a circumferential pattern, rotary motion would likewise be achievable.

Rotary Motion

One embodiment of a rotary motion device or motor **500** which incorporates various permanent magnet flux control aspects of the present invention is shown in the exploded view of **Fig.19** and in the partial assembled view of **Fig.20**. Motor **500** includes a rotor assembly which includes a shaft **502** and associated upper bearing **504**, a non-magnetic disk member **506** mounted for rotation with shaft **502**, and a rotor pole piece **508** which is mounted for rotation with disk member **506** such as by the use of screws **510**. Rotor pole piece **508** includes a ring-shaped portion having two inwardly extending magnetic flux path portions **512A** and **512B**. A stator assembly of motor **500** includes a doughnut or ring-shaped permanent magnet **514** having an upwardly directed north pole face positioned adjacent and in close proximity to rotor pole piece **508**, and a downward directed south pole face positioned adjacent and in contact with a stator pole piece **516**. Stator pole piece includes a ring-shaped portion having five inwardly projecting path portions **518A-518E**. Each path portion includes a respective winding post **520A-520E** extending therefrom and having a respective control coil **522A-522E** wound on it. Stator pole piece faces **524A-524E** are which can be positioned on respective winding posts **518A-518B** and, as shown in the partial assembly of **Fig.20**, are substantially aligned with the top surface of permanent magnet **514** so as to be which can be positioned adjacent rotor path portions **512A** and **512B** when aligned therewith. Each of winding posts **518A-518E** and stator pole piece faces are formed of magnetic material, and although shown as separate pieces, an integral, one piece stator could be formed with similar winding posts and pole piece faces machined on it. Lower bearing **526** is also shown.

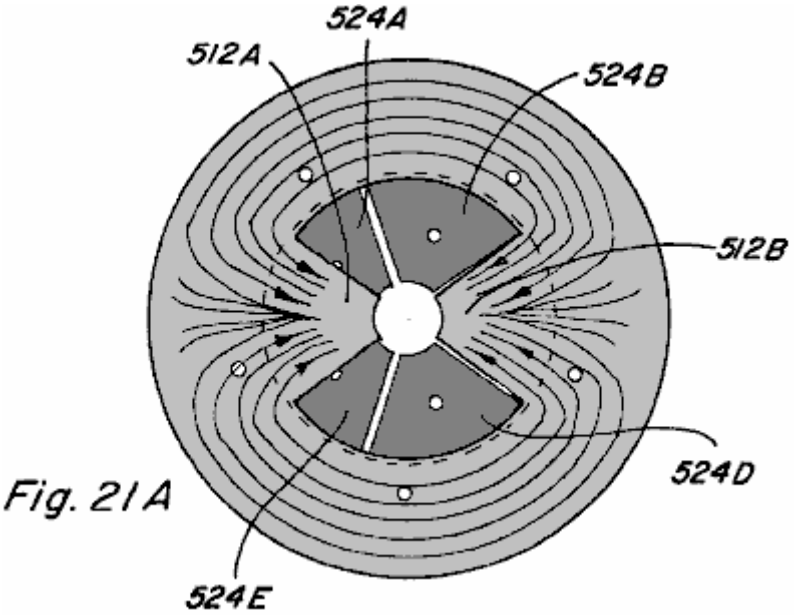

Fig. 21A

Figs.21A-21E illustrate top views of the partial assembly of **Fig.20** with magnetic flux shown. In **Fig.21A** magnetic flux travel when none of coils **522A-522E** are energised is depicted. Disregarding leakage flux, due to the low-reluctance path provided by rotor pole piece path portions **512A** and **512B**, the majority of magnetic flux from the north pole face of permanent magnet **514** will travel radially inward along one of such path portions before passing downward through the stator assembly and returning to the south pole face of permanent magnet **514**. It is noted that rotor pole piece **508** includes two path portions and stator pole piece **516** includes five path portions such that rotor pole piece path portions **512A** and **512B** will always be skewed relative to the stator pole piece faces **524A-524E**. Only one rotor pole piece path portion can directly align with a stator pole piece face at a given time. By alternately energising the control coils of each of the stator pole piece paths, rotary motion of the rotor may be achieved.

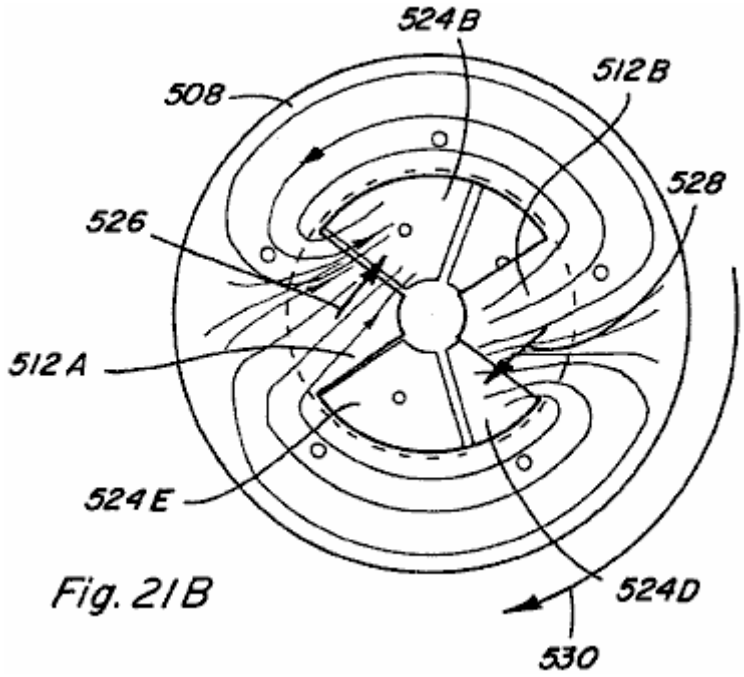

Fig. 21B

In particular, referring to **Figs.21B-21D**, an energising sequence which results in such rotary motion is described. In **Fig.21B**, control coils **522A** and **522C** are energised in a permanent magnet flux opposing manner. Permanent magnet magnetic flux travelling along rotor pole piece path portion **512A** tends to traverse to stator pole piece face **524B** causing a magnetic coupling force indicated by arrow **526**. Likewise, permanent magnet flux travelling along rotor pole piece path portion **512B** tends to traverse to stator pole piece face **524D** causing a magnetic coupling force indicated by arrow **528**. The result is rotation of rotor pole piece **508** in a clockwise direction as indicated by arrow **530**.

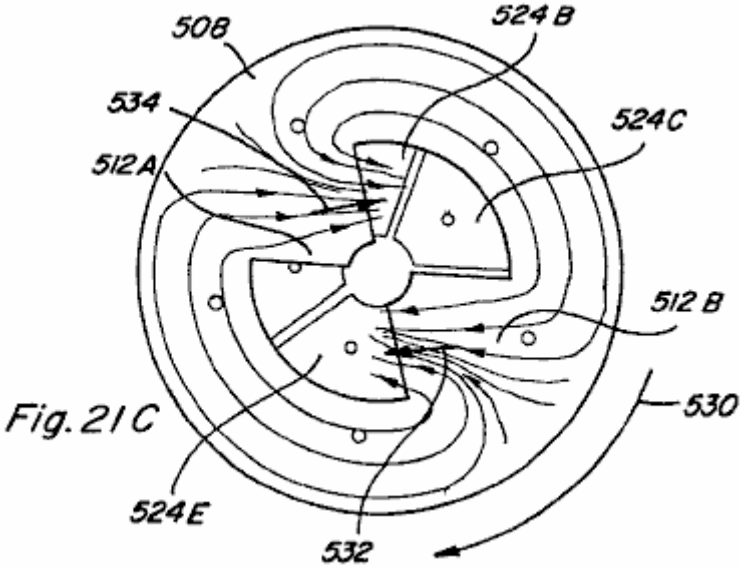

Fig. 21C

Referring to **Fig.21C**, just after rotor pole piece path portion **512B** is no longer aligned with stator pole piece face **524D**, control coil **522C** is de-energised and control coil **522D** is energised in an opposing manner such that the permanent magnet flux travelling along rotor pole piece path **512B** tends to traverse to stator pole piece face **524E** resulting in magnetic coupling force indicated by arrow **532**. Control coil **522A** remains energised such that a magnetic coupling force indicated by arrow **534** results. Accordingly, clockwise rotation of rotor pole piece **508** is continued.

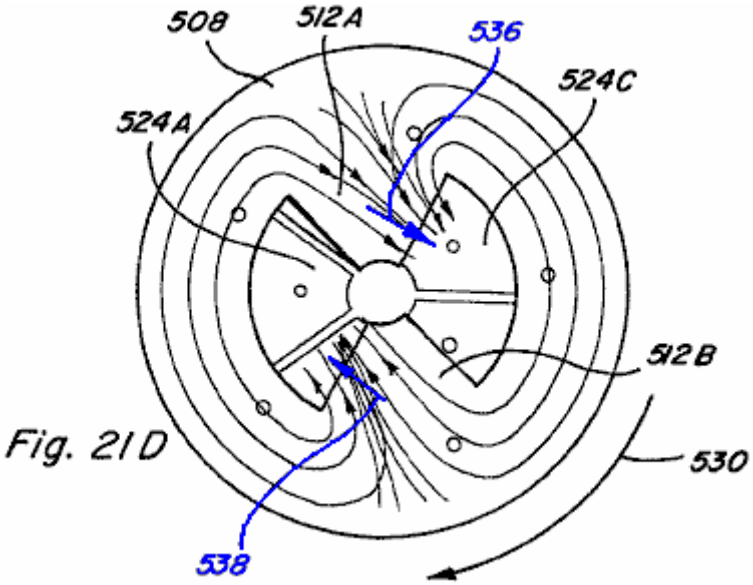

Fig. 21D

In **Fig.21D**, just after rotor pole piece path portion **512A** is no longer aligned with stator pole piece face **524B**, control coil **522A** is de-energised and control coil **522B** is energised in a permanent magnet magnetic flux opposing manner such that the permanent magnet magnetic flux travelling along rotor pole piece path **512A** tends to traverse to stator pole piece face **524C** such that a magnetic coupling force indicated by arrow **536** results. Control coil **522D** remains energised such that a magnetic coupling force indicated by arrow **538** results, and clockwise rotation of rotor pole piece **508** is continued.

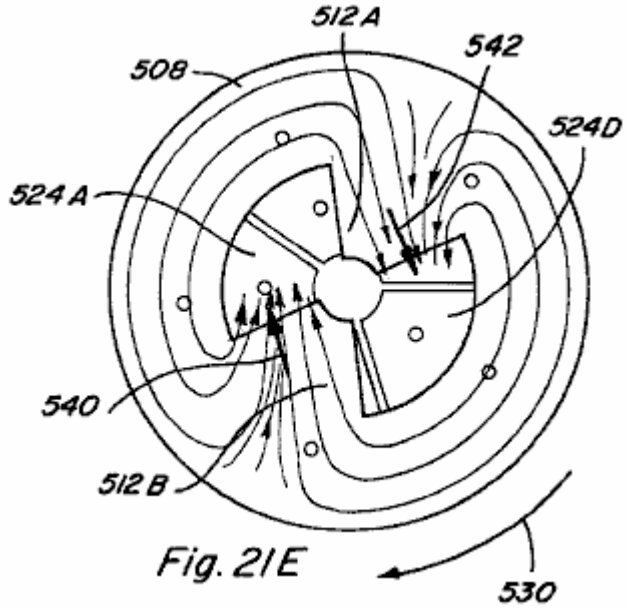

Fig. 21E

As shown in **Fig.21E**, just after rotor pole piece path portion **512B** is no longer aligned with stator pole piece face **524E**, control coil **522D** is de-energised and control coil **522E** is energised in a permanent magnet magnetic flux opposing manner such that the permanent magnet magnetic flux travelling along rotor pole piece path **512B** tends to traverse to stator pole piece face **524A** such that a magnetic coupling force indicated by arrow **540** results. Control coil **522B** remains energised such that a magnetic coupling force indicated by arrow **542** results, and clockwise rotation of rotor pole piece **508** is continued.

Thus, by alternating energising and de-energising control coils **522A-522E**, in a predetermined timed sequence based upon rotation of the rotor assembly, continued rotation movement of rotor pole piece **508** may be achieved. Such an energisation/de-energisation scheme can be achieved utilising circuitry common in the art, such as the control circuitry described in Applicant's U.S. Pat. Nos. 5,463,263 and 5,455,474, as well as various of the circuit configurations described below.

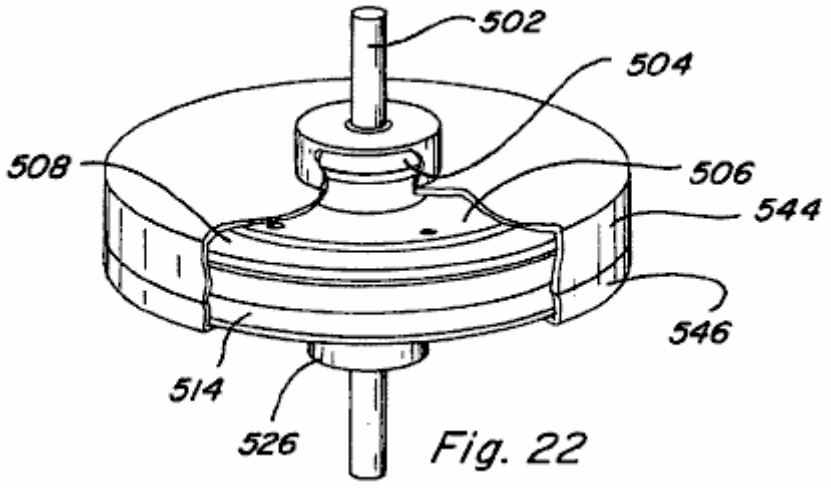

Fig. 22

Referring now to **Fig.22**, an assembled view of rotary motor **500** is shown including a housing or cover formed by an upper housing member **544** and a lower housing member **546**, with portions of each housing member cut away to expose motor structure described above. It is recognised that such housing members **544** and **546** should be constructed from a non-magnetic material, and likewise that motor shaft **502** and bearings **504**, **526** should be constructed from a non-magnetic material.

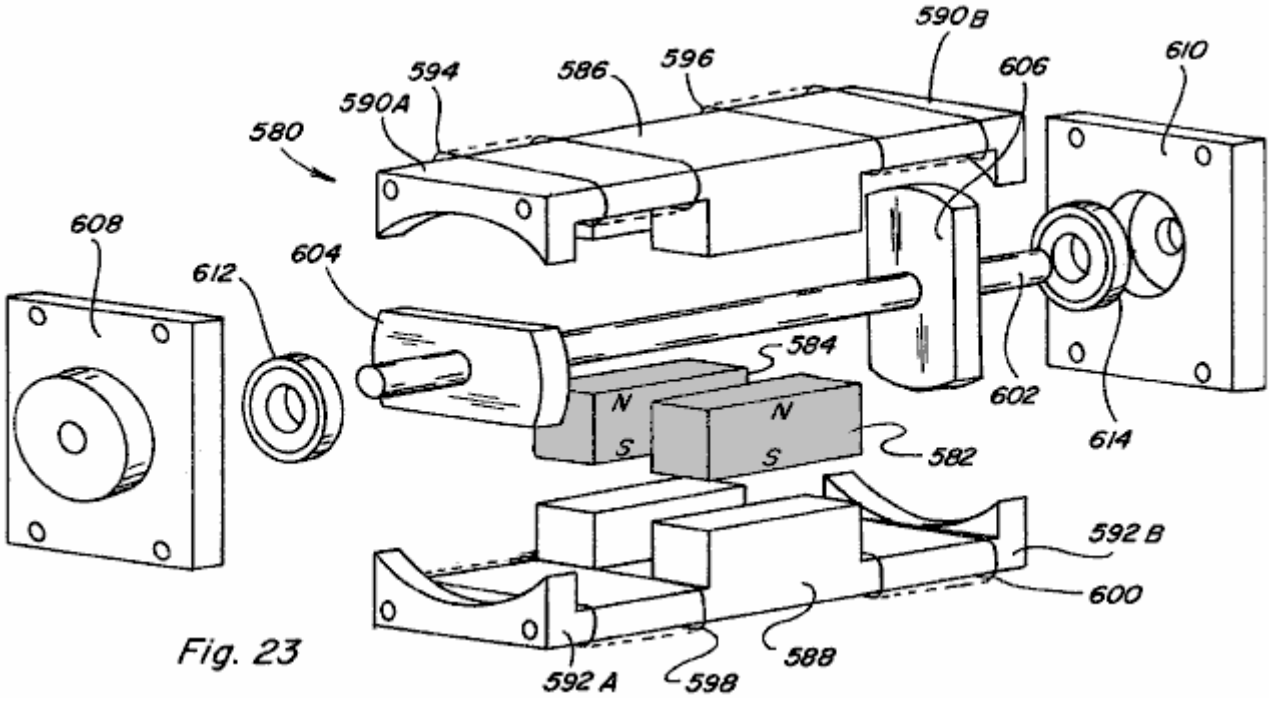

Fig. 23

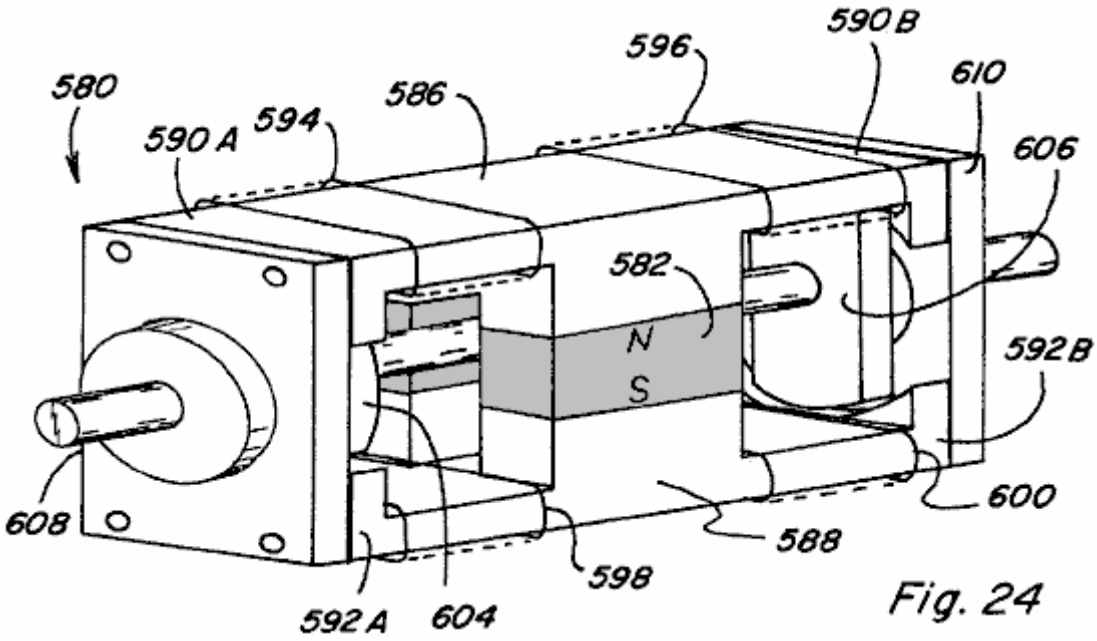

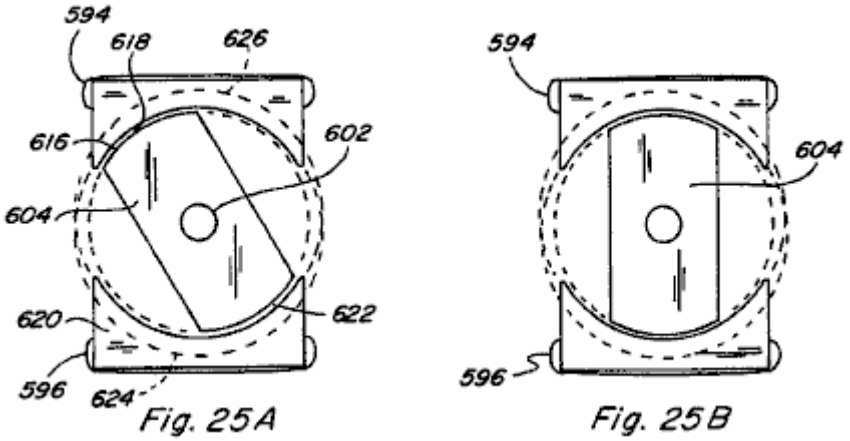

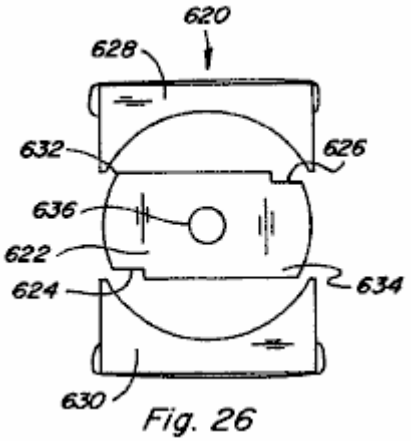

Fig. 24

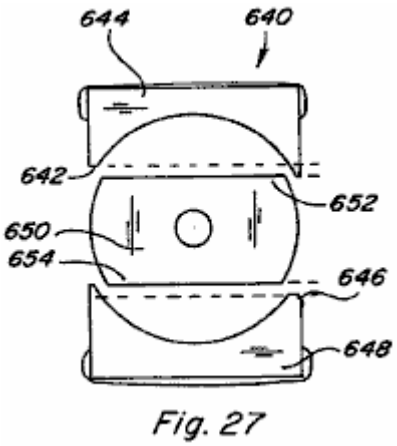

In another embodiment, a rotary motion device or motor **580** in accordance with the present invention is shown in an exploded perspective view in **Fig.23** and in an assembled perspective view in **Fig.24**. Two spaced permanent magnets **582** and **584** are positioned between stator pole pieces **586** and **588**. Stator pole piece **586** includes two path portions **590A** and **590B** extending away from permanent magnets **582**, **584** in opposite directions. Likewise, stator pole piece **588** includes two path portions **592A** and **592B** extending away from permanent magnets **582**, **584** in opposite directions and which can be aligned with stator pole piece path portions **590A** and **590B**. Control coils **594**, **596**, **598**, and **600** are each positioned along a stator pole piece path portion as shown. A non-magnetic shaft **602** includes a pair of matching elongated rotor members **604** and **606**, formed of magnetic material, mounted at spaced locations on the shaft and being set at an angle to each other, shaft **602** passing between spaced permanent magnets **582** and **584**. Two end cap members **608** and **610**, made from non-magnetic material, are attached to the ends of stator pole pieces **586** and **588** and are configured for receiving shaft **602** and respective bearings **612** and **614**.

The ends of the stator pole pieces **506** and **508** are configured for a given desired coupling relationship with rotor members **604** and **606**. For example, as shown in the exemplary end views of **Fig.25A** and **Fig.25B**, with end cap **608** removed, the end of stator pole piece **586** may include an curved portion **616** which is configured to create a variable-reluctance air gap **618** with elongated rotor member **604**. The end of stator pole piece **588** includes an curved portion **620** which is also configured to create a variable-reluctance air gap **622** with rotor member **604**.

In particular, portion **618** includes a circumferential curvature which has a centre point offset below the axis of rotation of shaft **602** and rotor member **604** as indicated by circle **624** shown in shadow. Similarly, portion **620** includes a circumferential radius of curvature which has a centre point offset above the axis of rotation of shaft **602** and rotor member **604**. When magnetic flux is passing along the path which includes a given end of the assembly, maximum coupling between the rotor member and stator pole pieces occurs when the rotor is positioned as shown in **Fig.25B**. Accordingly, the illustrated rotor member and stator pole piece configurations of themselves do not provide any skewing to the direction of rotation of the rotor assembly.

In this regard, various configurations for the rotor and ends of the stator pole piece are shown in the end views of **Figs.26-28**, which configurations provide skewing the direction of rotation. In particular, in device **620** of **Fig.26** a

rotor member **622** having notches **624** and **626**, which notches provide for greater magnetic coupling with the stator pole pieces **628** and **630** at corners **632** and **634** such that rotation is skewed in the clockwise direction. If notches were instead located at corners **632** and **634**, skewed rotation in the counterclockwise direction would be the result. In device **620** such counterclockwise rotation could also be achieved by removing rotor **622** from shaft **636**, flipping it end to end, and replacing it on shaft **636**.

In the device **640** of **Fig.27**, a portion **642** of the curved end portion of stator pole piece **644** is removed and a portion **646** of the curved end portion of stator pole piece **648** is removed. This configuration results in greater magnetic coupling between rotor member **650** and stator pole piece **644** at corner **652**, and greater magnetic coupling between rotor member **650** and stator pole piece **648** at corner **654**, such that rotation is skewed in the counterclockwise direction. Clockwise rotation could be achieved by instead modifying the opposite side of stator pole pieces **644** and **648**.

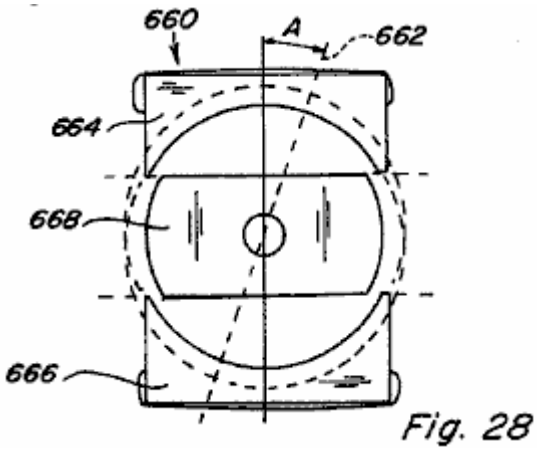

Fig. 28

Fig.28 depicts an end view of a device **660** in which the axis **662** of the curved end portion of upper stator pole piece **664** and lower stator pole piece **666** is placed at an angle **A** as shown. This configuration creates an unequal variable-reluctance air gap where opposite corners of rotor member **668** are closer to stator pole pieces **664** and **666**. Further, the angle at which maximum magnetic coupling between rotor member **668** and stator pole pieces **664** and **666** occurs is retarded by angle **A**. Rotation would be in the counterclockwise direction for the illustrated configuration.

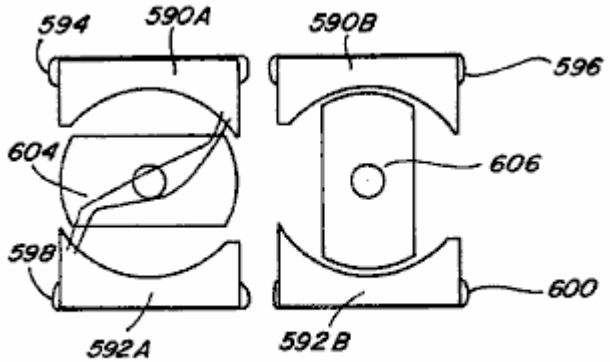

Fig. 29A

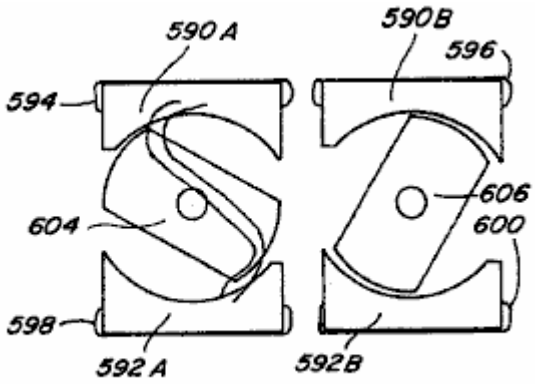

Fig. 29B

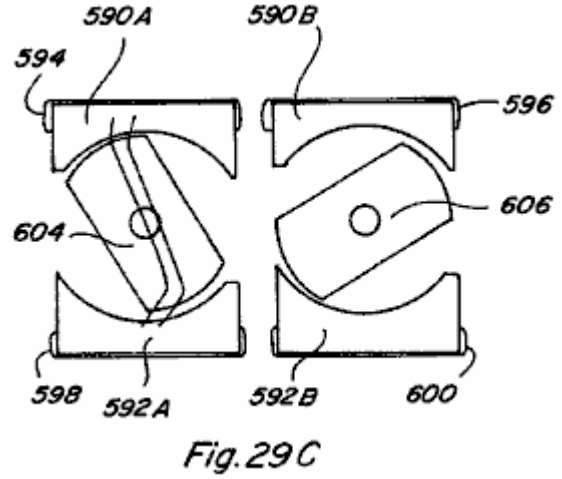

Fig. 29C

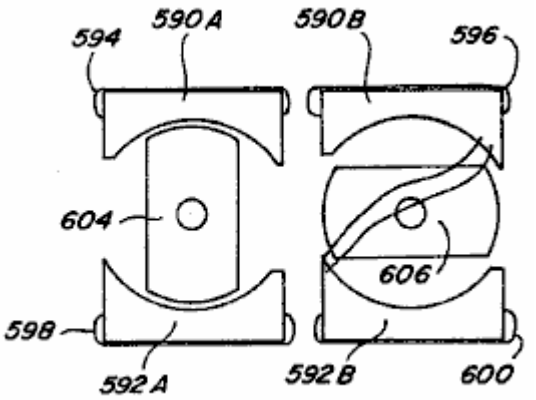

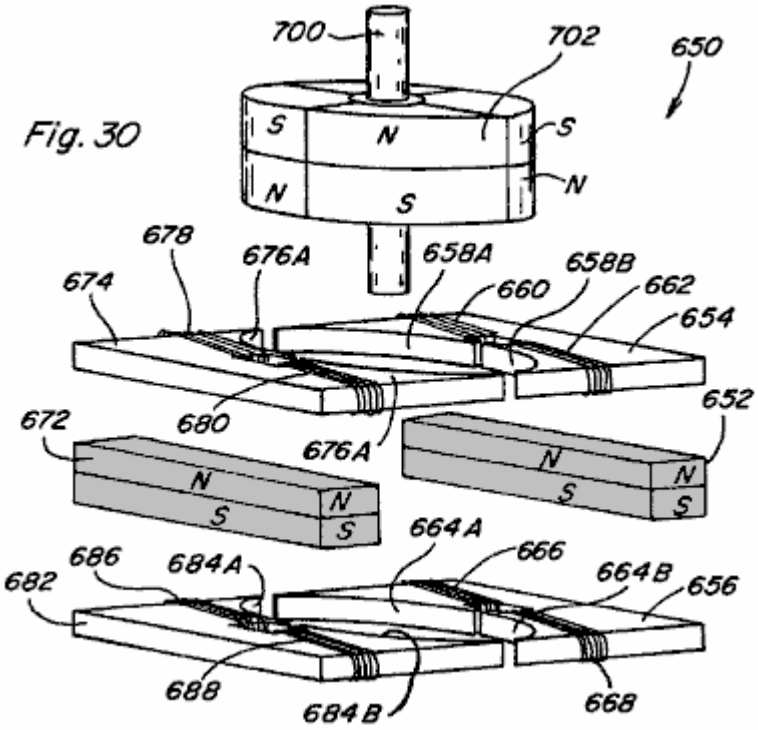

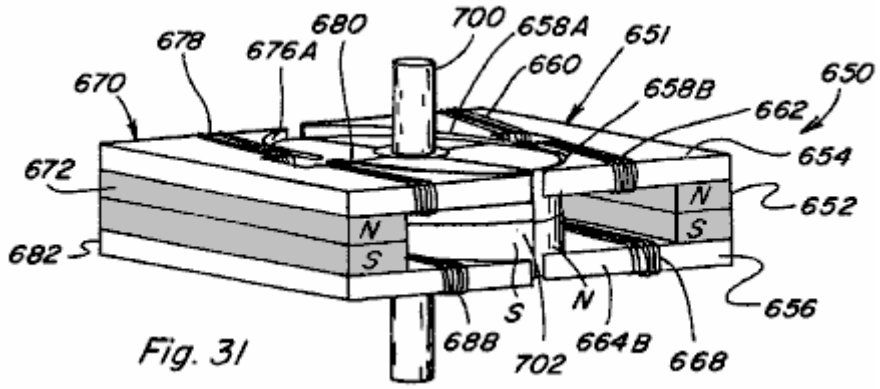

Fig. 29 D

Referring again to motor **580** of **Figs.23-25**, rotary motion of such device is depicted in the end views of **Figs.29A-29D**. In each end view the end cap has been removed to show rotation of the rotor members and in each of **Figs.29A-29D** an end view depicting rotor member **604** and an end view depicting rotor member **606** are shown side-by-side. In **Fig.29A**, rotor member **604** is defined as being at zero degrees and rotor member **606** is defined as being at ninety degrees. Control coils **594**, **598** are energised in a permanent magnet magnetic flux aiding manner such that no magnetic flux passes through stator pole piece path portions **590B** and **592B**. This allows rotor member **606** to move out of its ninety degree position and the magnetic coupling between rotor member **604** and stator pole piece path portions **590A** and **592A** will cause rotation to the position shown in **Fig.29B** and then **Fig.29C**. When rotor member **604** reaches the ninety degree position shown in **Fig.29D** control coils **594**, **598** are de-energised and control coils **596**, **600** are energised in a permanent magnet magnetic flux aiding manner causing rotation to continue due to the magnetic coupling between rotor member **606** and stator pole piece path portions **590B** and **592B**. Thus, by alternately energising the control coils of each path with every ninety degree rotation of rotor members **604** and **606**, continuous rotary motion is achieved.

The initial direction of rotation can be controlled by the circuit means used to energise control coils **594**, **598** and **596**, **600**, which circuit means includes circuitry for detecting the angular position of the rotor members. In particular, if rotor members **604** and **606** are at rest in the position shown in **Fig.29A**, and coils **594**, **598** are energised in an aiding manner, rotation may be clockwise or counterclockwise. If the desired direction is clockwise but upon energisation of coils **594**, **598** the rotor members begin to move counterclockwise, the detection circuitry will immediately de-energise coils **594**, **598** and energise coils **596**, **600** so that the clockwise direction is achieved.

Further, bypasses around permanent magnets **582** and **584** could be provided in rotary motion device **580**, such as those shown in **Fig.12**, and rotor members **604** and **606** could be formed by permanent magnets so as to take advantage of energising the control coils in an exceeding manner.

A third embodiment of a rotary motion device or motor **650** is shown in the exploded partial perspective view of **Fig.30** and in the assembled partial perspective view of **Fig.31**. In motor **650** the stator assembly includes a control component **651** including a permanent magnet **652** having a stator pole piece **654** positioned adjacent to one pole face of the magnet and a stator pole piece **656** positioned adjacent to the opposite pole face. Stator pole piece **654** includes a path portion **658A** extending to one side of permanent magnet **652** and a path portion **658B** extending to the one side thereof and spaced from first path portion **658A**. Control coils **660** and **662** are positioned along respective stator pole piece path portions **658A** and **658B**.

In the same way, stator pole piece **656** includes path portions **664A** and **664B** which extend in a similar manner from it so as to be aligned with stator path portions **658A** and **658B** respectively. Control coils **666** and **668** are positioned along respective stator pole piece path portions **664A** and **664B**. Positioned opposite, and facing control component **651**, is a similar control component **670** including permanent magnet **672** stator pole piece **674** with path portions **676A** and **676B** having the control coils **678** and **680**, and stator pole piece **682** with path portions **684A** and **684B** having their control coils **686** and **688**. The end of each of the pole piece path portions **658A, 658B, 664A, 664B, 676A, 676B, 684A**, and **684B** is of a generally curved configuration.

A rotor assembly of motor **650** includes a non-magnetic shaft **700** having a permanent magnet rotor member **702** mounted on it and which rotates with it. Permanent magnet rotor member **702** is generally ring-shaped and segmented to include distinct north and south pole faces which reverse about every ninety degrees around them. When assembled, the top and bottom surfaces of permanent magnet rotor member **702** align with pole pieces **654, 656, 674**, and **682** of the stator assembly and are preferably configured so that there is a minimal gap between the outer surface of permanent magnet rotor member **702** and the curved surfaces of the pole piece path portions.

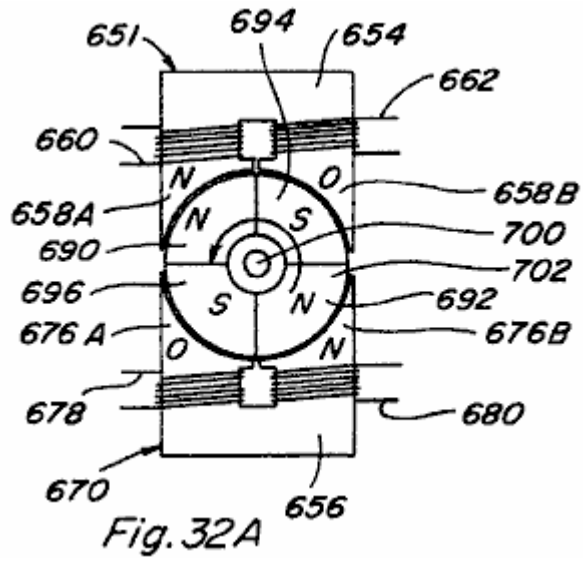

Fig. 32A

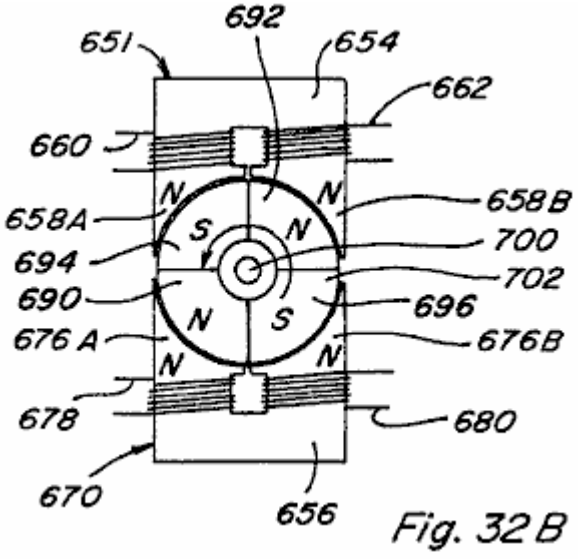

Fig. 32B

Rotation of device **650** can be achieved by controlled, timed energising and de-energising of control coils **660, 662, 666, 668, 678, 680, 686**, and **688**. Exemplary rotation is demonstrated with reference to the top views of **Figs.32A-32B** which depict counterclockwise rotation of permanent magnet rotor member **702** through one-hundred and eighty degrees. In **Fig.32A** stator pole piece path portion **658A** of component **651** is active and stator pole piece path portion **658B** is not active, which may be achieved by energising control coil **660** in a permanent magnet magnetic flux aiding manner or by energising control coil **662** in a permanent magnet magnetic flux opposing manner. Stator pole piece path portion **676B** of component **670** is active and stator pole piece path portion **676A** is not active, which may be achieved by energising control coil **680** in a permanent magnet magnetic flux aiding manner or by energising control coil **678** in a permanent magnet magnetic flux opposing manner.

Thus, portions **690** and **692** of permanent magnet rotor member **702**, which both have a north magnetic polarity, will be repelled by the north polarity of stator pole piece path portions **658A** and **676B** aligned with it. Portions **694** and **696** of permanent magnet rotor member **702**, both of which have a south magnetic polarity, will be attracted to the active path portions **658A** and **676B**. At the instant that rotor member portion **694** becomes aligned with stator pole piece path portion **658A**, as shown in **Fig.32B**, all coils are de-energised such that all pole piece path portions will be active as shown. Pole piece path portions **658B** and **676A** are then kept active while pole piece path portions **658A** and **676B** are made inactive. This is achieved by energising control coils **662** and **678** in a permanent magnet magnetic flux aiding manner or by energising control coils **660** and **680** in a permanent magnet magnetic flux opposing manner. Rotor member portions **690** and **692** will again be repelled by the north polarity of path portions **658B** and **676A** aligned with it so that rotation of permanent magnet rotor **702** is continued.

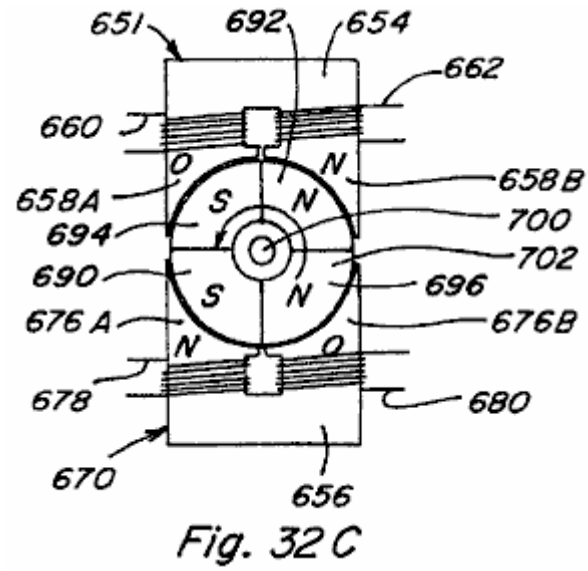

Fig. 32C

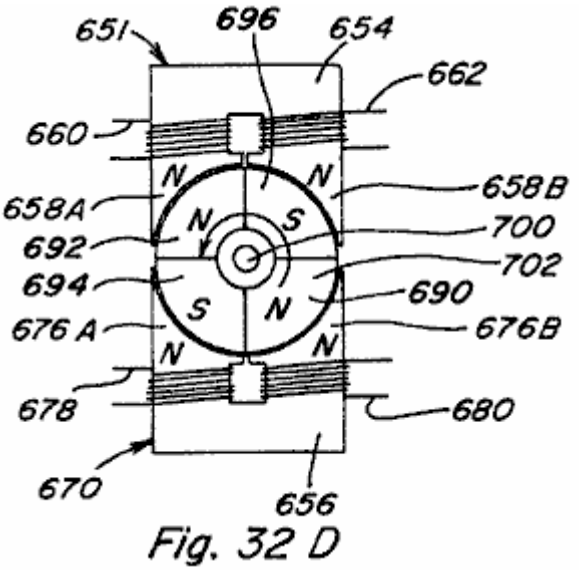

Fig. 32D

In **Fig.32D** all coils are shown de-energised when rotor portion **692** aligns with pole piece path portion **658A**. By continuing this timed sequence of energisation and de-energisation of the control coils, continued rotary movement is achieved. As explained above, the initial direction of rotation can be controlled by circuit means

which detects the initial direction of permanent magnet rotor **702** and immediately alters the coil energisation scheme if the initial direction is incorrect.

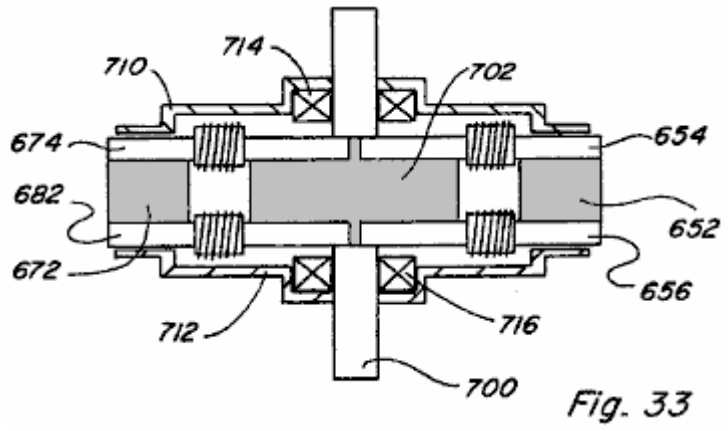

Fig. 33

A side view of assembled motor **650** is shown in **Fig.33** and includes an upper housing or enclosure portion **710**, a bottom housing portion **712**, upper bearing **714**, and a lower bearing **716**.

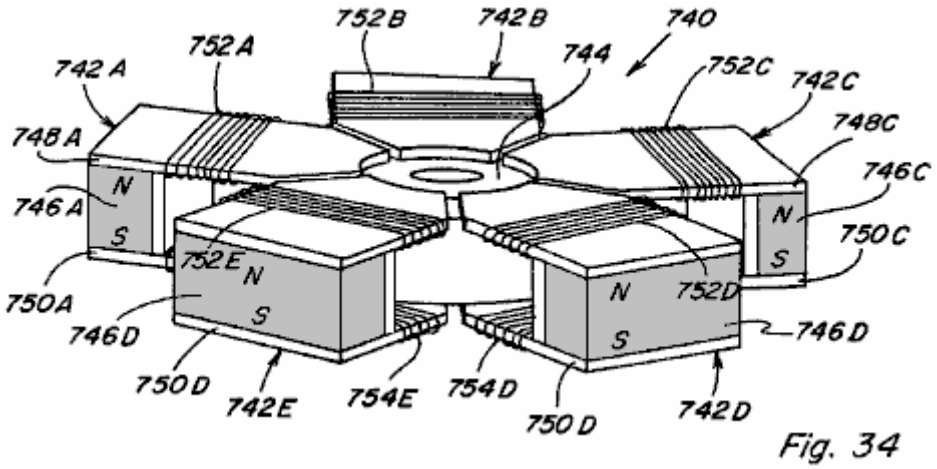

Fig. 34

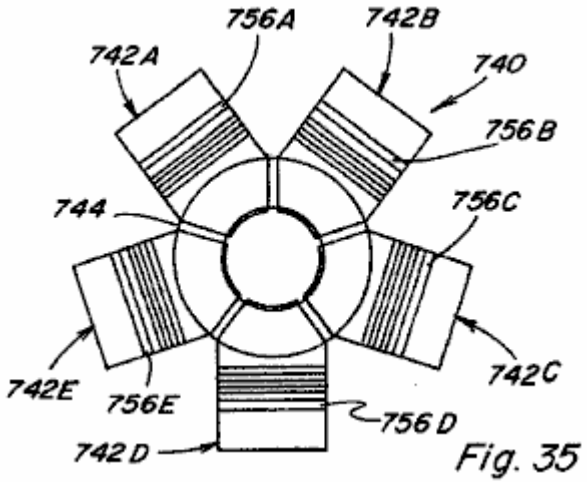

Fig. 35

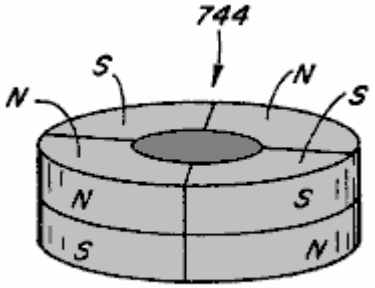

Fig. 36

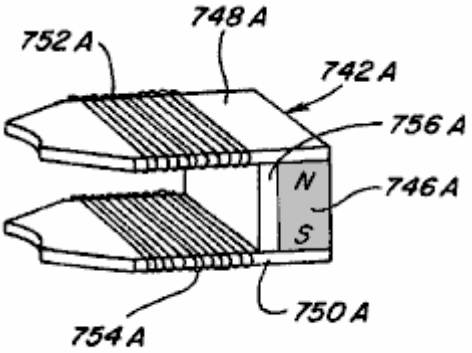

Fig. 37

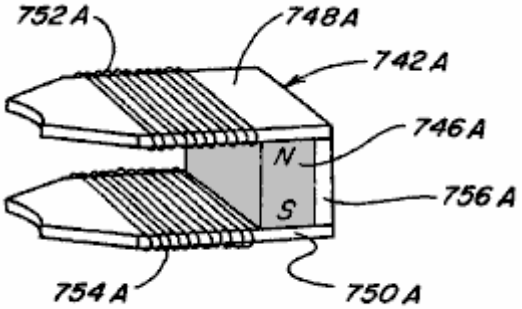

Fig. 38

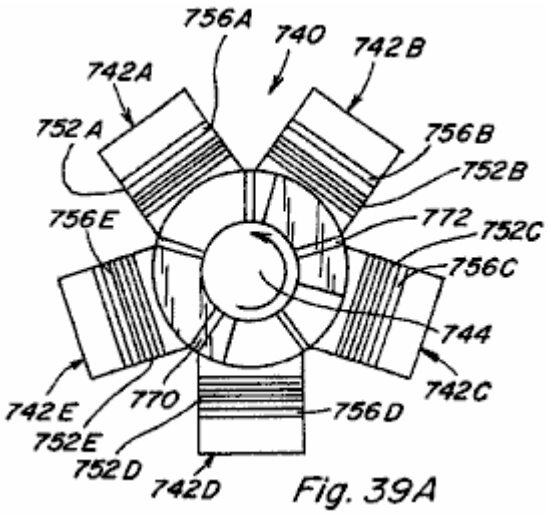

Fig. 39A

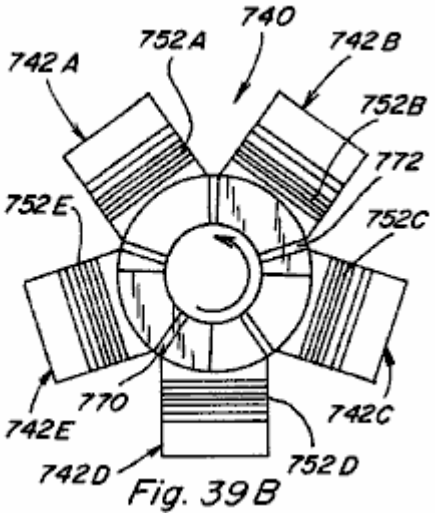

Fig. 39B

A fourth embodiment of a rotary motion device or motor **740** is illustrated in **Figs.34-39**. Motor **740** includes five stator control components **742A-742E** positioned around a ring shaped permanent magnet rotor member **744** (**Fig.36**). As shown with reference to component **742A** in **Fig.37**, each stator component **742A** includes a permanent magnet **746A** with an upper pole piece **748A** positioned adjacent to one pole face and a lower pole piece **750A** positioned adjacent to the opposite pole face. Control coils **752A**, **754A** are positioned along respective pole pieces **748A**, **750A**. A bypass **756A** extends from pole piece **748A** to pole piece **750A** and is positioned between permanent magnet **746A** and control coils **752A**, **754A**. Alternatively, bypass **756A** could be provided on the opposite side of permanent magnet **746A** as shown in **Fig.38**. Although not shown, it is anticipated that permanent magnet rotor member **744** would be mounted on an axis for rotation with it and that a motor housing or enclosure could be provided, such as shown in relation to motor **650** of **Fig.33**.

Referring to the top views of **Figs.39A-39D**, rotary motion of rotor member **744** is depicted by the sequence of views. Regions **770** and **772** in **Figs.39A-39D** represent the magnetic north regions of the top of permanent magnet rotor **744**. In **Fig.39A** control coils **752E** and **752C** are energised in a permanent magnet aiding and exceeding manner such that regions **770** and **772** of permanent magnet rotor **744** are repulsed by components **742E** and **742C** while permanent magnet motor regions **774** and **776** are attracted by components **742E** and **742C**. The resultant coupling forces act to move permanent magnet rotor in a counterclockwise direction to the location shown in **Fig.39B**. Just after permanent magnet rotor region **772** passes the point shown in **Fig.39C**, control coil **752B** is energised in a permanent magnet aiding and exceeding manner, while control coils **752E** and **752C** also remain energised, and counterclockwise rotation of permanent magnet rotor **744** is continued. Just

after permanent magnet rotor region **772** passes by control component **742C** control coil **752C** is de-energised, while control coils **752E** and **752B** remain energised, so as to continue counterclockwise rotation. Then, just after permanent magnet rotor region **770** reaches the location shown in **Fig.39D** control coil **752D** is energised in a permanent magnet flux aiding and exceeding manner, while coils **752E** and **752B** remain energised, so as to continue counterclockwise rotation. Thus, as in the other embodiments, repeated and timed energisation and de-energisation of the control coils produces the desired rotational movement.

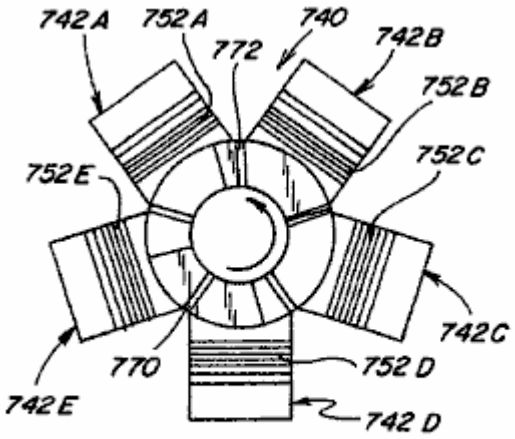

Fig. 39 C

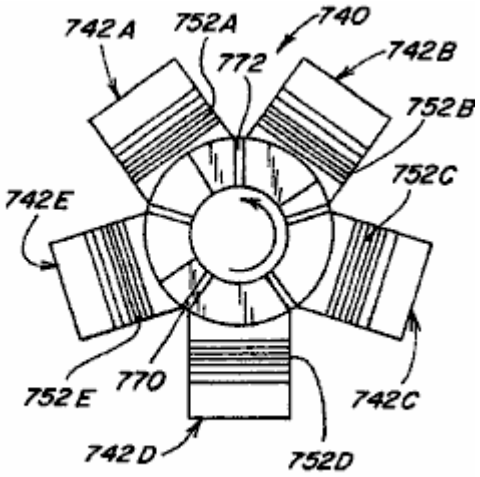

Fig. 39 D

In terms of controlling the energisation of coils in the devices described above, various electronic control circuit/switching means and electromechanical control circuit/switching machines are depicted in **Figs.40-44**. In circuit **800** of **Fig.40** a given coil **802** is placed in series between an electrical energy source **804** and a power MOSFET **806**. An LED **808** is connected to electrical energy source **804** through resistor **810** and is positioned to impinge upon a phototransistor **812** which is connected in series with resistor **814**. A control input of MOSFET **806** is connected between phototransistor **812** and resistor. Accordingly, when LED **808** activates phototransistor **812** the voltage drop across resistor **814** activates, or turns ON, MOSFET **806** and coil **802** is energised. Timed energisation of coil **802** is provided by mounting an interrupter **816**, such as shown in **Fig.42**, to the shaft **816** of the motor device to be controlled, such that as interrupter **814** rotates with shaft **816** coil **802** is alternately energised and de-energised. In a device with a plurality of coils a corresponding plurality of LED/photoresistor pairs may be provided.

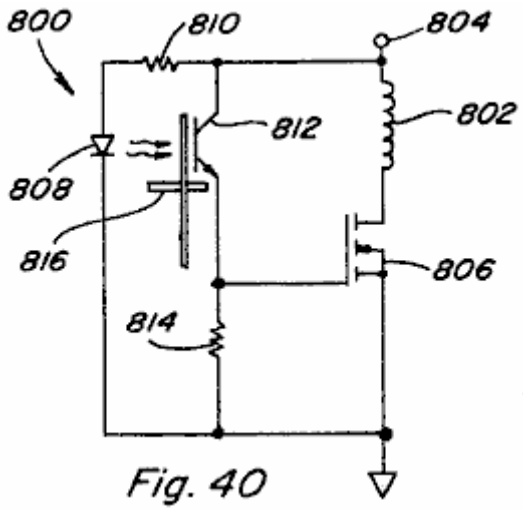

Fig. 40

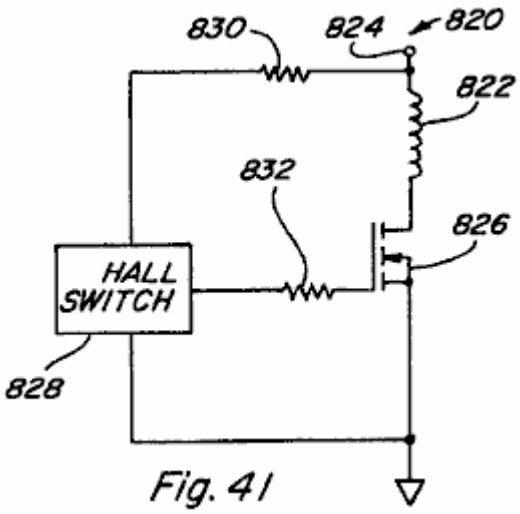

Fig. 41

In circuit **820** of **Fig.41** a coil **822** is positioned between electrical energy source **824** and power MOSFET **826**. A hall switch **828** is connected in series with resistor **830**. Hall switch **828** is also connected to the control input of MOSFET **826** through resistor **832**. In a given device hall switch **828** would be positioned to react to a change in magnetic flux so as to control the ON/OFF switching of MOSFET **826**, and thus the alternate energisation and de-energisation of coil **822**.

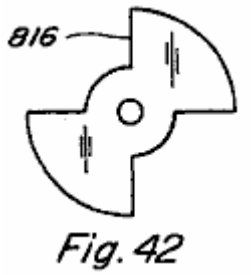

Fig. 42

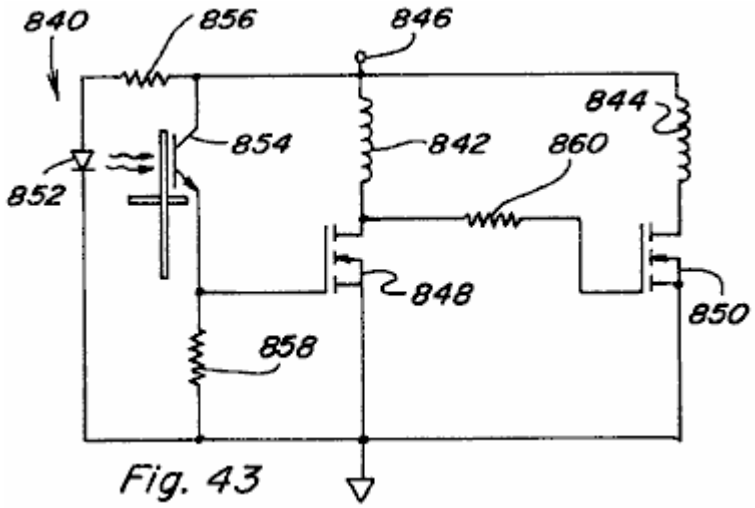

Fig. 43

In **Fig.43** a circuit **840** for controlling two coils in an opposite manner is provided such that when coil **842** is energised coil **844** is de-energised, and such that when coil **842** is de-energised coil **844** is energised. Both coils **842** and **844** are connected in series between electrical energy source **846** and respective power MOSFETs **848** and **850**. An LED **852** and phototransistor **854** arrangement is provided, LED connected in series with resistor **856** and phototransistor connected in series with resistor **858**. When LED **852** turns phototransistor **854** ON the voltage drop across resistor **858** turns MOSFET **848** ON and coil **842** is energised. At that time the voltage applied at the control input of MOSFET **850** will be low and therefore MOSFET **850** will be OFF and coil **844** will be de-energised. When interrupter **814** blocks LED 852, phototransistor **854** is turned OFF and MOSFET **848** is likewise turned OFF. The control input of MOSFET **850** is therefore pulled high through resistor **860** and MOSFET **850** is turned ON such that coil **844** is energised.

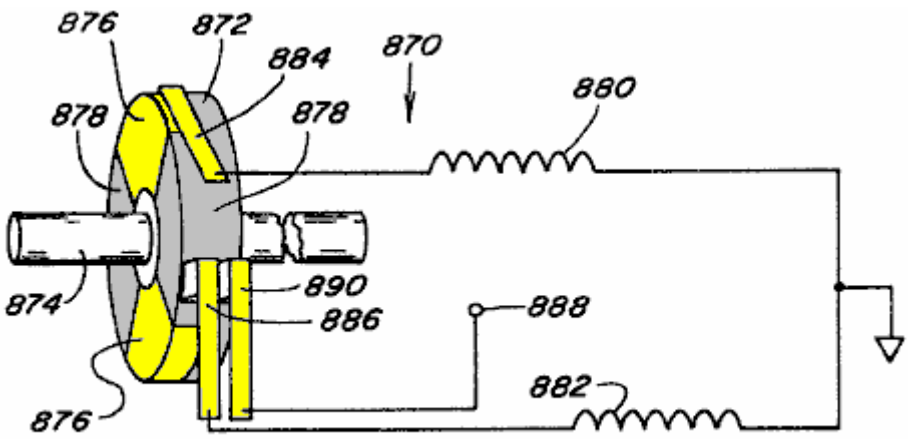

Fig. 44

In **Fig.44** a system **870** including member **872** mounted on rotating shaft **874** is provided, with the left side of member **872** being alternately conductive at **876** and non-conductive at **878**. Coils **880** and **882** are connected to respective brushes **884** and **886** which are positioned to contact member **872** during each rotation of the shaft. Member **872** is connected through brush **890** to power supply **888**. Thus, coils **880** and **882** will alternately be energised and de-energised as the respective brushes thereof contact the conductive and non-conductive portions of member **872**.

Any of such circuit means, variations thereof, or other circuit means may be used to provide the timed energisation of the control coils in the various embodiments of the present invention.

From the preceding description of the illustrated embodiments, it is evident that the objects of the invention are attained. Although the invention has been described and illustrated in detail, it is to be clearly understood that the same is intended by way of illustration and example only and is not to be taken by way of limitation.

For example, although the magnetic flux control techniques of the present invention have been discussed as applicable mainly to various motive applications, such magnetic flux control techniques are also useful in static applications.

Power Conversion

Referring to **Figs.45A-45C** there is shown the permanent magnet device **900** of **Figs.45A-45C** which has two magnetic flux paths provided by rectangular pole piece **902** which includes upper portion **904** and lower portion **906** each positioned against a respective pole face of permanent magnet **910**. Unlike the device of **Figs.7-9**, fall away armatures are not provided. Instead, fixed armatures in the form of integral pole piece portions **912** and **914** extend from upper portion **904** to lower portion **906** completing the two flux paths in a permanent manner. Control coils **916**, **918** are provided along one flux path and control coils **920**, **922** are provided along the other flux path, such control coils acting as primary windings in device **900**. One coil **924** is positioned around pole piece portion **912** and another coil **926** is positioned around pole piece portion **914**, such coils **924**, **926** acting as secondary windings in device **900**.

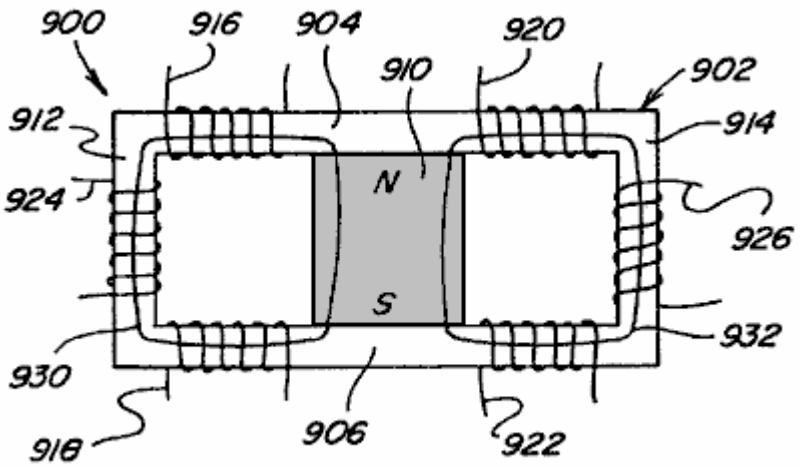

Fig. 45A

In **Fig.45A** no coils are energised and the permanent magnet magnetic flux splits evenly between paths **930** and **932**, coupling with both coil **924** and coil **926**.

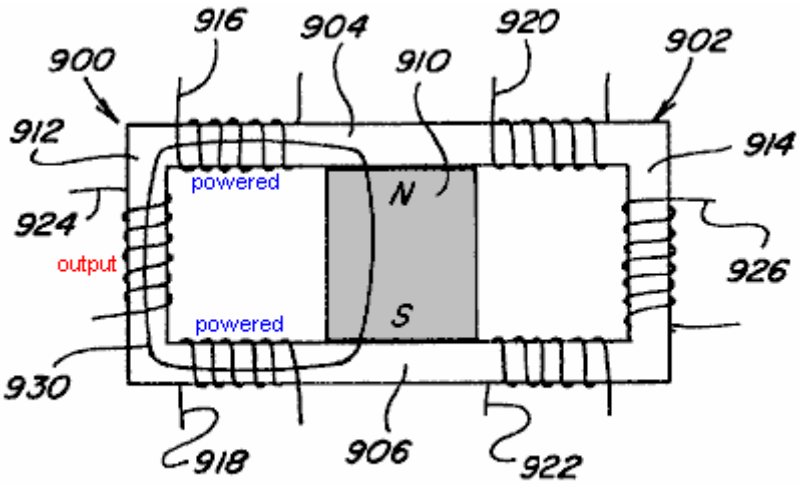

Fig. 45B

In **Fig.45B** coils **916**, **918** are energised in a permanent magnet magnetic flux aiding manner so as to couple with all the magnetic flux of permanent magnet **910**. All magnetic flux flows along path **930** as shown and thus couples with coil **924**.

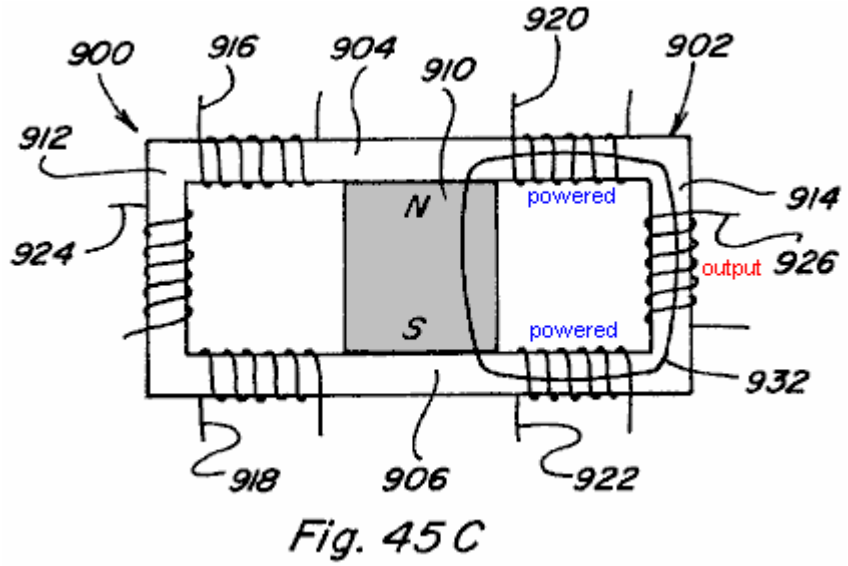

Fig. 45 C

In **Fig.45C** coils **920**, **922** are energised in a permanent magnet magnetic flux aiding manner such that all magnetic flux traverses path **932** and couples with coil **926**. By continuously alternately energising and de-energising coils **916**, **918** and **920**, **922** in such a manner energy conversion is achieved due to the coupling with coils **924** and **926**. The magnetic flux in the integral pole piece portions **912** and **914**, and thus the flux coupling with respective coils **924** and **926**, varies by a factor of twice the amount of magnetic flux generated by energising coils **916**, **918** and **920**, **922**.

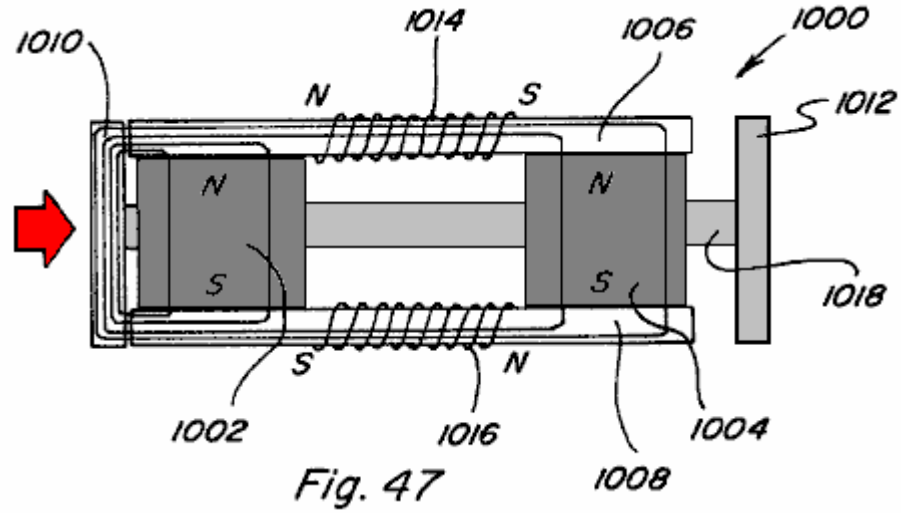

Fig. 47

The construction shown in **Fig.45A** and **Fig.45X** are similar to the construction shown in **Fig.7** and **Fig.47**. The difference in both cases relates to replacing the two flux paths and armatures with one continues flux path. The arrangement in **Fig.7** has one permanent magnet and four coils and the arrangement in **Fig.47** has two permanent magnets and two coils. Although the physical aspects of the two arrangements and the details of the flux control vary, the control method for varying the permanent magnets flux are similar and will be described simultaneously and only differences will be pointed out.

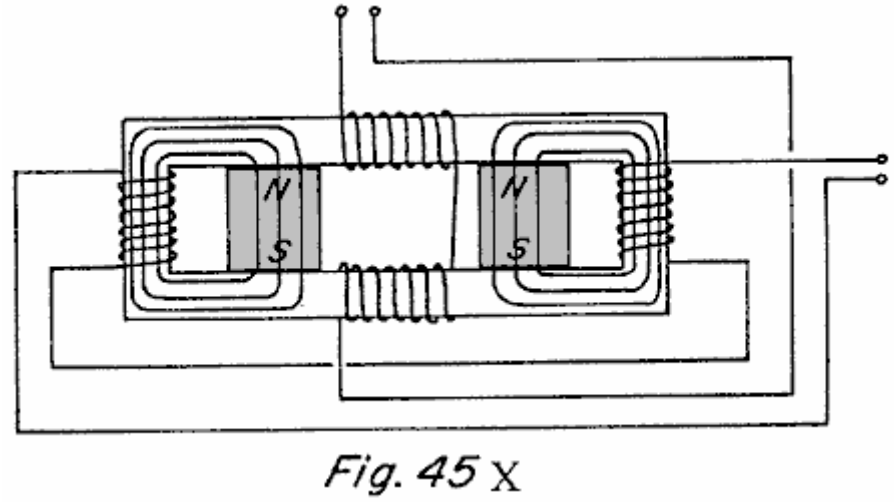

Fig. 45 X

With continuous flux paths the static flux from the permanent magnet or magnets is useless. However, if the static flux of the permanent magnet confined to the flux paths were modified to be time varying it would have utility for electromagnetic induction devices for power conversion like transformers and power inverters. However, the same basic method for controlling the flux of a permanent magnet to provide linear and rotary motion can also be applied to time varying the static flux from the permanent magnet. The construction shown in **Fig.45X** utilises four control coils and a single permanent magnet while the construction shown in **Fig.45A** uses two control coils and two permanent magnets. The flux that would normally be supplied by a primary winding is supplied by the static flux of the permanent magnet or magnets and the control coils convert this static flux into a time varying flux in a novel way. Both arrangements use two secondary coils, the secondary coils are placed in the region of the continuous flux path that would be occupied by an armature or rotor in the linear or rotary arrangements. The regions of the flux paths that perform work are the same in all cases.

In all cases the control coils can either be wired in series or parallel and the secondary coils can be either wound in series or parallel. More than one secondary coil or secondary coils with multiple taps can be placed in the working regions and further multiple flux paths can be utilised with one or more secondary coils placed in each of the working regions. This is made obvious by the disclosures of the linear and rotary devices herein and based on the fact that the working regions of the flux paths are identical.

Fig.45X and **Fig.45A** also show the paths of the static flux of the permanent magnet or magnets when no current is flowing in the control coils. In the arrangement shown in **Fig.45X** the flux from the single permanent magnet divides between the two working areas of the flux path. In the arrangement of **Fig.45A** all of the flux of one of the permanent magnets passes through one of the working regions and all of the flux of the second permanent magnet passes through the other working region. Each of the working regions in both cases are occupied by secondary coils.

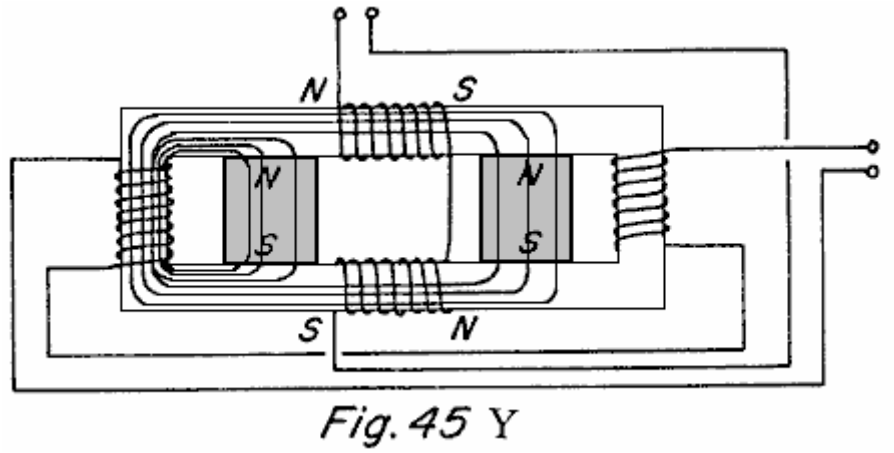

Fig. 45 Y

Fig.45Y and **Fig.45B** show the control coils energised with the polarity shown with respect to the polarity of the permanent magnet or magnets included. In **Fig.45Y** the opposing coil, blocks the passage of flux from the permanent magnet, and the aiding coil couples with the flux of the permanent magnet and therefore all of the flux of the permanent magnet passes through one working region as shown. In **Fig.45B** the opposing side of the coil blocks the passage of flux from the permanent magnet on the opposing side of the coil and the aiding side of the

coil couples with the flux of the other permanent magnet and therefore all of the flux of both the permanent magnets passes through the working region as shown.

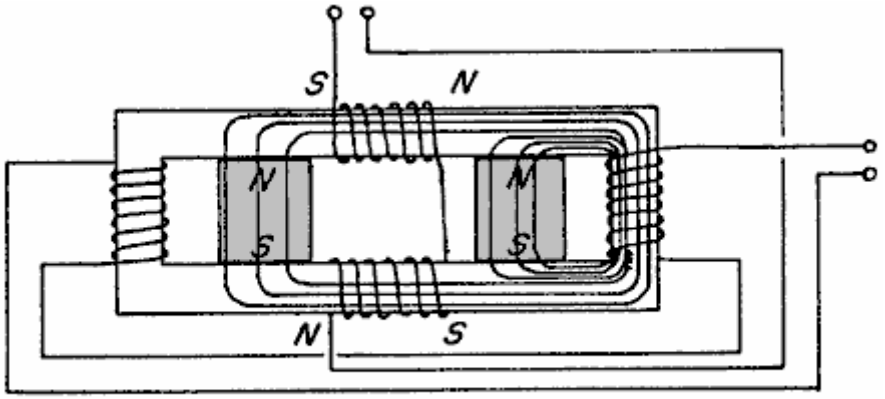

Fig. 45 Z

Fig.45Z and **Fig.45C** show the control coils energised with a polarity opposite of that shown in **Fig.45Y** and **Fig.45B**. The same action occurs and results in all of the permanent magnet or magnets path flux passing through the opposite working regions.

By alternating the polarity of the control coils during one cycle, one working region experiences an increasing flux and the opposite region experiences a decreasing flux and during the next cycle the opposite occurs. This results in the induction of a voltage in the secondary coils that is decided by the magnitude of the change in flux in the working region and the time in which this change occurs. The novelty of this discovery is that the primary flux inducing the voltage in the secondary coils is supplied by the permanent magnet or magnets and is far greater than the flux supplied by the control coils.

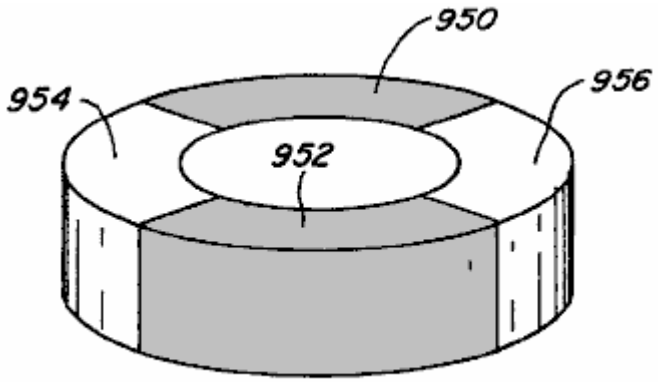

Fig. 46

Further, in the rotary motion devices of **Fig.31** and **Fig.34**, it is not necessary that respective rotor members **702** and **744** be formed of permanent magnets. Each could take the form shown in **Fig.46** where sections **950** and **952** are formed of magnetic material such as soft iron and sections **954** and **956** are formed by a non-magnetic filler material.

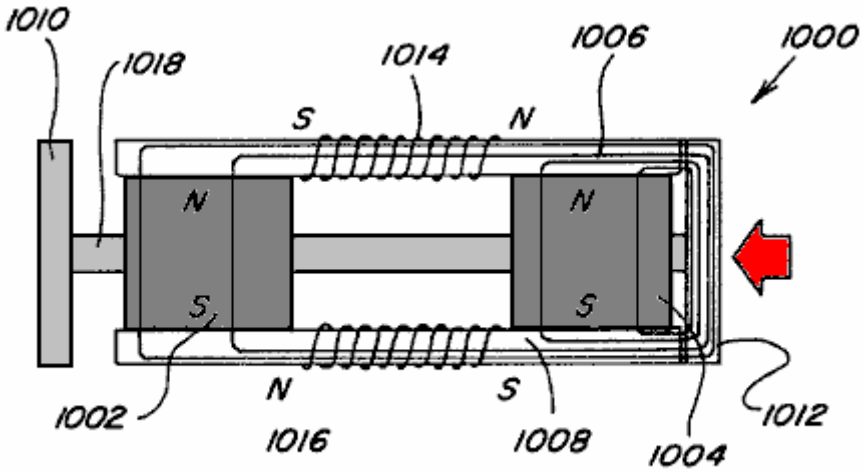

Fig. 48

Fig.47 and **Fig.48** show another embodiment **1000** of the subject device. The embodiment **1000** includes two spaced permanent magnets **1002** and **1004** each of which has its north pole adjacent to the upper surface and its south pole adjacent to the lower surface. A magnetisable bridging member **1006** extends across and makes contact with the north magnetic poles of the magnets **1002** and **1004** and another magnetisable bridging member **1008** makes contact with the south magnetic poles of the two permanent magnets **1002** and **1004**.

The members **1006** and **1008** extend slightly beyond the opposite sides of the respective permanent magnets **1002** and **1004** and a pair of spaced armature members **1010** and **1012** are positioned to move into and out of engagement with the ends of the members **1006** and **1008**. Coils **1014** and **1016** are mounted respectively on the members **1006** and **1008** in the space between the permanent magnets **1002** and **1004**, and the armatures **1010** and **1012** are shown connected together by a rod **1018** which enables them to move backwards and forwards into engagement with the respective members **1006** and **1008** when different voltages are applied to the respective coils **1014** and **1016**.

In **Fig.47**, the coils **1014** and **1016** are energised as shown with the coil **1014** having its north magnetic end to the left and its south magnetic end to the right and the opposite is true of the coil **1016**. In **Fig.48**, the voltage applied to the respective coils **1014** and **1016** is reversed so that the polarity of the left end of coil **1014** is south and the polarity of the opposite end of the same coil **1014** is a north magnetic pole. The reverse is true of the coil **1016**. In **Fig.47** and **Fig.48** it should be noted that the relationship of aiding and opposing is indicated on the figures to indicate the relationship when the coils are energised. For example, in **Fig.47** when the coils are energised as shown the relationship is opposing for the permanent magnet **1002** and is aiding with respect to the permanent magnet **1004**. The reverse is true when the voltage on the coils is reversed as shown in **Fig.48**. The movement of the armature is therefore controlled by the proper timing of the voltage on these coils. The same principles can be applied to produce rotating movement as shown in **Fig.42**.

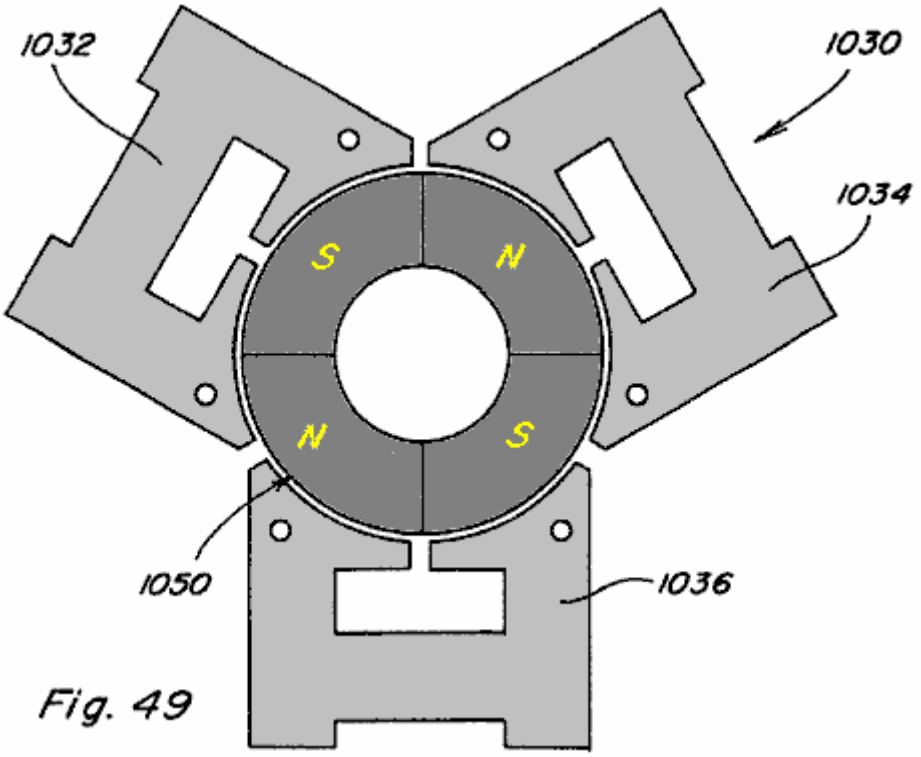

Fig. 49

Fig.49 shows another embodiment **1030** of the subject invention using principles similar to those described in connection with **Fig.47** and **Fig.48**. The embodiment **1030** includes a plurality, three being shown, of stationary members **1032**, **1034** and **1036**.

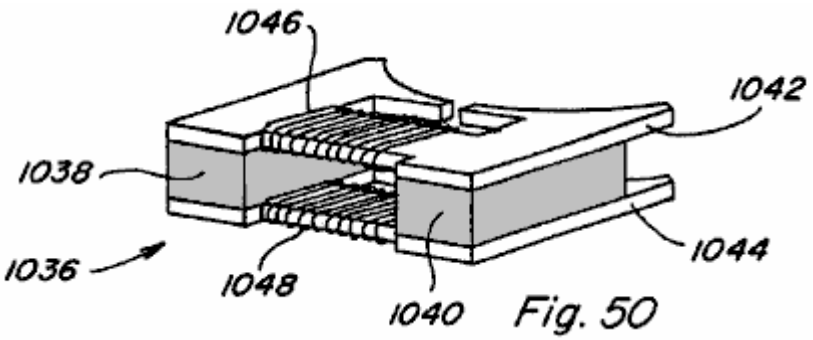

Fig. 50

The details of these members are better shown in **Fig.50** which shows the details of the member **1036**. This member includes a pair of permanent magnets **1038** and **1040**, each of which has magnetisable members mounted adjacent to it's opposite sides, as in the previous construction. The members **1042** and **1044** also have coils **1046** and **1048**, respectively, and the coils are energised as described in connection with **Fig.47** and **Fig.48** to produce aiding and opposing magnetism. The construction shown in **Fig.49** may have three stator portions as shown or it may have more stator portions as desired. The rotor **1050** is positioned in the space between the members **1032**, **1034** and **1036** and includes a permanent magnet portion part of which has its north magnetic pole on the surface as shown and the other parts has its south magnetic pole in the same surface as shown. The permanent magnets **1038** and **1040** on the stators interact with the permanent magnets on the rotor to produce the rotating motion and is controlled by the energising of the coils.

Other applications and advantages of the devices and methods of the present invention exist and various modifications are possible, and therefore the present invention is not intended to be limited to the specific examples disclosed herein. Accordingly, the spirit and scope of the invention are to be limited only by the terms of the appended claims.

CLAIMS

1. A permanent magnet device, comprising a permanent magnet having north and south pole faces, a first pole piece, a second pole piece, a first control coil, a second control coil, and circuit means, the first pole piece positioned adjacent the north pole face of the permanent magnet and including a first path portion, a second path portion and a third portion, the first path portion extending beyond a perimeter of the north pole face in

one direction and the second path portion extending beyond the perimeter of the north pole face in another direction to define first and second flux paths for magnetic flux emanating from the north pole face of the permanent magnet, the first path portion of the first pole piece connected to the second path portion of the first pole piece by the third portion which extends across the north pole face of the permanent magnet, the second pole piece positioned adjacent the south pole face and including a first path portion and a second path portion, the first path portion extending beyond a perimeter of the south pole face and substantially aligned with the first path portion of the first pole piece, the second path portion extending beyond the perimeter of the south pole face and substantially aligned with the second path portion of the first pole piece, the first control coil positioned around the first path portion of the first pole piece, the second control coil positioned around the second path portion of the first pole piece, the circuit means connected to each of the first control coil and the second control coil to alternately energise the first coil and the second coil in a timed sequential manner.

2. The permanent magnet device as set forth in claim 1, wherein the first control coil and the second control coil are alternately energised in a permanent magnet magnetic flux aiding manner.

3. The permanent magnet device as set forth in claim 1, wherein the first control coil and the second control coil are alternately energised in a permanent magnet magnetic flux opposing manner.

4. The permanent magnet device as set forth in claim 1, further comprising a rotor member mounted on a shaft for rotation therewith, the rotor member sized, shaped, and positioned to extend substantially from the first path portion of the first pole piece to the first path portion of the second pole piece during at least some part of its rotation.

5. The permanent magnet device as set forth in claim 4, wherein the rotor member is formed by at least one permanent magnet.

6. The permanent magnet device as set forth in claim 1, wherein the second path portion of the first pole piece and the second path portion of the second pole piece are positioned alongside the first path portion of the first pole piece and the first path portion of the first pole piece.

7. The permanent magnet device as set forth in claim 1, further comprising a first bypass extending from the first path portion of the first pole piece to the first path portion of the second pole piece, one end of the first bypass positioned adjacent the first path portion of the first pole piece and between the permanent magnet and the first control coil.

8. The permanent magnet device as set forth in claim 6, further comprising a second bypass extending from the second path portion of the first pole piece to the second path portion of the second pole piece, one end of the second bypass positioned adjacent the second path portion of the first pole piece and between the permanent magnet and the second control coil.

9. The permanent magnet device as set forth in claim 1, further comprising a plurality of armatures arranged to define a path of movement, wherein the second path portion of the first pole piece and the second path portion of the second pole piece are positioned alongside the first path portion of the first pole piece and the first path portion of the second pole piece, and wherein all of such pole piece path portions include an end face positioned adjacent the path of movement defined by the plurality of armatures.

10. The permanent magnet device as set forth in claim 1, wherein the first control coil and the second control coil are simultaneously energised one in a permanent magnet magnetic flux aiding manner and one in a permanent magnet magnetic flux opposing manner.

11. The permanent magnet device as set forth in claim 1, further comprising two shaft connected armatures which can be positioned adjacent the ends of the first and second pole pieces, wherein each of the armatures is formed by a permanent magnet.

12. The permanent magnet device of claim 1 further comprising a first fixed armature extending between the first path portion of the first pole piece to the first path portion of the second pole piece and a second fixed armature extending between the second path portion on the first pole piece to the second path portion of the second pole piece.

13. The permanent magnet device of claim 12 where a first secondary coil is wrapped around the first fixed armature and a second secondary coil is wrapped around the second fixed armature.

14. The permanent magnet device of claim 13 including circuit means connected to the control coils to control the energising thereof to produce a varying flux in the armatures and to induce voltage in the secondary coils.

15. The permanent magnet device of claim 1 wherein there are at least two permanent magnets each having north and south pole faces, the first pole piece being positioned extending between the north pole faces of the permanent magnets and the second pole piece positioned extending between adjacent south pole faces of the permanent magnets.

16. A method for controlling the path of magnetic flux from a permanent magnet, the method comprising the steps of:

(**a**) placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face;

(**b**) placing a second pole piece adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece;

(**c**) placing a first control coil along and around the first path portion of the first pole piece;

(**d**) placing a second control coil along and around the second path portion of the first pole piece;

(**e**) repeatedly energising the first control coil in a permanent magnet magnetic flux opposing manner so as to prevent magnetic flux of the permanent magnet from traversing the first path portion of the first pole piece; and

(**f**) repeatedly energising the second control coil in a permanent magnet magnetic flux opposing manner so as to prevent magnetic flux of the permanent magnet from traversing the second path portion of the first pole piece.

17. The method as set forth in claim 16 wherein the energisation of steps (e) and (t) take place in a simultaneous manner.

18. A method for controlling the path of magnetic flux from a permanent magnet, the method comprising the steps of:

(**a**) placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face;

(**b**) placing a second pole piece adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece;

(**c**) placing a first control coil along and around the first path portion of the first pole piece;

(**d**) placing a second control coil along and around the second path portion of the first pole piece; and

(**e**) alternately performing the following steps in a repeated manner:

(**i**) energising the first control coil in a permanent magnet magnetic flux aiding manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the second path portion of the first pole piece when the first control coil is so energised; and

(**ii**) energising the second control coil in a permanent magnet magnetic flux opposing manner so as to couple with substantially all magnetic flux of the permanent magnet such that substantially no magnetic flux of the permanent magnet traverses the first path portion of the first pole piece when the second control coil is so energised.

19. A method for controlling the path of magnetic flux from a permanent magnet the method comprising the steps of:

(**a**) placing a first pole piece adjacent a first pole face of the permanent magnet so as to have at least first and second path portions extending beyond a perimeter of the first pole face;

(**b**) placing a second pole piece adjacent a second pole face of the permanent magnet so as to include at least one portion which substantially aligns with the first and second path portions of the first pole piece;

(**c**) placing a first control coil along and around the first path portion of the first pole piece;

(**d**) placing a second control coil along and around the second path portion of the first pole piece; and

(**e**) alternately performing the following steps in a repeated manner:

(**i**) simultaneously energising the first control coil in a permanent magnet magnetic flux aiding manner and the second control coil in a permanent magnet flux opposing manner; and

(**ii**) simultaneously energising the first control coil in a permanent magnet flux opposing manner and the second control coil in a permanent magnet magnetic flux aiding manner.

20. A rotary motion device, comprising a rotor assembly including a shaft which defines an axis of rotation of the assembly, a rotor pole piece mounted for rotation with the shaft, the rotor pole piece including an outer ring portion having at least two path portions extending inwardly from a periphery of the outer ring portion;

a stator assembly including a permanent magnet having a generally ring-shaped configuration, a first pole face of the permanent magnet positioned adjacent the outer ring portion of the rotor pole piece, the stator assembly further comprising a stator pole piece including an outer ring portion positioned adjacent a second pole face of the permanent magnet and having a plurality of path portions extending inwardly from the periphery, each path portion further including a respective portion which extends toward a plane defined by the first pole face of the permanent magnet and capable of being aligned with each of the rotor pole piece path portions at certain rotational positions of the rotor pole piece, each path portion including a control coil positioned along it;

and circuit means connected to each of the coils and including a source of electrical energy and switch means for energising respective ones of the control coils in a predetermined timed sequence based upon rotation of the rotor assembly.

21. A rotary motion device, comprising:

a rotor assembly including a shaft which defines an axis of rotation of the assembly, a pair of spaced elongated rotor members mounted on the shaft at spaced locations thereon and angularity oriented with respect to each other, each of the elongated rotor members formed of a magnetic material;

a stator assembly including a permanent magnet having opposed first and second pole faces, a first pole piece positioned adjacent the first pole face and a second pole piece positioned adjacent the second pole face, each pole piece including a respective first path portion extending beyond a perimeter of its adjacent pole face and having an curved shaped end portion, the first path portion of the first pole piece aligned with the first path portion of the second pole piece, each pole piece further including a respective second path portion extending beyond the perimeter of its adjacent pole face in a direction opposite to that of the first path portions and having an curved shaped end portion, the second path portion of the first pole piece aligned with the second path portion of the second pole piece, at least one of the first path portions of the first pole piece and the first path portion of the second pole piece including a control coil mounted on at least one of the pole pieces, at least one of the second path portions of the first pole piece and the second path portion of the second pole piece including a control coil mounted on at least one of the pole pieces,

wherein the rotor assembly extends from end to end of the stator assembly such that the elongate members are aligned with the curved shaped end portions of the path portions of the pole pieces;

and circuit means connected to each of the coils and including a source of electrical energy and switch means for energising respective ones of the control coils in a predetermined timed sequence based upon rotation of the rotor assembly.

22. A rotary motion device comprising:

a rotor assembly including a shaft which defines an axis of rotation of the assembly, a ring-shaped rotor member mounted for rotation with the shaft, the ring-shaped rotor member including a plurality of distinct circumferential regions;

a stator assembly including a first permanent magnet, a first pole piece positioned against a first pole face and a second pole piece positioned against a second pole face, the first pole piece including at least a first path portion extending beyond a perimeter of the first pole face, the second pole piece including at least a first path portion extending beyond a perimeter of the second pole face, the first path portion of the first pole piece aligned with the first path portion of the second pole piece, at least a portion of the ring-shaped rotor member

positioned between the first path portion of the first pole piece and the first path portion of the second pole piece, at least one of the first path portions of the first pole piece and the first path portion of the second pole piece including a first control coil positioned at a point intermediate the first permanent magnet and the ring-shaped rotor member;

and circuit means connected to the first control coil and including a source of electrical energy and switch means for energising the first control coil in a predetermined timed manner based upon rotation of the rotor assembly.

23. The rotary motion device as set forth in claim 22, wherein the ring-shaped rotor member is formed by a permanent magnet having distinct circumferential regions of opposite polarity.

24. The rotary motion device as set forth in claim 23, wherein the first pole piece includes a second path portion spaced from and extending adjacent to the first path portion, the second pole piece including a second path portion spaced from and extending adjacent to the first path portion such that the second path portion of the first pole piece is aligned with the second path portion of the second pole piece, at least a portion of the ring-shaped permanent magnet rotor member positioned between the second path portion of the first pole piece and the second path portion of the second pole piece, at least one of the second path portions of the first pole piece and the second path portion of the second pole piece having a second control coil mounted on at least one of the pole pieces at a point intermediate the first permanent magnet and the ring-shaped permanent magnet rotor member, the second control coil connected to the circuit means so as to be energised in a predetermined timed manner based upon rotation of the rotor assembly.

25. The rotary motion device as set forth in claim 22, wherein the stator assembly further comprises a second permanent magnet, a third pole piece positioned adjacent a first pole face of the second permanent magnet and a fourth pole piece positioned adjacent a second pole face of the second permanent magnet, the third pole piece including at least a first path portion extending beyond a perimeter of the second permanent magnet first pole face, the fourth pole piece including at least a first path portion extending beyond a perimeter of the second permanent magnet second pole face, the first path portion of the third pole face aligned with the first path portion of the fourth pole piece, at least a portion of the ring-shaped permanent magnet rotor member positioned between the first path portion of the third pole piece and the first path portion of the fourth pole piece, at least one of the first path portions of the third pole piece and the first path portion of the fourth pole piece including a third control coil mounted on at least one of the pole pieces at a point intermediate the second permanent magnet and the ring-shaped permanent magnet rotor member, the third pole piece including a second path portion spaced from and extending adjacent to the first path portion the fourth pole piece including a second path portion spaced from and extending adjacent to the first path portion thereof such that the second path portion of the third pole piece is aligned with the second path portion of the fourth pole piece, at least a portion of the ring-shaped permanent magnet rotor member positioned between the second path portion of the third pole piece and the second path portion of the fourth pole piece, at least one of the second path portions of the third pole piece and the second path portion of the fourth pole piece including a fourth control coil mounted on at least one of the pole pieces at a point intermediate the second permanent magnet and the ring-shaped permanent magnet rotor member, wherein each of the third and fourth control coils are connected to the circuit means so as to be energised in a predetermined timed manner based upon rotation of the rotor assembly.

26. A device for producing rotary motion comprising:

a rotor assembly including a shaft which defines an axis of rotation for the assembly, a ring-shaped rotor member mounted for rotation with the shaft, the ring-shaped rotor member having a plurality of distinct circumferentially positioned regions extending around the axis, a stator assembly including a first permanent magnet, a first pole piece positioned against the first pole face of the first pole piece and a second pole piece positioned against a second pole face of the first pole piece, the first pole piece including at least a first path portion extending beyond a perimeter of the first pole face, the second pole piece including at least a first path portion extending beyond the perimeter of the second pole face, the first path portion of the first pole piece aligned with the first path portion of the second pole piece, at least a portion of the ring-shaped rotor member positioned between the first path portion of the first pole piece and the first path portion of the second pole piece, at least one of the first path portions of the first pole piece and the first path portion of the second pole piece including a first control coil mounted on at least one of the pole pieces at a point intermediate the first permanent magnet and the ring-shaped rotor member; and circuit means connected to the first control coil and including a source of electrical energy and switch means for energising the first control coil in a predetermined timed manner based upon position of the rotor assembly during rotation of the rotor assembly.

27. The device for producing rotary motion of claim 26 wherein the circuit means includes means for timing the energising of the first control coil includes means for adjusting the timing thereof.

28. The device for producing rotor motion of claim 26 including means to vary the flux generated in the first and second pole pieces.

29. A device for handling the flux between two separate permanent magnets each of which has a north magnetic pole adjacent one side face and the south magnetic pole adjacent to the opposite side face, the north and south side pole faces respectively of both magnets being substantially in alignment, a first member in surface-to-surface contact with the north magnetic faces of the spaced permanent magnets, a second member in surface-to-surface contact with the south magnetic faces of the spaced permanent magnets, first and second armatures each positioned adjacent opposite ends of the first and second permanent magnets and adjacent to opposite ends of the spaced members, a coil mounted on each of the members in the space between the adjacent permanent magnets, and means for applying voltages of predetermined polarities across the respective coils to change the magnetic coupling between the permanent magnets and between the armatures.

30. A device for producing rotational movement comprising:

a rotor having a shaft rotatable about the axis thereof, a member constructed of permanent magnets mounted on the shaft, said member having circumferential portions some of which have a north magnetic pole and others a south magnetic pole adjacent to the same side thereof, the opposite surface of the permanent magnet member having north magnetic poles opposite the south magnetic poles and south magnetic poles opposite the north magnetic poles, a stator having a plurality of circumferentially spaced portions each of which includes at least one permanent magnet and a pair of members mounted adjacent opposite sides of the permanent magnets, the members being positioned adjacent to the periphery of the rotor permanent magnet member and means on the member adjacent each opposite side of the stator permanent magnet for mounting a coil, and means for energising the coil on each stator portion in sequence to produce magnetic coupling force between the stator and the rotor in a direction to produce rotating motion of the rotor.

31. A device including a rotating member and a stationary member, each having a permanent magnet portion positioned to produce magnetic coupling force between them in predetermined positions thereof, the rotor including a shaft rotatable about its axis and the permanent magnet extending around the shaft and formed by a plurality of adjacent portions of permanent magnet material whereby adjacent portions have their north and south magnetic pole faces on opposite sides of the rotor permanent magnet, a plurality of stator members each stator member having at least one permanent magnet having a north magnetic pole adjacent one side and a south magnetic pole adjacent to the opposite side, a pair of members positioned adjacent respective opposite sides of the stator permanent magnet in position to extend to adjacent the rotor permanent magnet whereby a flux path is formed between the members and the stator and rotor permanent magnets, a coil mounted on each member of the stator and means for applying a voltage of predetermined polarity to each of said coils to control the flux through a path between the permanent magnets and to control the coupling force between the permanent magnets on the stator and the permanent magnets on the rotor.

32. A motion producing device comprising at least one permanent magnet having a north pole opposite and spaced from a south pole, a pair of spaced substantially parallel members adjacent respectively the north and south poles of the at least one permanent magnet and extending outwardly to substantially aligned opposite edges, a flux supporting member positioned adjacent the respective opposite edges of each pair of parallel members, a coil on selected ones of the parallel members, and a source of electrical energy connected to each of the coils for energising the coils to change the flux in the parallel members and in the flux supporting members.

33. The motion producing device of claim 32 wherein there are at least two spaced permanent magnets extending between the parallel members.

34. The motion producing device of claim 32 wherein one of said pair of parallel members is subdivided into a plurality of sidewardly extending portions extending to one of said opposite side edges, at least one of said coils being positioned on at least one of said sidewardly extending portions.

35. The motion producing device of claim 34 wherein there are coils on a plurality of respective ones of the sidewardly extending portions.

36. The motion producing device of claim 32 wherein the permanent magnet and the parallel members are annular in shape.

37. The motion producing device of claim 32 including a by-pass member extending between the pair of spaced substantial parallel members adjacent one side of the permanent magnet.

38. A permanent magnet device comprising at least two permanent magnets each having north and south pole faces, a first pole piece, a second pole piece, a first control coil, a second control coil and circuit means, the first pole piece positioned adjacent the north pole faces of the at least two permanent magnets and including a first path portion, a second path portion and a third path portion, the first path portion extending beyond the perimeter of the north pole faces and the second path portion extending beyond the perimeter of the north pole faces to define first and second flux paths for magnetic flux emitting from the north pole faces of the at least two permanent magnets, the first path portion of the first pole piece connected to the second path portion of the first pole piece by a third portion which extends across the north pole face of the at least two permanent magnets, the second pole piece positioned adjacent to the south pole faces of the at least two permanent magnets and including a first path portion and a second path portion, the first path portion extending beyond a perimeter of the south pole faces and substantially aligned with the first path portion of the first pole piece, the second path portion extending beyond the perimeter of the south pole faces and substantially aligned with the second path portion of the first pole piece, the first control coil positioned around the first path portion of the first pole piece, the second control coil positioned around the second path portion of the first pole piece, and the circuit means connected to each of the first control coil and the second control coil to alternately energise the first coil and the second coil in a timed sequential manner.

39. The permanent magnet device of claim 38 further comprising a first fixed armature extending between the first path portion of the first pole piece to the first path portion of the second pole piece and a second fixed armature extending between the second path portion of the first pole piece to the second path portion of the second pole piece.

40. The permanent magnet device of claim 39 where a first secondary coil is wrapped around the first fixed armature and a second secondary coil is wrapped around the second fixed armature.

41. The permanent magnet device of claim 40 including circuit means connected to the control coils to control the energising thereof to produce a varying flux in the armatures and to induce voltage in the secondary coils.

42. The permanent magnet device of claim 38 wherein there are at least two permanent magnets each having north and south pole faces, the first pole piece being positioned extending between the north pole faces of the permanent magnets and the second pole piece positioned extending between the south pole faces of the permanent magnets.

MOTIONLESS ELECTROMAGNETIC GENERATOR

Please note that this is a re-worded excerpt from this patent. It describes an electrical device which both powers itself and supplies current to additional external equipment.

ABSTRACT

An electromagnetic generator without moving parts includes a permanent magnet and a magnetic core including first and second magnetic paths. A first input coil and a first output coil extend around portions of the first magnetic path, while a second input coil and a second output coil extend around portions of the second magnetic path. The input coils are alternatively pulsed to provide induced current pulses in the output coils. Driving electrical current through each of the input coils reduces a level of flux from the permanent magnet within the magnet path around which the input coil extends. In an alternative embodiment of an electromagnetic generator, the magnetic core includes annular spaced-apart plates, with posts and permanent magnets extending in an alternating fashion between the plates. An output coil extends around each of these posts. Input coils extending around portions of the plates are pulsed to cause the induction of current within the output coils.

DESCRIPTION

1. Field of the Invention: This invention relates to a magnetic generator without moving parts, used to produce electrical power, and more particularly, to such a device capable of powering itself.

2. Description of the Related Art: The patent literature describes a number of magnetic generators, each of which includes a permanent magnet, two magnetic paths external to the permanent magnet, each of which extends between the opposite poles of the permanent magnet, switching means for causing magnetic flux to flow alternately along each of the two magnetic paths, and one or more output coils in which current is induced to flow by means of changes in the magnetic field within the device. These devices operate in accordance with an extension of Faraday's Law, indicating that an electrical current is induced within a conductor within a changing magnetic field, even if the source of the magnetic field is stationary.

A method for switching magnetic flux to flow predominantly along either of two magnetic paths between opposite poles of a permanent magnet is described as a "flux transfer" principle by R. J. Radus in Engineer's Digest, Jul. 23, 1963. This principle is used to exert a powerful magnetic force at one end of both the north and south poles and a very low force at the other end, without being used in the construction of a magnetic generator. This effect can be caused mechanically, by keeper movement, or electrically, by driving electrical current through one or more control windings extending around elongated versions of the pole pieces **14**. Several devices using this effect are described in U.S. Patent Nos. 3,165,723, 3,228,013, and 3,316,514.

Another step toward the development of a magnetic generator is described in U.S. Patent No. 3,368,141, as a device including a permanent magnet in combination with a transformer having first and second windings about a core, with two paths for magnetic flux leading from each pole of the permanent magnet to either end of the core, so that, when an alternating current induces magnetic flux direction changes in the core, the magnetic flux from the permanent magnet is automatically directed through the path which corresponds with the direction taken by the magnetic flux through the core due to the current. In this way, the magnetic flux is intensified. This device can be used to improve the power factor of a typically inductively loaded alternating current circuit.

Other patents describe magnetic generators in which electrical current from one or more output coils is described as being made available to drive a load, in the more conventional manner of a generator. For example, U.S. Patent No. 4,006,401 describes an electromagnetic generator including a permanent magnet and a core member, in which the magnetic flux flowing from the magnet in the core member is rapidly alternated by switching to generate an alternating current in a winding on the core member. The device includes a permanent magnet and two separate magnetic flux circuit paths between the north and south poles of the magnet. Each of the circuit paths includes two switching means for alternately opening and closing the

circuit paths, generating an alternating current in a winding on the core member. Each of the switching means includes a switching magnetic circuit intersecting the circuit path, with the switching magnetic circuit having a coil through which current is driven to induce magnetic flux to saturate the circuit path extending to the permanent magnet. Power to drive these coils is derived directly from the output of a continuously applied alternating current source. What is needed is an electromagnetic generator not requiring the application of such a current source.

U.S. Patent No. 4,077,001 describes a magnetic generator, or dc/dc converter, comprising a permanent magnet having spaced-apart poles and a permanent magnetic field extending between the poles of the magnet. A variable-reluctance core is disposed in the field in fixed relation to the magnet and the reluctance of the core is varied to cause the pattern of lines of force of the magnetic field to shift. An output conductor is disposed in the field in fixed relation to the magnet and is positioned to be cut by the shifting lines of permanent magnetic force so that a voltage is induced in the conductor. The magnetic flux is switched between alternate paths by means of switching coils extending around portions of the core, with the flow of current being alternated between these switching coils by means of a pair of transistors driven by the outputs of a flip-flop. The input to the flip flop is driven by an adjustable frequency oscillator. Power for this drive circuit is supplied through an additional, separate power source. What is needed is a magnetic generator not requiring the application of such a power source.

U.S. Patent No. 4,904,926 describes another magnetic generator using the motion of a magnetic field. The device includes an electrical winding defining a magnetically conductive zone having bases at each end, the winding including elements for the removing of an induced current therefrom. The generator further includes two pole magnets, each having a first and a second pole, each first pole in magnetic communication with one base of the magnetically conductive zone. The generator further includes a third pole magnet, the third pole magnet oriented intermediately of the first poles of the two pole electromagnets, the third pole magnet having a magnetic axis substantially transverse to an axis of the magnetically conductive zone, the third magnet having a pole nearest to the conductive zone and in magnetic attractive relationship to the first poles of the two pole electromagnets, in which the first poles thereof are like poles. Also included in the generator are elements, in the form of windings, for cyclically reversing the magnetic polarities of the electromagnets. These reversing means, through a cyclical change in the magnetic polarities of the electromagnets, cause the magnetic flux lines associated with the magnetic attractive relationship between the first poles of the electromagnets and the nearest pole of the third magnet to correspondingly reverse, causing a wiping effect across the magnetically conductive zone, as lines of magnetic flux swing between respective first poles of the two electromagnets, thereby inducing electron movement within the output windings and thus generating a flow of current within the output windings.

U.S. Patent No. 5,221,892 describes a magnetic generator in the form of a direct current flux compression transformer including a magnetic envelope having poles defining a magnetic axis and characterised by a pattern of magnetic flux lines in polar symmetry about the axis. The magnetic flux lines are spatially displaced relative to the magnetic envelope using control elements which are mechanically stationary relative to the core. Further provided are inductive elements which are also mechanically stationary relative to the magnetic envelope. Spatial displacement of the flux relative to the inductive elements causes a flow of electrical current. Further provided are magnetic flux valves which provide for the varying of the magnetic reluctance to create a time domain pattern of respectively enhanced and decreased magnetic reluctance across the magnetic valves, and, thereby, across the inductive elements.

Other patents describe devices using superconductive elements to cause movement of the magnetic flux. These devices operate in accordance with the Meissner effect, which describes the expulsion of magnetic flux from the interior of a superconducting structure as the structure undergoes the transition to a superconducting phase. For example, U.S. Patent No. 5,011,821 describes an electric power generating device including a bundle of conductors which are placed in a magnetic field generated by north and south pole pieces of a permanent magnet. The magnetic field is shifted back and forth through the bundle of conductors by a pair of thin films of superconductive material. One of the thin films is placed in the superconducting state while the other thin film is in a non-superconducting state. As the states are cyclically reversed between the two films, the magnetic field is deflected back and forth through the bundle of conductors.

U.S. Patent No. 5,327,015 describes an apparatus for producing an electrical impulse comprising a tube made of superconducting material, a source of magnetic flux mounted about one end of the tube, a means, such as a coil, for intercepting the flux mounted along the tube, and a means for changing the temperature of the superconductor mounted about the tube. As the tube is progressively made superconducting, the magnetic field is trapped within the tube, creating an electrical impulse in the means for intercepting. A reversal of the superconducting state produces a second pulse.
None of the patented devices described above use a portion of the electrical power generated within the device to power the reversing means used to change the path of magnetic flux. Thus, like conventional rotary generators, these devices require a steady input of power, which may be in the form of electrical power

driving the reversing means of one of these magnetic generators or the torque driving the rotor of a conventional rotary generator. Yet, the essential function of the magnetic portion of an electrical generator is simply to switch magnetic fields in accordance with precise timing. In most conventional applications of magnetic generators, the voltage is switched across coils, creating magnetic fields in the coils which are used to override the fields of permanent magnets, so that a substantial amount of power must be furnished to the generator to power the switching means, reducing the efficiency of the generator.

Recent advances in magnetic material, which have particularly been described by Robert C. O'Handley in Modern Magnetic Materials, Principles and Applications, John Wiley & Sons, New York, pp. 456-468, provide nanocrystalline magnetic alloys, which are particularly well suited forth rapid switching of magnetic flux. These alloys are primarily composed of crystalline grains, or crystallites, each of which has at least one dimension of a few nanometres. Nanocrystalline materials may be made by heat-treating amorphous alloys which form precursors for the nanocrystalline materials, to which insoluble elements, such as copper, are added to promote massive nucleation, and to which stable, refractory alloying materials, such as niobium or tantalum carbide are added to inhibit grain growth. Most of the volume of nanocrystalline alloys is composed of randomly distributed crystallites having dimensions of about 2-40 nm. These crystallites are nucleated and grown from an amorphous phase, with insoluble elements being rejected during the process of crystallite growth. In magnetic terms, each crystallite is a single-domain particle. The remaining volume of nanocrystalline alloys is made up of an amorphous phase in the form of grain boundaries having a thickness of about 1 nm.

Magnetic materials having particularly useful properties are formed from an amorphous Co--Nb--B (cobalt-niobium-boron) alloy having near-zero magnetostriction and relatively strong magnetisation, as well as good mechanical strength and corrosion resistance. A process of annealing this material can be varied to change the size of crystallites formed in the material, with a resulting strong effect on DC coercivity. The precipitation of nanocrystallites also enhances AC performance of the otherwise amorphous alloys.

Other magnetic materials are formed using iron-rich amorphous and nanocrystalline alloys, which generally show larger magnetisation that the alloys based on cobalt. Such materials are, for example, Fe--B--Si--Nb--Cu (iron-boron-silicon-niobium-copper) alloys. While the permeability of iron-rich amorphous alloys is limited by their relatively large levels of magnetostriction, the formation of a nanocrystalline material from such an amorphous alloy dramatically reduces this level of magnetostriction, favouring easy magnetisation.

Advances have also been made in the development of materials for permanent magnets, particularly in the development of materials including rare earth elements. Such materials include samarium cobalt, SmCo.sub.5, which is used to form a permanent magnet material having the highest resistance to demagnetisation of any known material. Other magnetic materials are made, for example, using combinations of iron, neodymium, and boron.

SUMMARY OF THE INVENTION:

It is a first objective of the present invention, to provide a magnetic generator which eliminates the need for an external power source during operation of the generator.

It is a second objective of the present invention to provide a magnetic generator in which a magnetic flux path is changed without a need to overpower a magnetic field to change its direction.

It is a third objective of the present invention to provide a magnetic generator in which the generation of electricity is accomplished without moving parts.

In the apparatus of the present invention, the path of the magnetic flux from a permanent magnet is switched in a manner not requiring the overpowering of the magnetic fields. Furthermore, a process of self-initiated iterative switching is used to switch the magnetic flux from the permanent magnet between alternate magnetic paths within the apparatus, with the power to operate the iterative switching being provided through a control circuit consisting of components known to use low levels of power. With self-switching, a need for an external power source during operation of the generator is eliminated, with a separate power source, such as a battery, being used only for a very short time during start-up of the generator.

According to a first aspect of the present invention, an electromagnetic generator is provided, including a permanent magnet, a magnetic core, first and second input coils, first and second output coils, and a switching circuit. The permanent magnet has magnetic poles at opposite ends. The magnetic core includes a first magnetic path, around which the first input and output coils extend, and a second magnetic path, around which the second input and output coils extend, between opposite ends of the permanent magnet. The switching circuit drives electrical current alternately through the first and second input coils. The electrical

current driven through the first input oil causes the first input coil to produce a magnetic field opposing a concentration of magnetic flux from the permanent magnet within the first magnetic path. The electrical current driven through the second input coil causes the second input coil to produce a magnetic field opposing a concentration of magnetic flux from the permanent magnet within the second magnetic path.

According to another aspect of the present invention, an electromagnetic generator is provided, including a magnetic core, a plurality of permanent magnets, first and second pluralities of input coils, a plurality of output coils, and a switching circuit. The magnetic core includes a pair of spaced-apart plates, each of which has a central aperture, and first and second pluralities of posts extending between the spaced-apart plates. The permanent magnets each extend between the pair of spaced apart plates. Each permanent magnet has magnetic poles at opposite ends, with the magnetic fields of all the permanent magnets being aligned to extend in a common direction. Each input coil extends around a portion of a plate within the spaced-apart plates, between a post and a permanent magnet. An output coil extends around each post. The switching circuit drives electrical current alternately through the first and second input coils. Electrical current driven through each input coil in the first plurality of input coils causes an increase in magnetic flux within each post within the first plurality of posts from permanent magnets on each side of the post and a decrease in magnetic flux within each post within the second plurality of posts from permanent magnets on each side of the post. Electrical current driven through each input coil in the second plurality of input coils causes a decrease in magnetic flux within each post within the first plurality of posts from permanent magnets on each side of the post and an increase in magnetic flux within each post within the second plurality of posts from permanent magnets on each side of the post.

FIG. 12

DETAILED DESCRIPTION OF THE INVENTION:

Fig.1 is a partly schematic front elevation, of an electromagnetic generator **10**, built in accordance with a first embodiment of the present invention, to include a permanent magnet **12** to supply input lines of magnetic flux moving from the north pole **14** of the magnet **12,** outward into magnetic flux path core material **16**.

The flux path core material **16** is configured to form a right magnetic path **18** and a left magnetic path **20**, both of which extend externally between the north pole **14** and the south pole **22** of the magnet **12**.

The electromagnetic generator **10** is driven by means of a switching and control circuit **24**, which alternately drives electrical current through a right input coil **26** and a left input coil **28**. These input coils each extend around a portion of the core material **16**, with the right input coil **26** surrounding a portion of the right magnetic path **18** and with the left input coil **28** surrounding a portion of the left magnetic path **20**. A right output coil **29** also surrounds a portion of the right magnetic path **18**, while a left output coil **30** surrounds a portion of the left magnetic path **20**.

In accordance with a preferred version of the present invention, the switching and control circuit **24** and the input coils **26, 28** are arranged so that, when the right input coil **26** is energised, a north magnetic pole is present at its left end **31**, the end closest to the north pole **14** of the permanent magnet **12**, and so that, when the left input coil **28** is energised, a north magnetic pole is present at its right end **32**, which is also the end closest to the north pole **14** of the permanent magnet **12**. Thus, when the right input coil **26** is magnetised, magnetic flux from the permanent magnet **12** is repelled from extending through the right input coil **26**. Similarly, when the left input coil **28** is magnetised, magnetic flux from the permanent magnet **12** is repelled from extending through the left input coil **28**.

Thus, it is seen that driving electrical current through the right input coil **26** opposes a concentration of flux from the permanent magnet **12** within the right magnetic path **18**, causing at least some of this flux to be transferred to the left magnetic path **20**. On the other hand, driving electrical current through the left input coil **28** opposes a concentration of flux from the permanent magnet **12** within the left magnetic path **20**, causing at least some of this flux to be transferred to the right magnetic path **18**.

While in the example of **Fig.1**, the input coils **26, 28** are placed on either side of the north pole of the permanent magnet **12**, being arranged along a portion of the core **16** extending from the north pole of the permanent magnet **12**, it is understood that the input coils **26, 28** could as easily be alternately placed on either side of the south pole of the permanent magnet **12**, being arranged along a portion of the core **16** extending from the south pole of the permanent magnet **12**, with the input coils **26, 28** being wired to form, when energised, magnetic fields having south poles directed toward the south pole of the permanent magnet **12**. In general, the input coils **26, 28** are arranged along the magnetic core on either side of an end of the permanent magnet forming a first pole, such as a north pole, with the input coils being arranged to produce magnetic fields of the polarity of the first pole directed toward the first pole of the permanent magnet.

Further in accordance with a preferred version of the present invention, the input coils **26, 28** are never driven with so much current that the core material **16** becomes saturated. Driving the core material **16** to saturation means that subsequent increases in input current can occur without effecting corresponding changes in magnetic flux, and therefore that input power can be wasted. In this way, the apparatus of the present

invention is provided with an advantage in terms of the efficient use of input power over the apparatus of U.S. Patent No. 4,000,401, in which a portion both ends of each magnetic path is driven to saturation to block flux flow.

In the electromagnetic generator **10**, the switching of current flow within the input coils **26, 28** does not need to be sufficient to stop the flow of flux in one of the magnetic paths **18, 20** while promoting the flow of magnetic flux in the other magnetic path. The electromagnetic generator **10** works by changing the flux pattern; it does not need to be completely switched from one side to another.

Experiments have determined that this configuration is superior, in terms of the efficiency of using power within the input coils **26, 28** to generate electrical power within the output coils **29, 30**, to the alternative of arranging input coils and the circuits driving them so that flux from the permanent magnet is driven through the input coils as they are energised. This arrangement of the present invention provides a significant advantage over the prior-art methods shown, for example, in U.S. Patent No. 4,077,001, in which the magnetic flux is driven through the energised coils.

The configuration of the present invention also has an advantage over the prior-art configurations of U.S. Patent Nos. 3,368,141 and 4,077,001 in that the magnetic flux is switched between two alternate magnetic paths **18, 20** with only a single input coil **26, 28** surrounding each of the alternate magnetic paths. The configurations of U.S. Patent Nos. 3,368,141 and 4,077,001 each require two input coils on each of the magnetic paths. This advantage of the present invention is significant both in the simplification of hardware and in increasing the efficiency of power conversion.

The right output coil **29** is electrically connected to a rectifier and filter **33**, having an output driven through a regulator **34**, which provides an output voltage adjustable through the use of a potentiometer **35**. The output of the linear regulator **34** is in turn provided as an input to a sensing and switching circuit **36**. Under start up conditions, the sensing and switching circuit **36** connects the switching and control circuit **24** to an external power source **38**, which is, for example, a starting battery. After the electromagnetic generator **10** is properly started, the sensing and switching circuit **36** senses that the voltage available from regulator **34** has reached a predetermined level, so that the power input to the switching and control circuit **24** is switched from the external power source **38** to the output of regulator **34**. After this switching occurs, the electromagnetic generator **10** continues to operate without an application of external power.

The left output coil **30** is electrically connected to a rectifier and filter **40**, the output of which is connected to a regulator **42**, the output voltage of which is adjusted by means of a potentiometer **43**. The output of the regulator **42** is in turn connected to an external load **44**.

Fig.2 is a schematic view of a first version of the switching and control circuit **24**. An oscillator **50** drives the clock input of a flip-flop **54**, with the Q and Q' outputs of the flip-flop **54** being connected through driver circuits **56, 58** to power FETs **60, 62** so that the input coils **26, 28** are driven alternately. In accordance with a preferred version of the present invention, the voltage V applied to the coils **26, 28** through the FETs **60, 62** is derived from the output of the sensing and switching circuit **36**.

Fig.3 is a graphical view of the signals driving the gates of FETs **60, 62** of **Fig.2**, with the voltage driving the gate of FET **60** being represented by line **64**, and with the voltage driving FET **62** being represented by line **66**. Both of the coils **26, 28** are driven with positive voltages.

Fig.4 is a schematic view of a second version of the switching and control circuit **24**. In this version, an oscillator **70** drives the clock input of a flip-flop **72**, with the Q and Q' outputs of the flip-flop **72** being connected to serve as triggers for one-shots **74, 76**. The outputs of the one-shots **74, 76** are in turn connected through driver circuits **78, 80** to drive FETs **82, 84**, so that the input coils **26, 28** are alternately driven with pulses shorter in duration than the Q and Q' outputs of the flip flop **72**.

Fig.5 is a graphical view of the signals driving the gates of FETs **82, 84** of **Fig.4**, with the voltage driving the gate of FET **82** being represented by line **86**, and with the voltage driving the gate of FET **84** being represented by line **88**.

Referring again to **Fig.1**, power is generated in the right output coil **29** only when the level of magnetic flux is changing in the right magnetic path **18**, and in the left output coil **30** only when the level of magnetic flux is changing in the left magnetic path **20**. It is therefore desirable to determine, for a specific magnetic generator configuration, the width of a pulse providing the most rapid practical change in magnetic flux, and then to provide this pulse width either by varying the frequency of the oscillator **50** of the apparatus of **Fig.2**, so that this pulse width is provided with the signals shown in **Fig.3**, or by varying the time constant of the one-shots **74, 76** of **Fig.4**, so that this pulse width is provided by the signals of **Fig.5** at a lower oscillator frequency. In this way, the input coils are not left on longer than necessary. When either of the input coils is left on for a

period of time longer than that necessary to produce the change in flux direction, power is being wasted through heating within the input coil without additional generation of power in the corresponding output coil.

A number of experiments have been conducted to determine the adequacy of an electromagnetic generator built as the generator **10** in **Fig.1**, to produce power both to drive the switching and control logic, providing power to the input coils **26, 28**, and to drive an external load **44**. In the configuration used in this experiment, the input coils **26, 28** had 40 turns of 18-gauge copper wire, and the output coils **29, 30** had 450 turns of 18-gauge copper wire. The permanent magnet **12** had a height of 40 mm (1.575 in. between its north and south poles, in the direction of arrow **89**, a width of 25.4 mm (1.00 in.), in the direction of arrow **90**, and in the other direction, a depth of 38.1 mm (1.50 in.). The core **16** had a height, in the direction of arrow **89**, of 90 mm (3.542 in.), a width, in the direction of arrow **90**, of 135 mm (5.315 in.) and a depth of 70 mm (2.756 in.). The core **16** had a central hole with a height, in the direction of arrow **89**, of 40 mm (1.575 mm) to accommodate the magnet **12**, and a width, in the direction of arrow **90**, of 85 mm (3.346 in.). The core **16** was fabricated of two "C"-shaped halves, joined at lines **92**, to accommodate the winding of output coils **29, 30** and input coils **26, 28** over the core material.

The core material was a laminated iron-based magnetic alloy sold by Honeywell as METGLAS Magnetic Alloy 2605SA1. The magnet material was a combination of iron, neodymium, and boron.

The input coils **26, 28** were driven at an oscillator frequency of 87.5 KHz, which was determined to produce optimum efficiency using a switching control circuit configured as shown in **Fig.2**. This frequency has a period of 11.45 microseconds. The flip flop **54** is arranged, for example, to be set and reset on rising edges of the clock signal input from the oscillator, so that each pulse driving one of the FETs **60, 62** has a duration of 11.45 microseconds, and so that sequential pulses are also separated to each FET are also separated by 11.45 microseconds.

Fig.6A to **Fig.6H**, are graphical views of signals which occurred simultaneously during the operation of the apparatus shown in **Fig.1** and **Fig.2**, when the input voltage applied was 75 volts. **Fig.6A** shows a first drive signal **100** driving FET **60**, which conducts to drive the right input coil **26**. **Fig.6B** shows a second drive signal **102**, driving FET **62**, which, when it conducts, provides the drive to the left input coil **28**.

Fig.6C and **Fig.6D** show voltage and current signals produced when the current driving the FETs **60, 62** is provided from a battery source. **Fig.6C** shows the level **104** of voltage V. While the nominal voltage of the battery was 75 volts, a decaying transient signal **106** is superimposed on this voltage each time one of the FETs **60, 62** is switched on. The specific pattern of this transient signal depends on the internal resistance of the battery, as well as on a number of characteristics of the magnetic generator **10**. Similarly, **Fig.6D** shows the current **106** flowing into FETs **60, 62** from the battery source. Since the signals **104, 106** show the effects of current flowing into both FETs **60, 62** the transient spikes are 11.45 microseconds apart.

Figs.6E to 6H, show the voltage and current levels measured at the output coils **29, 30**. **Fig.6E** shows a voltage output signal **108** of the right output coil **29**, while **Fig.6F** shows a voltage output signal **110** of the left output coil **30**. For example, the output current signal **116** of the right output coil **29** includes a first transient spike **112** caused when a pulse of current is generated in the left input coil **28** in order to boost the magnetic flux passing through the right magnetic path **18**, and a second transient spike **114** caused when the left input coil **28** is turned off as the right input coil **26** is being turned on. **Fig.6G** shows an output current signal **116** of the right output coil **29**, while **Fig.6H** shows an output current signal **118** of the left output coil **30**.

Fig.7 is a graphical view of output power measured using the electromagnetic generator **10** and eight levels of input voltage, varying from 10v to 75v. The oscillator frequency was retained at 87.5 KHz. The measured values are represented by points **120**, while the curve **122** is generated by polynomial regression, (a least squares fit).

Fig.8 is a graphical view of a coefficient of performance, defined as the ratio of the output power to the input power, for each of the measurement points shown in **Fig.7**. At each measurement point, the output power was substantially higher than the input power. Real power measurements were computed at each data point using measured voltage and current levels, with the results being averaged over the period of the signal. These measurements agree with RMS power measured using a Textronic THS730 digital oscilloscope.

While the electromagnetic generator **10** was capable of operation at much higher voltages and currents without saturation, the input voltage was limited to 75 volts because of voltage limitations of the switching circuits being used. Those familiar with electronics will understand that components for switching circuits capable of handling higher voltages are readily available for use in this application.

The experimentally-measured data were extrapolated to predict operation at an input voltage of 100 volts, with the input current being 140 mA, the input power being 14 watts, and with a resulting output power being

48 watts for each of the two output coils **29, 30**, at an average output current of 12 mA and an average output voltage of 4000 volts. This means that for each of the output coils **29, 30**, the coefficient of performance ("COP") would be 3.44.

While an output voltage of 4000 volts may be needed for some applications, the output voltage can also be varied through a simple change in the configuration of the electromagnetic generator **10**. The output voltage is readily reduced by reducing the number of turns in the output windings. If this number of turns is decreased from 450 to 12, the output voltage is dropped to 106.7, with a resulting increase in output current to 0.5 amps for each output coil **29, 30**, (i.e. 53 watts). In this way, the output current and voltage of the electromagnetic generator can be varied by varying the number of turns of the output coils **29, 30**, without making a substantial change in the output power, which is instead determined by the input current, which determines the amount of magnetic flux shuttled during the switching process.

All of the **C**oefficients **O**f **P**erformance were significantly greater than 1. These are plotted in **Fig.8** and they indicate that the output power levels measured in each of the output coils **29, 30** were substantially greater than the corresponding input power levels driving both of the input coils **26, 28**. Therefore, it is apparent that the electromagnetic generator **10** can be built in a self-powered form, as discussed above in reference to **Fig.1**. In the example of **Fig.1**, except for a brief application of power from the external power source **38** to start the process of power generation, the power required to drive the input coils **26, 28** is derived entirely from power developed within the right output coil **29**. If the power generated in the single output coil **29**, is more than sufficient to drive the input coils **26, 28**, an additional load **126** may be added to be driven with power generated in the output coil **29**. On the other hand, each of the output coils **29, 30** may be used to drive a portion of the input coil power requirements, for example, output coils 26 can provide the driving voltage V for FET **60** while output coil 28 can provide the driving voltage V for FET **62**.

Regarding thermodynamic considerations, it is noted that when the electromagnetic generator **10** is operating, it is an open system not in thermodynamic equilibrium. The system receives static energy from the magnetic flux of the permanent magnet. Because the electromagnetic generator **10** is self-switched without an additional energy input, the thermodynamic operation of the system is an open dissipative system, receiving, collecting, and dissipating energy from its environment; in this case, from the magnetic flux stored within the permanent magnet. Continued operation of the electromagnetic generator **10** causes demagnetisation of the permanent magnet. The use of a magnetic material including rare earth elements, such as a samarium cobalt material or a material including iron, neodymium, and boron is preferable within the present invention, since such a magnetic material has a relatively long life in this application.

Thus, an electromagnetic generator operating in accordance with the present invention should not be considered as a perpetual-motion machine, but rather as a system in which flux radiated from a permanent magnet is converted into electricity, which is used both to power the apparatus and to power an external load. This is analogous to a system including a nuclear reactor, in which a number of fuel rods radiate energy which is used to keep the chain reaction going and to heat water for the generation of electricity to drive external loads.

Fig.9 is a cross-sectional elevation of an electromagnetic generator **130** built in accordance with a second version of the first embodiment of the present invention. This electromagnetic generator **130** is generally similar in construction and operation to the electromagnetic generator **10** built in accordance with the first version of this embodiment, except that the magnetic core **132** of the electromagnetic generator **10** is built in two halves joined along lines **134**, allowing each of the output coils **135** to be wound on a plastic bobbin **136** before being placed over the legs **137** of the core **132**.

Fig.9 also shows an alternate placement of an input coil **138**. In the example of **Fig.1**, both of the input coils **26, 28** were placed on the upper portion of the magnetic core **16**, with these coils being configured to generate magnetic fields having north magnetic poles at the inner ends **31, 32** of the coils **26, 28**, with these north magnetic poles thus being closest to the end **14** of the permanent magnet **12** having its north magnetic pole. In the example of **Fig.9**, a first input coil **26** is as described above in reference to **Fig.1**, but the second input coil **138** is placed adjacent the south pole **140** of the permanent magnet **12**. This input coil **138** is configured to generate a south magnetic pole at its inner end **142**, so that, when input coil **138** is turned on, flux from the permanent magnet **12** is directed away from the left magnetic path **20** into the right magnetic path **18**.

Fig.10 and **Fig.11** show an electromagnetic generator **150** built in accordance with a first version of a second embodiment of the present invention, with **Fig.10** being a top view, and **Fig.11** being a front elevation. This electromagnetic generator **150** includes an output coil **152, 153** at each corner, and a permanent magnet **154** extending along each side between output coils. The magnetic core **156** includes an upper plate **158**, a lower plate **160**, and a square post **162** extending within each output coil **152, 153**. Both the upper plate **158** and the lower plate **160** include central apertures **164**.

Each of the permanent magnets **154** is oriented with a like pole, such as a north pole, against the upper plate **158**. Eight input coils **166, 168** are placed in positions around the upper plate **158** between an output coil **152, 153** and a permanent magnet **154**. Each input coil **166, 168** is arranged to form a magnetic pole at its end nearest to the adjacent permanent magnet **154** of the same polarity as the magnetic poles of the magnets **154** adjacent the upper plate **158**. Thus, the input coils **166** are switched on to divert the magnetic flux of the permanent magnets **154** from the adjacent output coils **152**, into magnetic paths through the output coils **153**. Then, the input coils **168** are switched on to divert magnetic flux of the permanent magnets **154** from the adjacent output coils **153**, with this flux being diverted into magnetic paths through the output coils **152**. Thus, the input coils form a first group of input coils **166** and a second group of input coils **168**, with these first and second groups of input coils being alternately energised in the manner described above in reference to **Fig.1** for the single input coils **26, 28**. The output coils produce current in a first train of pulses occurring simultaneously within coils **152** and in a second train of pulses occurring simultaneously within coils **153**.

Thus, driving current through input coils **166** causes an increase in flux from the permanent magnets **154** within the posts **162** extending through output coils **153** and a decrease in flux from the permanent magnets **154** within the posts **162** extending through output coils **152**. On the other hand, driving current through input coils **168** causes a decrease in flux from the permanent magnets **154** within the posts **162** extending through output coils **153** and an increase in flux from the permanent magnets **154** within the posts **162** extending through output coils **152**.

While the example of **Fig.10** and **Fig.11** shows all of the input coils **166,168** deployed along the upper plate **158**, it is understood that certain of these input coils **166, 168** could alternately be deployed around the lower plate **160**, in the manner generally shown in **Fig.9**, with one input coil **166**, **168** being within each magnetic circuit between a permanent magnet **154** and an adjacent post **162** extending within an output coil **152, 153**, and with each input coil **166, 168** being arranged to produce a magnetic field having a magnetic pole like the closest pole of the adjacent permanent magnet **154**.

Fig.12 is a top view of a second version **170** of the second embodiment of the present invention, which is similar to the first version thereof, which has been discussed in reference to **Fig.10** and **Fig.11**, except that an upper plate **172** and a similar lower plate (not shown) are annular in shape, while the permanent magnets **174** and posts **176** extending through the output coils **178** are cylindrical. The input coils **180** are oriented and switched as described above in reference to **Fig.9** and **Fig.10**.

While the example of **Fig.12** shows four permanent magnets, four output coils and eight input coils it is understood that the principles described above can be applied to electromagnetic generators having different numbers of elements. For example, such a device can be built to have two permanent magnets, two output coils, and four input coils, or to have six permanent magnets, six output coils, and twelve input coils.

In accordance with the present invention, material used for magnetic cores is preferably a nanocrystalline alloy, and alternately an amorphous alloy. The material is preferably in a laminated form. For example, the core material is a cobalt-niobium-boron alloy or an iron based magnetic alloy.

Also in accordance with the present invention, the permanent magnet material preferably includes a rare earth element. For example, the permanent magnet material is a samarium cobalt material or a combination of iron, neodymium, and boron.

While the invention has been described in its preferred versions and embodiments with some degree of particularity, it is understood that this description has been given only by way of example and that numerous changes in the details of construction, fabrication, and use, including the combination and arrangement of parts, may be made without departing from the spirit and scope of the invention.

CLAIMS:

1. An electromagnetic generator comprising: a permanent magnet having magnetic poles at opposite ends; a magnetic core including first and second magnetic paths between said opposite ends of said permanent magnet, wherein said magnetic core comprises a closed loop, said permanent magnet extends within said closed loop, and said opposite ends of said permanent magnet are disposed adjacent opposite sides of said closed loop and against internal surfaces of said magnetic core comprising said closed loop; a first input coil extending around a portion of said first magnetic path, a second input coil extending around a portion of said second magnetic path, a first output coil extending around a portion of said first magnetic path for providing a first electrical output; a second output coil extending around a portion of said second magnetic path for providing a second electrical output; and a switching circuit driving electrical current alternately through said first and second input coils, wherein said electrical current driven through said first input coil causes said first input coil to produce a magnetic field opposing a concentration of magnetic flux

from said permanent magnet within said first magnetic path, and said electrical current driven through said second input coil causes said second input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said second magnetic path.

2. An electromagnetic generator comprising: a permanent magnet having magnetic poles at opposite ends; a magnetic core including first and second magnetic paths between said opposite ends of said permanent magnet, wherein said magnetic core comprises a closed loop, said permanent magnet extends within said closed loop, said opposite ends of said permanent magnet are disposed adjacent opposite sides of said closed loop, and a first type of pole of said permanent magnet is disposed adjacent a first side of said closed loop; a first input coil, disposed along said first side of said closed loop, extending around a portion of said first magnetic path, a second input coil, disposed along said first side of said closed loop, extending around a portion of said second magnetic path, a first output coil extending around a portion of said first magnetic path for providing a first electrical output; a second output coil extending around a portion of said second magnetic path for providing a second electrical output; and a switching circuit driving electrical current alternately through said first and second input coils, wherein said electrical current driven through said first input coil causes said first input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said first magnetic path, and additionally causes said first input coil to produce a magnetic field having said first type of pole at an end of said first input coil adjacent said permanent magnet, and said electrical current driven through said second input coil causes said second input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said second magnetic path, and additionally causes said second input coil to produce a magnetic field having said first type of pole at an end of said of said second input coil adjacent said permanent magnet.

3. An electromagnetic generator comprising: a permanent magnet having magnetic poles at opposite ends; a magnetic core including first and second magnetic paths between said opposite ends of said permanent magnet, wherein said magnetic core comprises a closed loop, said permanent magnet extends within said closed loop, and said opposite ends of said permanent magnet are disposed adjacent opposite sides of said closed loop, a first type of pole of said permanent magnet is disposed adjacent a first side of said closed loop, and a second type of pole, opposite said first type of pole, of said permanent magnet is disposed adjacent a second side of said closed loop; a first input coil extending around a portion of said first magnetic path, wherein said first input coil is disposed along said first side of said closed loop; a second input coil extending around a portion of said second magnetic path wherein said second input coil is disposed along said second side of said closed loop; a first output coil extending around a portion of said first magnetic path for providing a first electrical output; a second output coil extending around a portion of said second magnetic path for providing a second electrical output; and a switching circuit driving electrical current alternately through said first and second input coils, wherein said electrical current driven through said first input coil causes said first input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said first magnetic path, and additionally causes said first input coil to produce a magnetic field having said first type of pole at an end of said first input coil adjacent said permanent magnet, and said electrical current driven through said second input coil causes said second input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said second magnetic path, and additionally causes said second input coil to produce a magnetic field having said second type of pole at an end of said of said second input coil adjacent said permanent magnet.

4. An electromagnetic generator comprising: a permanent magnet having magnetic poles at opposite ends; a magnetic core including first and second magnetic paths between said opposite ends of said permanent magnet; a first input coil extending around a portion of said first magnetic path, a second input coil extending around a portion of said second magnetic path, a first output coil extending around a portion of said first magnetic path for providing a first electrical output; a second output coil extending around a portion of said second magnetic path for providing a second electrical output; and a switching circuit driving electrical current alternately through said first and second input coils, wherein said electrical current driven through said first input coil causes said first input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said first magnetic path, and wherein said electrical current driven through said second input coil causes said second input coil to produce a magnetic field opposing a concentration of magnetic flux from said permanent magnet within said second magnetic path, wherein a portion of electrical power induced in said first output coil provides power to drive said switching circuit.

5. The electromagnetic generator of claim 4, wherein said switching circuit is driven by an external power source during a starting process and by power induced in said first output coil during operation after said starting process.

6. The electromagnetic generator of claim 2, wherein said magnetic core is composed of a nanocrystalline magnetic alloy.

7. The electromagnetic generator of claim 6, wherein said nanocrystalline magnetic alloy is a cobalt-niobium-boron alloy.

8. The electromagnetic generator of claim 6, wherein said nanocrystalline magnetic alloy is an iron-based alloy.

9. The electromagnetic generator of claim 2, wherein said changes in flux density within said magnetic core occur without driving said magnetic core to magnetic saturation.

10. The electromagnetic generator of claim 2, wherein said switching circuit drives said electrical current through said first input coil in response to a first train of pulses, said switching circuit drives said electrical current through said second input coil in response to a second train of pulses, alternating with pulses within said first train of pulses, and said pulses in said first and second trains of pulses are approximately 11.5 milliseconds in duration.

11. The electromagnetic generator of claim 2, wherein said permanent magnet is composed of a material including a rare earth element.

12. The electromagnetic generator of claim 11, wherein said permanent magnet is composed essentially of samarium cobalt.

13. The electromagnetic generator of claim 11, wherein said permanent magnet is composed essentially of iron, neodymium, and boron.

14. An electromagnetic generator comprising: a magnetic core including a pair of spaced-apart plates, wherein each of said spaced-apart plates includes a central aperture, and first and second pluralities of posts extending between said spaced-apart plates; a plurality of permanent magnets extending individually between said pair of spaced-apart plates and between adjacent posts within said plurality of posts, wherein each permanent magnet within said plurality of permanent magnets has magnetic poles at opposite ends, wherein all magnets within said plurality of magnets are oriented to produce magnetic fields having a common direction; first and second pluralities of input coils, wherein each input coil within said first and second pluralities of input coils extends around a portion of a plate within said spaced-apart plates between a post in said plurality of posts and a permanent magnet in said plurality of permanent magnets; an output coil extending around each post in said first and second pluralities of posts for providing an electrical output; a switching circuit driving electrical current alternatively through said first and second pluralities of input coils, wherein said electrical current driven through each input coil in said first plurality of input coils causes an increase in magnetic flux within each post within said first plurality of posts from permanent magnets on each side of said post and a decrease in magnetic flux within each post within said second plurality of posts from permanent magnets on each side of said post, and wherein said electrical current driven through input coil in said second plurality of input coils causes a decrease in magnetic flux within each post within said first plurality of posts from permanent magnets on each side of said post and an increase in magnetic flux within each post within said second plurality of posts from permanent magnets on each side of said post.

15. The electromagnetic generator of claim 14, wherein each input coil extends around a portion of a magnetic path through said magnetic core between said opposite ends a permanent magnet adjacent said input coil, said magnetic path extends through a post within said magnetic core adjacent said input coil, and driving electrical current through said input coil causes said input coil to produce a magnetic field opposing a concentration of magnetic flux within said magnetic path.

16. The electromagnetic generator of claim 14, wherein said switching circuit is driven by an external power source during a starting process and by power induced in said output coils during operation after said starting process.

17. The electromagnetic generator of claim 14, wherein said magnetic core is composed of a nanocrystalline magnetic alloy.

18. The electromagnetic generator of claim 2, wherein a portion of electrical power induced in said first output coil provides power to drive said switching circuit.

19. The electromagnetic generator of claim 18, wherein said switching circuit is driven by an external power source during a starting process and by power induced in said first output coil during operation after said starting process.

20. The electromagnetic generator of claim 3, wherein a portion of electrical power induced in said first output coil provides power to drive said switching circuit.

21. The electromagnetic generator of claim 20, wherein said switching circuit is driven by an external power source during a starting process and by power induced in said first output coil during operation after said starting process.

22. The electromagnetic generator of claim 3, wherein said magnetic core is composed of a nanocrystalline magnetic alloy.

23. The electromagnetic generator of claim 22, wherein said nanocrystalline magnetic alloy is a cobalt-niobium-boron alloy.

24. The electromagnetic generator of claim 22, wherein said nanocrystalline magnetic alloy is an iron-based alloy.

25. The electromagnetic generator of claim 3, wherein said changes in flux density within said magnetic core occur without driving said magnetic core to magnetic saturation.

26. The electromagnetic generator of claim 3, wherein said switching circuit drives said electrical current through said first input coil in response to a first train of pulses, said switching circuit drives said electrical current through said second input coil in response to a second train of pulses, alternating with pulses within said first train of pulses, and said pulses in said first and second trains of pulses are approximately 11.5 milliseconds in duration.

27. The electromagnetic generator of claim 3, wherein said permanent magnet is composed of a material including a rare earth element.

28. The electromagnetic generator of claim 27, wherein said permanent magnet is composed essentially of samarium cobalt.

29. The electromagnetic generator of claim 27, wherein said permanent magnet is composed essentially of iron, neodymium, and boron.

ACOUSTIC-MAGNETIC POWER GENERATOR

Please note that this is a re-worded excerpt from this patent. If the content interests you, then you should obtain a full copy via the www.freepatentsonline.com web site. This patent describes an electrical device very similar to the MEG device, capable of powering itself while powering additional external items of equipment.

ABSTRACT

The Acoustic Magnetic Field Power Generator uses an acoustic signal focused into a permanent magnet to stimulate the nuclear structure of the magnet to cause the magnetic field of the permanent magnet to move or oscillate. This effect can be used to tap power from the oscillating magnetic field by putting a coil of wire in the oscillating field. When an alternating current signal generator is connected simultaneously to an acoustic transducer and a stimulating coil; whereby, both the acoustic transducer and the stimulating coil are located within the magnetic field of the magnet, the acoustic signal enhances the stimulating effect to the permanent magnet transformer. The acoustic transducer can be any acoustic generation device such as a piezoelectric, magnetostrictive, or other acoustic transducer. The combined effect of the acoustic signal and the stimulating coil increases the efficiency of permanent magnet induction transformers.

BACKGROUND OF THE INVENTION

The present invention relates to a solid state electrical generator having no moving parts. More particularly, the invention makes use of a new method of stimulating the nuclear material of a permanent magnet so that the electronic structure of the atom will vibrate and thus cause the magnetic field of the permanent magnet to oscillate. It is a well-known fact that an oscillating magnetic field will induce electrical current in a coil as was discovered by Michael Faraday in the last century. What is new in this invention, is the discovery of the ability of an acoustic field to stimulate the nuclear structure of a material to cause the electrons to wobble under the influence of the acoustic field. If the material is magnetic or temporarily magnetised by an external magnetic field then the magnetic field will vibrate under the stimulus of the acoustic field. If this effect is combined with a coil which is simultaneously stimulating the magnet then the efficiency of stimulating the permanent magnet's field is enhanced. If a pickup coil is placed in the oscillating magnetic field so as to create an induction transformer then the combination of the acoustic and magnetic stimulation will enhance the efficiency of the induction transformer.

The most relevant prior art known to the inventor comprises U.S. Pat. No. 4,904,926 (1990) to Mario Pasichinsky, entitled Magnet Motion Electrical Generator; and U.S. Pat. No. 4,077,001 (1978) to Frank Richardson, entitled Electromagnetic Converter With Stationary Variable-Reluctance Members; and U.S. Pat. No. 4,006,401 (1977) to de Rivas, entitled Electromagnetic Generator.

The above references to Pasichinsky, Richardson, and de Rivas, all use inductive methods to stimulate the motion of a permanent magnetic field. In the de Rivas invention, ‘Electromagnetic Generator’, the flux of the permanent magnet is "alternated by switching" using inductive coupling. In the Richardson disclosure an "energy conversion system" the flux of the permanent magnet is also "shifted" by inductive means. In the Pasichinsky disclosure, alternating magnetic coils induce flux changes in a closed magnetic circuit and output coils attached to the circuit are induced by the changing flux to produce a magnetic field. All of these devices are essentially variations of transformer design with permanent magnets as part of the transformer cores and all use magnetic induction. The transformer aspect of these references is the use of permanent magnets as the transformer core with coils wrapped around the magnetic core which are energised to produce oscillation or movement of the permanent magnet's field. The above references will, in this document, be called "permanent magnet transformers".

Other prior art relevant to the invention are U.S. Pat. No. 2,101,272 (1937) to H. J. Scott, entitled Combined Magnetostriction and Piezoelectric Selective Device; and U.S. Pat. No. 2,636,135 (1953) to R. L. Peek, Jr. entitled Stress Coupled Core and Crystal Transformer, and U.S. Pat. No. 2,834,943 (1958) to R. O. Grisdale, etal entitled Mechanically Coupled Electromechanical and Magnetomechanical Transducers, and U.S. Pat. No. 3,246,287 (1966) to H. F. Benson entitled Piezoelectric Transformer, and U.S. Pat. No. 3,261,339 (1966) to H. P. Quinn entitled Magnetostrictive Transformer, and U.S. Pat. No. 3,274,406 (1966) to H. S. Sommers, Jr. entitled Acoustic Electromagnetic Device, and U.S. Pat. No. 3,309,628 (1967) to F. A. Olson entitled YIG Variable Acoustic Delay Line, and U.S. Pat. No. 3,457,463 (1969) to L. Balamuth entitled Method and Apparatus for Generating Electric Currents of Small Magnitude, and U.S. Pat. No. 4,443,731 (1984) to Butler et al. entitled Hybrid Piezoelectric and

Magnetostrictive Acoustic Wave Transducer, and U.S. Pat. No. 4,552,071 (1985) to R. B. Thompson entitled Method and Apparatus for Measuring Stress.

The reference to Peek cited above, takes advantage of the difference in operation of piezoelectric and magnetostrictive crystals to produce a response in one when stimulated by the other. The Peek patent does not use an acoustic wave to stimulate a permanent magnet as in the present invention.

The reference to Sommers cited above, is a transducer which uses a conductive bar or tube, which supports relatively slow helicon waves, placed next to a piezoelectric or magnetostrictive crystal. The transducer is designed in such a way as to either enhance the acoustic wave or the electric wave by interaction of the two materials. The Sommers patent does not use an acoustic wave to stimulate a permanent magnet to enhance to oscillation of the magnetic field as the present invention does.

The reference to Balmuth cited above, uses mechanically resonant reeds, rods, or chambers which are coupled to transducers that are piezoelectric, magnetostrictive, or transistorised. The electrical output of the transducers stimulates an electrical circuit when the resonator receives acoustic energy and again does not use an acoustic wave to stimulate a permanent magnet to enhance to oscillation of the magnetic field as the present invention does.

The reference to Olson cited above, uses an acoustically responsive material such as a piezoelectric or a magnetostrictive to act as a delay line for microwave signals and again does not use an acoustic wave to stimulate a permanent magnet to enhance to oscillation of the magnetic field as the present invention does.

The references to Benson, Quinn, Grisdale, Scott, and Butler cited above, are all concerned with acoustic transducers which convert acoustic pressure to an electrical signal or vice versa using only the piezoelectric and/or the magnetostrictive effect. The Benson patent is an underwater acoustic transformer which converts acoustic waves hitting a transducer into an electromagnetic field which excites a transformer. The Quinn patent uses a magnetostrictive effect to stimulate piezoelectric crystals to output a high voltage which is a reverse of the Benson patent. The Grisdale patent uses mechanically stacked piezoelectric or magnetostrictive crystals to produce a more efficient mechanical gyrator. The Scott patent uses and electrical oscillator to stimulate magnetostrictive rods which put pressure on piezoelectric crystals to output a high voltage from the piezoelectric crystals. The Butler patent uses a combined effect of piezoelectric and magnetostrictive crystals to produce an enhanced acoustic energy detector.

The reference to Thompson cited above, uses a permanent magnetic transducer to induce eddy currents in metal which is in the field of the transducer or uses moving eddy currents in a piece of metal to stimulate a magnetic field. The induction of the eddy currents is the result of an oscillating magnetic field generated in the transducer.

None of the references cited above, use an acoustic wave to stimulate the atoms of a permanent magnet and hence are not related to this invention.

SUMMARY OF THE INVENTION

An object of this invention is to provide a power generator with no moving parts.

Another object of this invention is to use an acoustic field to stimulate the nuclear level of the magnetic material and provide a method of oscillating the magnetic field of permanent magnets.

Another object of this invention is to provide a simple method of generating electrical energy by including a piezoelectric transducer which is used to vibrate the magnetic field of a permanent magnet. When the nucleus of the atom is vibrated by the piezoelectric, it in turn, vibrates the electronic structure of all the atoms. Since the electronic structure is the basis of the magnetic field of the magnet then the entire magnetic field of the magnet is vibrated when the electronic structure is vibrated. Coils placed in the vibrating magnetic field will have voltage and current induced in them.

It is a well established fact, that when the magnetic field of a permanent magnet is vibrated, it is possible to generate an alternating current in a coil winding placed within the vibrating magnetic field. What is unique about this invention, is to increase the efficiency of permanent magnet transformers by using acoustic stimulation from piezoelectrics to further stimulate the permanent magnet so as to add to the inductive effects of permanent magnet transformers. This invention does this by stimulating the permanent magnet cores of permanent magnet transformers with an acoustic field generated by a piezoelectric or other acoustically active generator which is vibrated at the same frequency as the electrical induction of the permanent magnet transformers.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG.1 illustrates a frequency signal generator attached to and driving a piezoelectric transducer which is in the acoustic proximity of a bar type of permanent magnet with a output coil placed within the magnetic field of the permanent magnet.

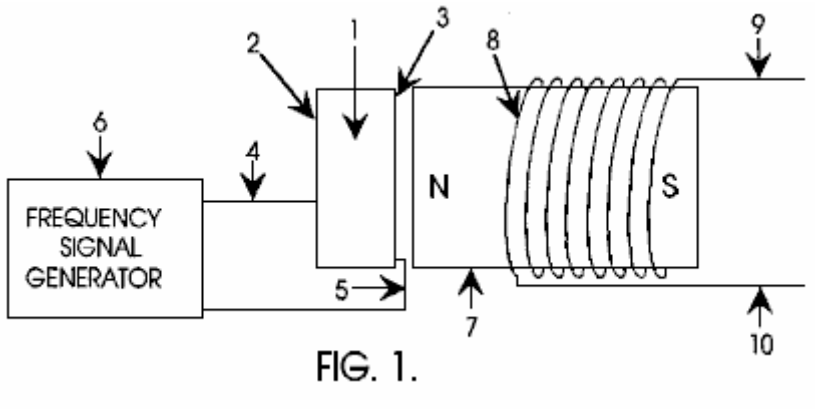

FIG. 1.

Fig.2 illustrates a frequency signal generator attached to and driving a piezoelectric transducer which is in the acoustic proximity of a torroidal type of permanent magnet with an output coil wrapped around the torroidal permanent magnet.

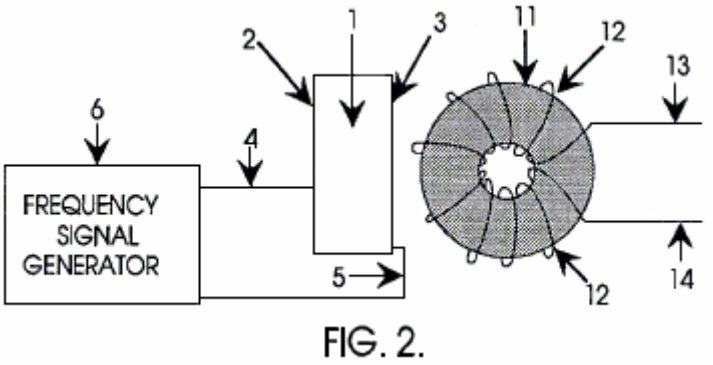

FIG. 2.

FIG. 4.

DETAILED DESCRIPTION OF THE INVENTION

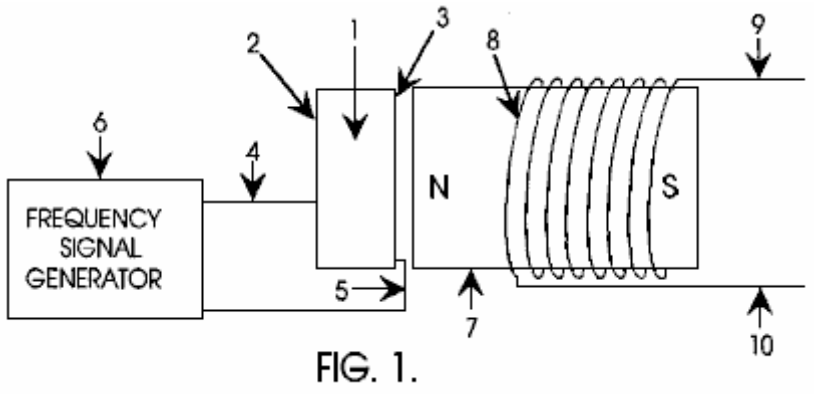

FIG. 1.

In **Fig.1**, a frequency signal generator **6** is connected to a piezoelectric transducer **1** via wires **4** and **5** connected to the electrode surfaces of the piezoelectric transducer **2** and **3** respectively. The piezoelectric transducer **1** is made from a high dielectric material such as barium titanate or lead zirconate titanate or any other acoustic transducer material suitable for sonic and ultrasonic generators. The piezoelectric transducer **1** is placed in close proximity to the permanent magnet **7** such that the acoustic field of the piezoelectric transducer **1** can radiate into the permanent magnet material. A permanent magnet transformer shown as coil **8** is positioned in the magnetic field of the permanent magnet **7**. When the piezoelectric transducer **1** is stimulated by the frequency generator **6** then a voltage and current is generated between the output leads **9** and **10** of the permanent magnet transformer.

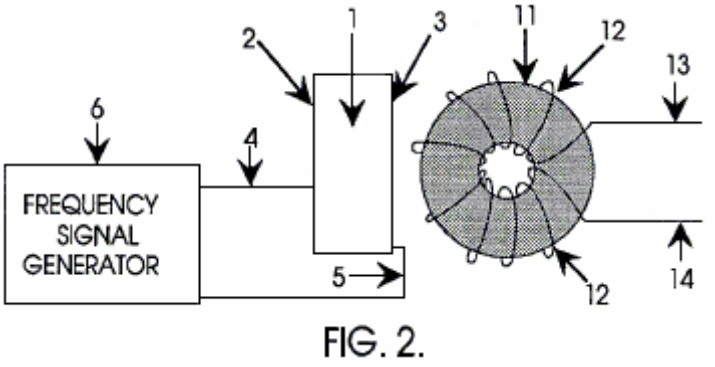

FIG. 2.

Another embodiment of this invention is shown in **Fig.2**. which is similar to **Fig.1**, with a similar frequency signal generator **6** connected to a piezoelectric material **1** via wires **4** and **5** connected to the electrode surfaces of the piezoelectric transducer **2** and **3**. The piezoelectric transducer **1** is as defined above, that is to say that it is constructed from a material suitable for sonic and ultrasonic generators. The piezoelectric transducer **1** is placed in close proximity to the permanent magnet **11** so that the acoustic field of the piezoelectric transducer **1** can radiate into the permanent magnet material. A permanent magnet transformer shown as coil **12** is placed in the magnetic field of the permanent magnet **11**. When the piezoelectric transducer **1** is stimulated by the frequency generator **6** then a voltage and current is generated between the output leads **13** and **14** of the above defined magnetic transformer.

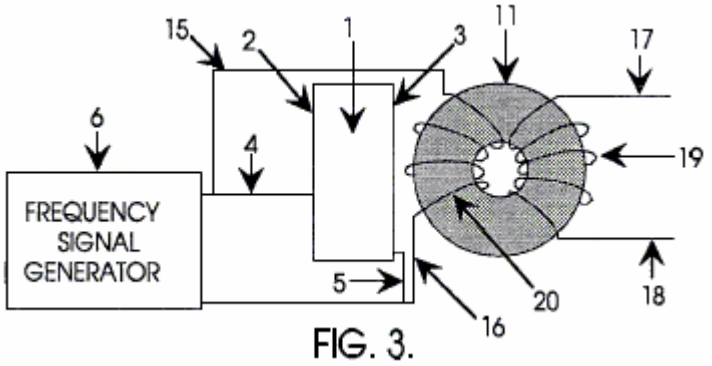

FIG. 3.

Fig.3 is similar to **Fig.1** and **Fig.2** with a frequency signal generator **6** connected to a piezoelectric transducer **1** via wires **4** and **5** connected to the electrode surfaces **2** and **3** of the piezoelectric transducer. The piezoelectric transducer **1** is as defined in the descriptions above. The signal generator **6** is also connected to the input coil **20**

of the permanent magnet transformer defined by the torroidal permanent magnet core **11**, input coil **20** and output coil **19**. The piezoelectric transducer **1** is placed in close proximity to the permanent magnet **11** so that the acoustic field of the piezoelectric transducer **1** can radiate into the permanent magnet material. The magnetic transformer defined by **11**, **19**, and **20** is in the magnetic field of the permanent magnet **11** and is connected to the frequency signal generator **6** via wires **15** and **16**. The frequency generator **6** stimulates the piezoelectric transducer **1** which stimulates the permanent magnet transformer via the acoustic field and at the same time the signal generator also stimulates the coil electromagnetically. A voltage and current is generated at the output coil **19** and power can be taken from the output wires **17** and **18** of the magnetic transformer.

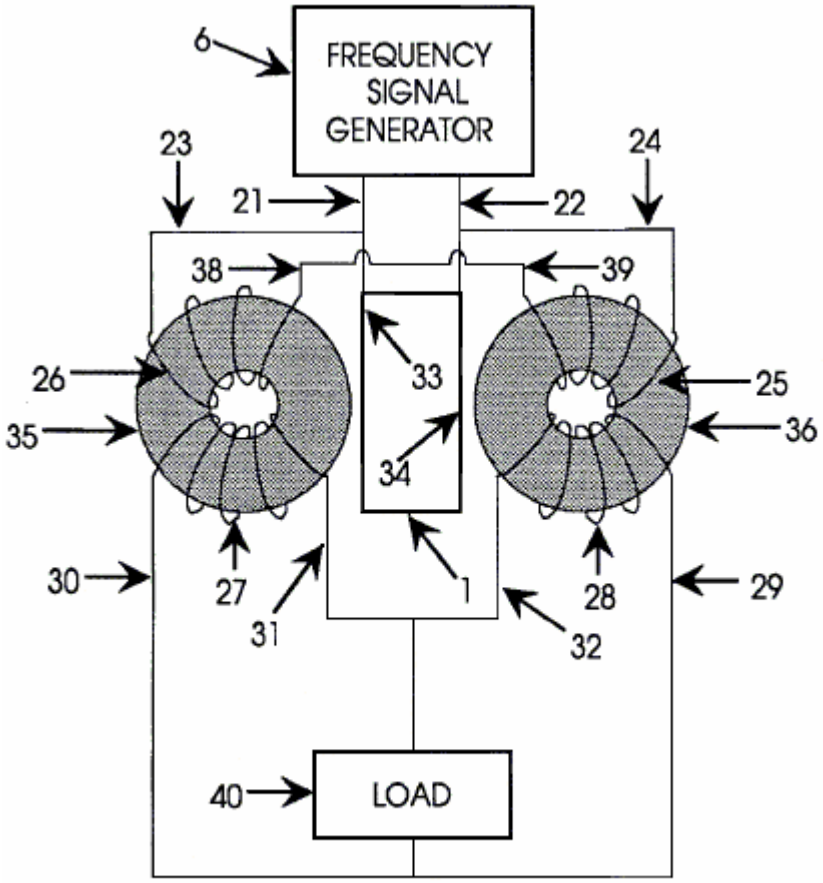

FIG. 4.

A further embodiment of this invention, shown in **Fig.4**, is a frequency signal generator **6** driving a pair of permanent magnet transformers defined by **26, 35, 27** and **25, 36, 28** respectively, also driving a piezoelectric transducer **1**. The piezoelectric transducer is as described above. The signal generator is connected via input wires **23** and **24** to the input coil **26** of the permanent magnet transformer on the left and to the input coil **25** of the transformer on the right respectively. The other input wire **38** of the left permanent magnet transformer is connected to the remaining input wire **39** of the right magnetic transformer. The output of the signal generator in also connected to the piezoelectric transducer **1** via connections **21** and **22** to the connector surface of the piezoelectric **33** and **34** respectively. The output of the permanent magnet transformer on the left is connected to a load **40** via wire **30** and the output of the permanent magnet transformer on the right is connected to the load via wire **29**. The remaining output wires **31** and **32** of the left and right permanent magnet transformers are also connected to the load. The load **40** can be anything such as a motor or electrical lights or any appliance.

This invention is not limited to the 4 different versions of the invention shown in **Figs. 1, 2, 3**, and **4** as there are any number of cascading and electrical hook-up techniques that can be accomplished to amplify power and to take advantage of the acoustic influence of the piezoelectric upon the magnetic material. Similarly, this invention is not limited to the torroidal core configuration as there can be many types of permanent magnet transformers with any number of magnetic core and coil configurations that can be enhanced with acoustic stimulation depending on power and output requirements according to the rules of electronics and those familiar with the state of the art in permanent magnet power transformers.

CLAIMS

1. An acoustic magnetic power generator composed of an alternating current signal generator connected to an acoustic transducer which stimulates the core of a permanent magnet such that the atoms of the magnet are caused to vibrate which in turn causes the magnetic field to vibrate and causes a current and voltage to be generated in an output coil wrapped around a permanent magnet or in the magnetic field of the permanent magnet which said current and voltage can be used for powering a load.

2. An acoustic magnetic power generator composed of an alternating signal generator connected to an acoustic transducer which stimulates the core of a permanent magnet and causes the core to vibrate; the signal generator further connected to a drive coil surrounding the permanent magnet, and an output coil within the field of the permanent magnet which by induction generates an electrical output.

3. A method of causing the magnetic field of permanent magnet transformers to oscillate by the application of an acoustic signal applied to the atomic structure of permanent magnet.

4. A method of maximising the efficiency of permanent magnet transformers by stimulating the core material of the permanent magnet transformers with both an acoustic vibration and an electromagnetic signal simultaneously.

DEVICE AND METHOD FOR UTILISING A MONOPOLE MOTOR TO CREATE BACK-EMF TO CHARGE BATTERIES

Please note that this is a re-worded excerpt from this patent. It describes a self-contained device which can charge an external battery or battery bank.

ABSTRACT

A back EMF monopole motor and method using a rotor containing magnets all of the same polarity and in a monopole condition when in momentary apposition with a magnetised pole piece of a stator having the same polarity, the stator being comprised of a coil with three windings: a power-coil winding, a trigger-coil winding, and a recovery-coil winding. The back EMF energy is rectified using a high voltage bridge, which transfers the back EMF energy to a high voltage capacitor for storage in a recovery battery. The stored energy can then be discharged across the recovery battery through the means of a contact rotor switch for further storage.

DESCRIPTION

Technical Field:

The invention relates generally to the capturing of available electromagnetic energy using a device and method for creating an electromagnetic force ('EMF') and then using the available stored energy for recycling into the system as stored energy. The method of creating back EMF is the result of coupling/uncoupling a coil to a voltage source.

Background:

The operation of present day normal magnetic motors, has the rotor pole attracting the stator pole, resulting in the generation of mechanical power from the magnets to the rotor and flywheel. During this phase, energy flows from the magnetics to the rotor/flywheel and is stored as kinetic energy in the increased rotation. A rotor pole leaving a stator pole and creating a condition of "drag" results in power having to be put back into the magnetic section by the rotor and flywheel to forcibly overcome the drag. In a perfect, friction-free motor, the net force field is therefore referred to as "most conservative". A most conservative EMF motor has maximum efficiency. Without extra energy continually fed to the motor, no net work can be done by the magnetic field, since half the time the magnetic field adds energy to the load (the rotor and flywheel) and the other half of the time it subtracts energy from the load (the rotor and flywheel). Therefore, the total net energy output is zero in any such rotary process without additional energy input. To use a present day magnetic motor, continuous energy must be fed to the motor to overcome drag and to power the motor and its load.

Motors and generators presently in use, all use such conservative fields and therefore, have internal losses. Hence, it is necessary to continually input all of the energy that the motor outputs to the load, plus more energy to cover losses inside the motor itself. EMF motors are rated for efficiency and performance by how much energy "input" into the motor actually results in "output" energy to the load. Normally, the Coefficient of Performance ('COP') rating is used as a measure of efficiency. The COP is the actual output energy going into the load and powering it, divided by the energy that must be input into the device with its motor/load combination. If there were zero internal losses in a motor, that "perfect" motor would have a COP equal to 1.0. That is, all energy input into the motor would be output by the motor directly into the load, and none of the input energy would be lost or dissipated in the motor itself.

In magnetic motor generators presently in use, however, due to friction and design flaws, there are always internal losses and inefficiencies. Some of the energy input into the motor is dissipated in these internal losses. As a consequence, the energy that gets to the load is always less than the input energy. So a standard motor operates with a COP of less than 1.0, which is expressed as COP<1.0. An inefficient motor may have a COP of 0.4 or 0.45, while a specially designed and highly efficient motor may have a COP of 0.85.

The conservative field inside of a motor itself is divided into two phases. Producing a conservative field involves net symmetry between the "power out" phase from the magnetics to the rotor/flywheel and the "power back in" phase from the rotor/flywheel back to the magnetics. That is, the two flows of energy are identical in magnitude but opposite in direction. Each phase alone is said to be "asymmetrical", that is, it either has: 1) a net energy flow out to the rotor/flywheel; or 2) a net energy flow back into the magnetics from the rotor/flywheel. In simplified terms, it is referred to as "power out" and "power back in" phases with respect to the motor magnetics.

For the power-out phase, energy is derived from the EMF existing between the stator pole and incoming rotor pole in an attraction mode. In this phase, the rotary motion (angular momentum and kinetic energy) of the rotor and flywheel is increased. In short, power is added to the rotor/flywheel (and thus to the load) from the fields between stator pole and rotor pole (the electromagnetic aspects of the system).

For the "power back in" phase, energy must be fed back into the magnetics from the rotor and flywheel (and the load) to overcome the drag forces existing between stator pole and outgoing rotor pole. In this phase, energy is returned to the internal magnetic system from the rotary motion of the rotor and flywheel (the angular momentum, which is the rotational energy multiplied by time). As is well known in physics, a rotor/flywheel's angular momentum provides a convenient way to store energy with the spinning rotor/flywheel mass acting as an energy reservoir.

Most present day conventional magnetic motors use various methods for overcoming and partially reversing back EMF. Back EMF may be defined as the return pulse from the coil out of phase and is the result of re-gauging, which is the process of reversing the magnetics polarity, that is, form North to South, etc. The back EMF is shorted out and the rotor is attracted back in, therefore eliminating drag. This can be accomplished by pouring more energy in, which overpowers the back EMF, thereby producing a forward EMF in that region. The energy required for this method is furnished by the operator.

It is well known that changing the voltage alone creates a back EMF and requires no work. This is because to change the potential energy does not require changing the form of that potential energy, but only its magnitude. Work is the changing of the form of energy. Therefore, as long as the form of the potential energy is not changed, the magnitude can be changed without having to perform work in the process. The motor of the present invention takes advantage of this permissible operation to create back EMF asymmetrically, and thereby change its own usable available potential energy.

In an electric power system, the potential (voltage) is changed by inputting energy to do work on the internal charges of the generator or battery. This potential energy is expended within the generator (or battery) to force the internal charges apart, forming a source dipole. Then the external closed circuit system connected to that source dipole ineptly pumps the spent electrons in the ground line back through the back EMF of the source dipole, thereby scattering the charges and killing the dipole. This shuts off the energy flow from the source dipole to the external circuit. As a consequence of this conventional method, it is a requirement to input and replace additional energy to again restore the dipole. The circuits currently utilised in most electrical generators have been designed to keep on destroying the energy flow by continually scattering all of the dipole charges and terminating the dipole. Therefore, it is necessary to keep on inputting energy to the generator to keep restoring its source dipole.

A search of prior art failed to reveal any monopole motor devices and methods that recycle available energy from back EMF to charge a battery or provide electrical energy for other uses as described in the present invention. However, the following prior art patents were reviewed:
U.S. Pat. No. 4,055,789 to Lasater, Battery Operated Motor with Back EMF Charging.
U.S. Pat. No. 2,279,690 to Z. T. Lindsey, Combination Motor Generator.

SUMMARY OF THE INVENTION

An aspect of the device and method of the present invention is a new monopole electromagnetic motor that captures back EMF energy. The captured back EMF energy may be used to charge or store electrical energy in a recovery battery. The amount of energy recoverable, as expressed in watts, is dependent upon the configuration, circuitry, switching elements and the number and size of stators, rotors, magnets and coils which comprise the motor.

The motor uses a small amount of energy from a primary battery to "trigger" a larger input of available energy by supplying back EMF, thus increasing the potential energy of the system. The system then utilises this available potential energy to reduce, or reverse, the back EMF, thereby increasing the efficiency of the motor and, therefore, the COP.

If the energy in phase 1 (the power-out phase) is increased by additional available energy in the electromagnetics themselves, then the energy in phase 1 can be made greater than the energy in phase 2 (the power-back-in phase) without the operator furnishing the energy utilised. This produces a non-conservative nett field. Nett power can then be taken from the rotating stator and flywheel, because the available energy added into the stator and flywheel by the additional effects, is transformed by the rotor/flywheel into excess angular momentum and stored as such. Angular momentum is conserved at all times, but now, some of the angular momentum added to the flywheel, is evoked by additional effects in the electromagnetics, rather than being furnished by the operator.

That is, the motor is designed to deliberately create a back EMF itself, and thus increase its potential energy, thereby retaining each extra force for a period of time and applying it to increase the angular momentum and kinetic energy of the rotor and flywheel. Specifically, this back EMF energy with its nett force is deliberately applied in the motor of the present invention to overcome and even reverse the conventional drag-back (the back EMF). Hence, less energy needs to be taken from the rotor and flywheel to overcome the reduced back EMF, and in the ideal case, none is required since the back EMF has been overpowered and converted to forward EMF by the back EMF energy and force. In the motor, the conventional drag section of the magnetics becomes a forward-EMF section and now adds energy to the rotor/flywheel instead of reducing it. The important feature is that the operator only pays for the small amount of energy necessary to trigger the back EMF from the primary battery, and does not have to furnish the much larger back EMF energy itself.

Thus, when the desired energy in phase 1 (the power-out phase) is made greater than the undesired drag energy in phase 2, then part of the output power normally taken from the rotor and flywheel by the fields in phase 2, is not required. Hence, in comparison to a system without special back EMF mechanisms, additional power is available from the rotor/flywheel. The rotor therefore maintains additional angular momentum and kinetic energy, compared to a system which does not produce back EMF itself. Consequently, the excess angular momentum retained by the rotor and flywheel can be utilised as additional shaft power to power an external load.

In this motor, several known processes and methods are utilised. These allow the motor to operate periodically as an open dissipative system (receiving available excess energy from back EMF) far from thermodynamic equilibrium, whereby it produces and receives its excess energy from a known external source.

A method is utilised to temporarily produce a much larger source of available external energy around an energised coil. Design features of this new motor provide a device and method that can immediately produce a second increase in that energy concurrently as the energy flow is reversed. Therefore, the motor is capable of producing two asymmetrical back EMFs, one after the other, of the energy within a single coil, which dramatically increases the energy available and causes that available excess energy to then enter the circuit as impulses which are collected and utilised.

The motor utilises this available excess back EMF energy to overcome and even reverse the drag EMF between stator pole and rotor pole, while furnishing only a small trigger pulse of energy from a primary battery necessary to control and activate the direction of the back EMF energy flow.

By using a number of such dual asymmetrical self back EMFs for every revolution of the rotor, the rotor and flywheel collectively focus all the excess impulsive inputs into increased angular momentum (expressed as energy multiplied by time), shaft torque, and shaft power.

Further, some of the excess energy deliberately generated in the coil by the utilisation of the dual process manifests in the form of excess electrical energy in the circuit and can be utilised to charge a recovery battery or batteries. The excess energy can also be used to power electrical loads or to power the rotor and flywheel, with the rotor/flywheel also furnishing shaft horsepower for powering mechanical loads.

The motor utilises a means to furnish the relatively small amount of energy from a primary battery to initiate the impulsive asymmetrical self back EMF actions. Then part of the available excess electrical power drawn off from back EMF created energy is utilised to charge a recovery battery with dramatically increased over-voltage pulses.

Design features of this monopole motor utilise one magnetic pole of each rotor and stator magnet. The number of impulsive self-back EMF in a single rotation of the rotor is doubled. Advanced designs can increase the number of self-back EMFs in a single rotor rotation with the result that there is an increase in the number of impulses per rotation, which increase the power output of this new motor.

The sharp voltage spike produced in the coil of this monopole motor by the rapidly collapsing field in the back EMF coil is connected to a recovery battery(s) in charge mode and to an external electrical load. The nett result is that the coil asymmetrically creates back EMF itself in a manner which adds available energy and impulse to the circuit. The available energy collected in the coil is used to reverse the back-EMF phase of the stator-rotor fields to a forward EMF condition, with the impulses adding acceleration and angular momentum to the rotor and flywheel. The available back EMF energy collected in the coil is used to charge a battery. Loads can then be driven by the battery.

A device and method in which the monopole motor alters the reaction cross section of the coils in the circuit, which briefly changes the reaction cross section of the coil in which it is invoked. Thus, since this new motor uses only a small amount of current in the form of a triggering pulse, it is able to evoke and control the immediate change of the coil's reaction cross section to this normally wasted energy-flow component. As a result, the motor captures and directs some of this usually wasted available environmental energy, collecting the available excess energy in the coil and then releasing it for use in the motor. Through timing and switching, the innovative gate

design of this new motor directs the available excess energy so that it overcomes and reverses the return EMF of the rotor-stator pole combination during what would normally be the back EMF and demonstrates the creation of the second back EMF of the system. Now, instead of an "equal retardation" force being produced in the back EMF region, a forward EMF is produced which adds to the rotor/flywheel energy, rather than subtracting from it. In short, it further accelerates the rotor/flywheel.

This results in a non-conservative magnetic field along the rotor's path. The line integral of the field around that path (i.e., the net work on the rotor/flywheel to increase its energy and angular momentum) is not zero but a significant amount. Hence, the creation of an asymmetrical back EMF impulse magnetic motor:
1) Takes its available excess energy from a known external source, the huge usually non-intercepted portion of the energy flow around the coil;
2) Further increases the source dipolarity by this back EMF energy; and
3) Produces available excess energy flow directly from the source dipole's increased broken symmetry in its fierce energy exchange with the local vacuum.

By operating as an open dissipative system, not in thermodynamic equilibrium with the active vacuum, the system can permissibly receive available energy from a known environmental source and then output this energy to a load. As an open dissipative system not in thermodynamic equilibrium, this new and unique monopole motor can tap in on back EMF to energise itself, loads and losses simultaneously, fully complying with known laws of physics and thermodynamics.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig.1 is a perspective side view of a monopole back EMF motor with a single stator and a single rotor.

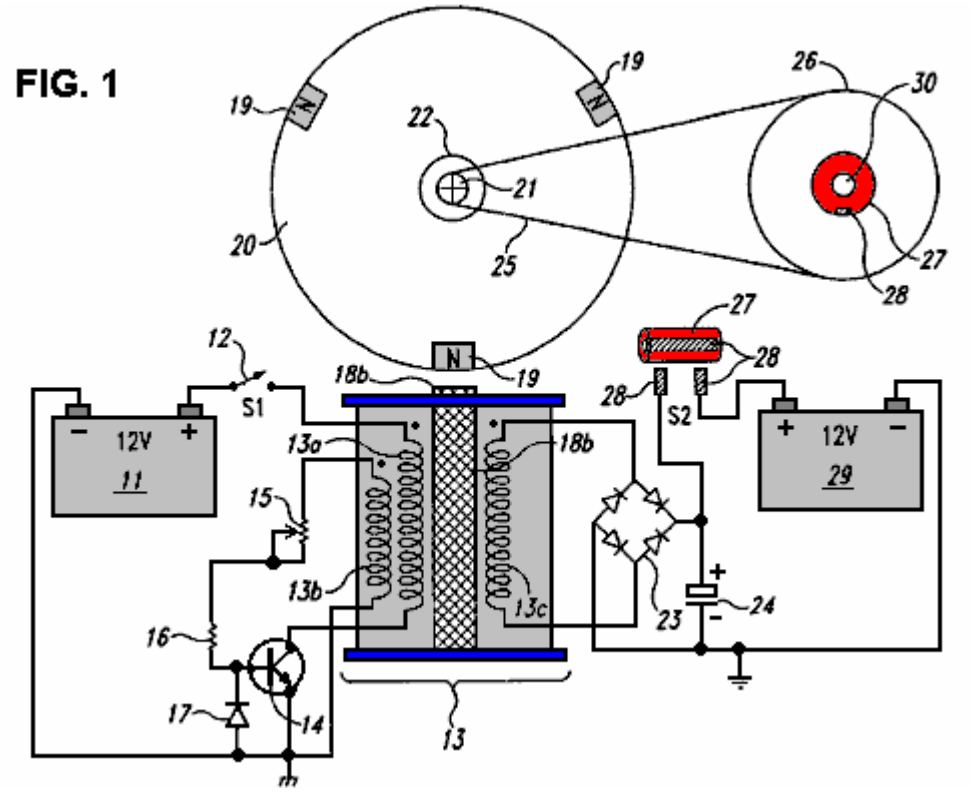

Fig.2 is a perspective top view of a monopole back EMF motor with a single stator and a single rotor.

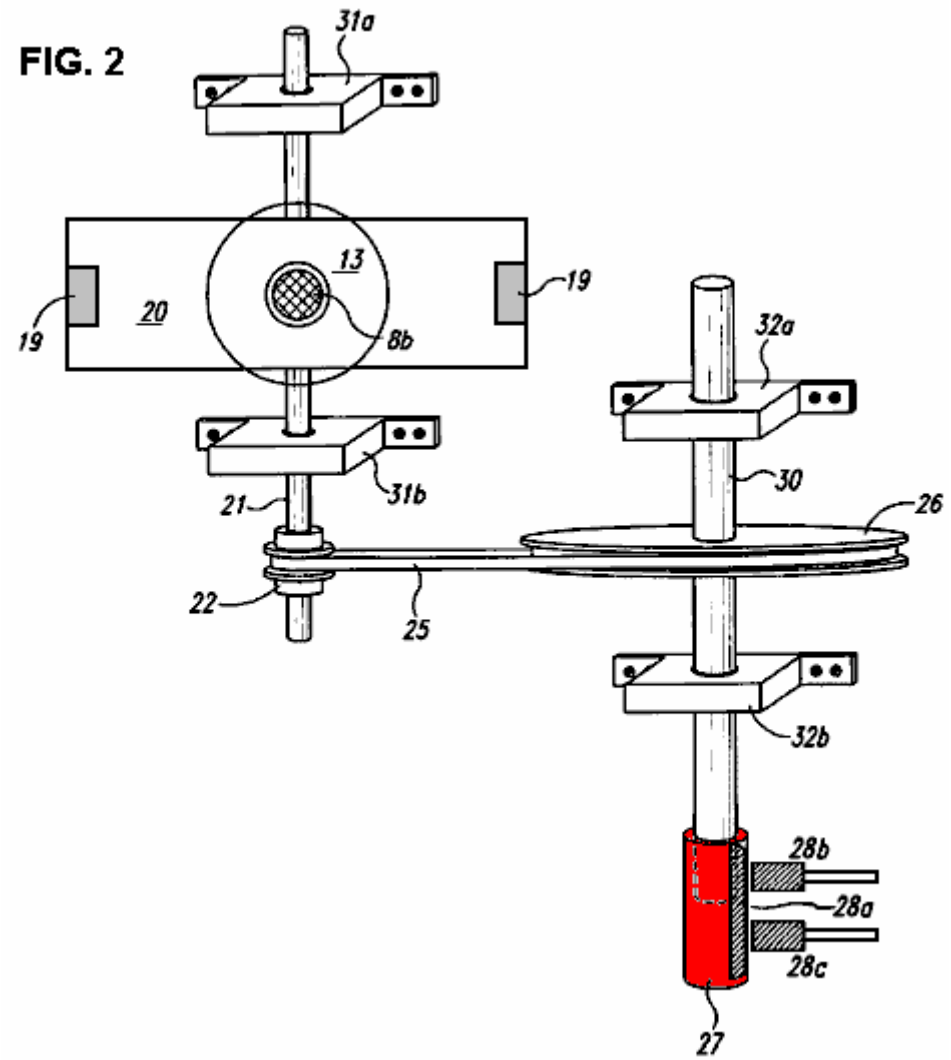
FIG. 2



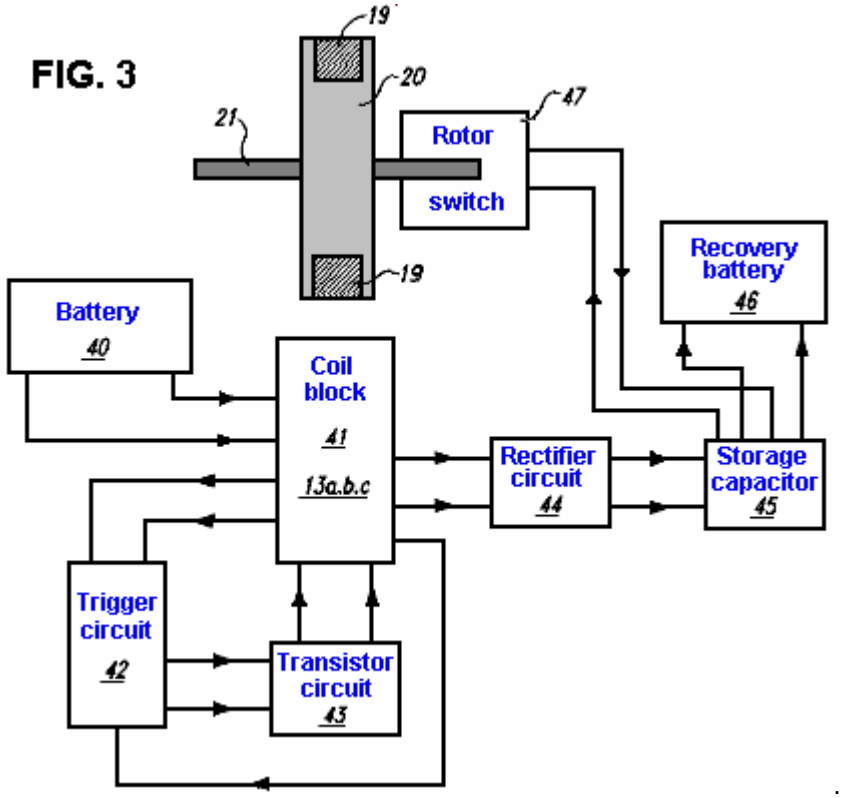


Fig.3 is a block diagram demonstrating the circuitry for a monopole back EMF motor.

DETAILED DESCRIPTION OF THE INVENTION

An embodiment of the present invention is a device and method for a monopole back EMF electromagnetic motor. As described in the Summary of the Invention, this monopole motor conforms to all applicable electrodynamic laws of physics and is in harmony with the law of the conservation of energy, the laws of electromagnetism and other related natural laws of physics.

The monopole back EMF electromagnetic motor comprises a combination of elements and circuitry to capture available energy (back EMF) in a recovery element, such as a capacitor, from output coils. The available stored energy in the recovery element is used to charge a recovery battery.

As a starting point, an arbitrary method in describing this device will be employed, namely, the flow of electrical energy and mechanical forces will be tracked from the energy's inception at the primary battery to its final storage in the recovery battery.

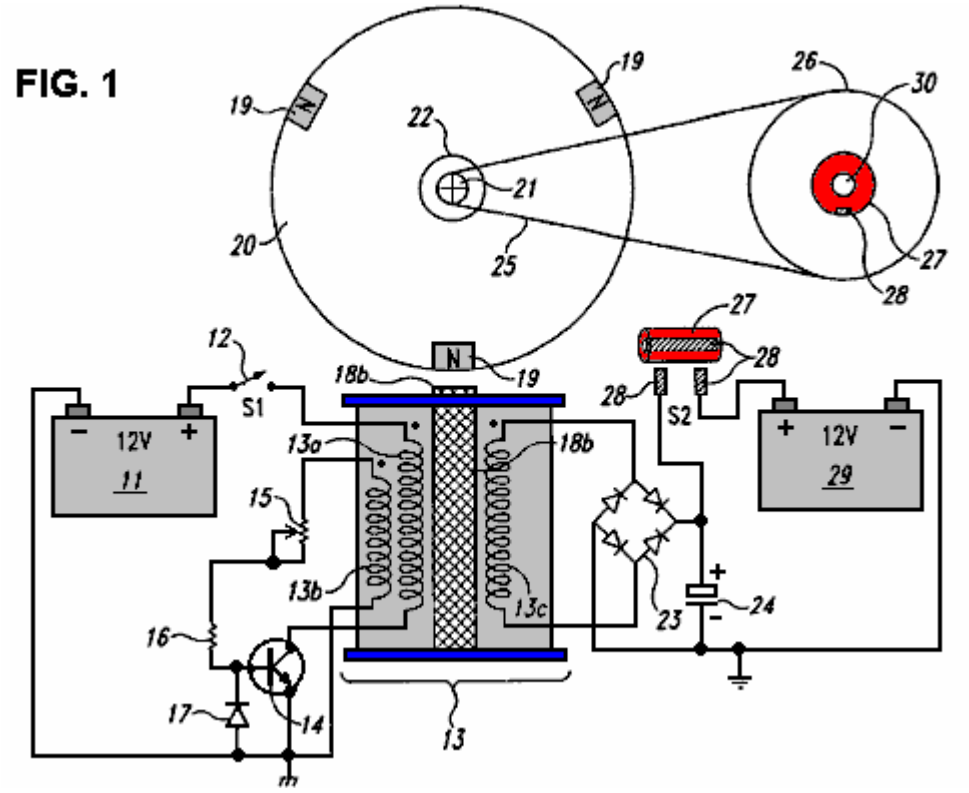

Fig.1 is a perspective side view of the monopole motor according to an embodiment of the invention. As shown in **Fig.1**, electrical energy from primary battery **11** periodically flows through power switch **12** and through power-coil wiring **13a**. In one embodiment, power switch **12** is merely an On-Off mechanical switch and is not electronic. However, the switch **12** may be a solid-state switching circuit, a magnetic Reed switch, a commutator, an optical switch, a Hall-effect switch, or any other conventional transistorised or mechanical switch. Coil **13** is comprised of three windings: power-coil winding **13a**, trigger-coil winding **13b**, and recovery-coil winding **13c**. However, the number of windings can be more or fewer than three, depending upon the size of the coil **13**, size of the motor and the amount of available energy to be captured, stored and used, as measured in watts. Electrical energy then periodically flows from power-coil winding **13a** and through transistor **14**.

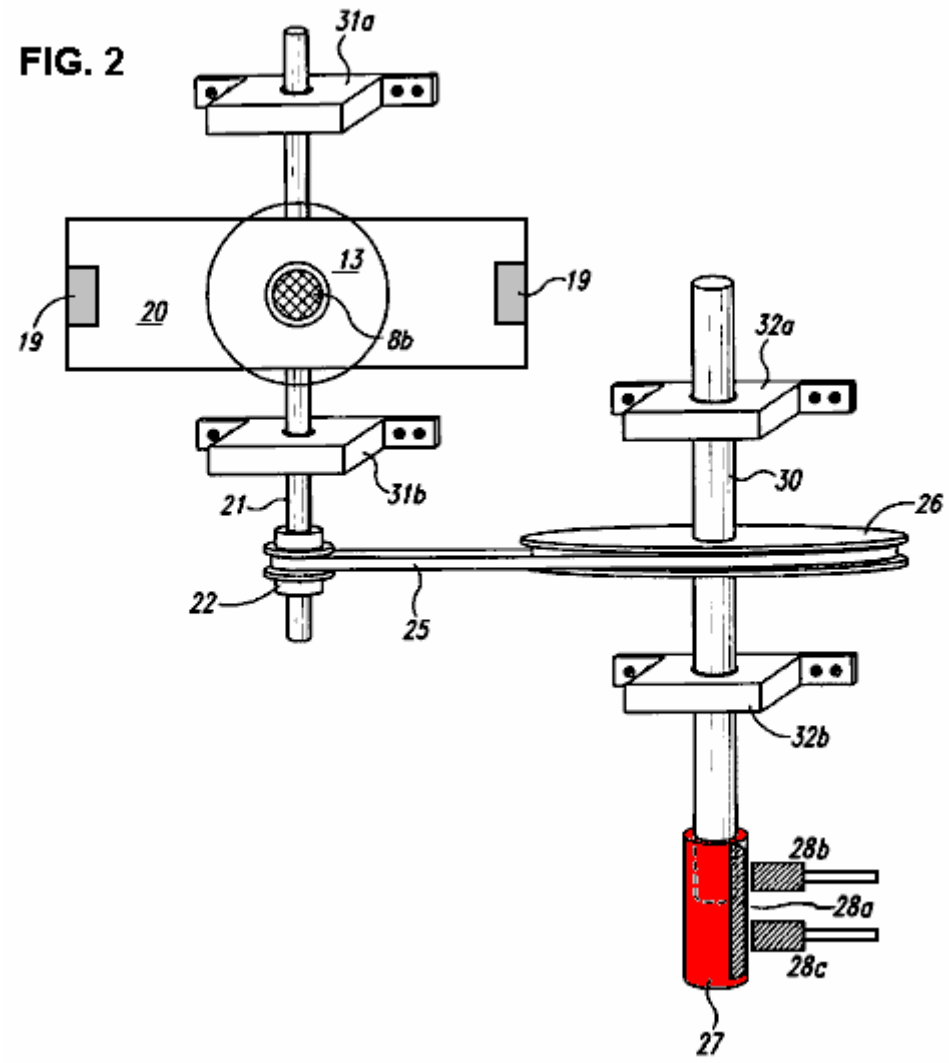
Trigger energy also periodically flows through variable resistor **15** and resistor **16**. Clamping diode **17** clamps the reverse base-emitter voltage of transistor switch **14** at a safe reverse-bias level that does not damage the transistor. Energy flows to stator **18a** and pole piece **18b**, an extension of stator **18a**. Pole piece **18b** is electrically magnetised only when transistor switch **14** is on and maintains the same polarity as the rotor poles **19** - North pole in this instance - when electrically magnetised. The North rotor poles **19a**, **19b** and **19c**, which are attached to rotor **20**, come in momentary apposition with pole piece **18b** creating a momentary monopole interface. The poles **19a,b,c**, which are actually permanent magnets with their North poles facing outward from the rotor **20**, maintain the same polarity when in momentary alignment with pole piece **18b**.

Rotor **20** is attached to rotor shaft **21**, which has drive pulley **22**. Attached to rotor shaft **21** are rotor-shaft bearing blocks **31a** and **31b**, as seen in **Fig.2**. As rotor **20** begins to rotate, the poles **19a,b,c** respectively comes into alignment with magnetised pole piece **18b** in a momentary monopole interface with energy flowing through diode bridge rectifier **23** and capacitor **24**. The number of capacitors may be of a wide range, depending upon the amount of energy to be temporarily stored before being expelled or flash charged into recovery battery **29**. Timing belt **25** connects drive pulley **22** on timing shaft **21** to timing wheel **26**. Attached to timing wheel **26** is contact rotor **27**, a copper insulated switch that upon rotation, comes in contact with brushes on mechanical switch **28**. The means for counting the number of rotor revolutions may be a timing gear or a timing belt. Finally, the available energy derived from the back EMF that is stored in capacitor **24** is then discharged and stored in recovery battery **29**.



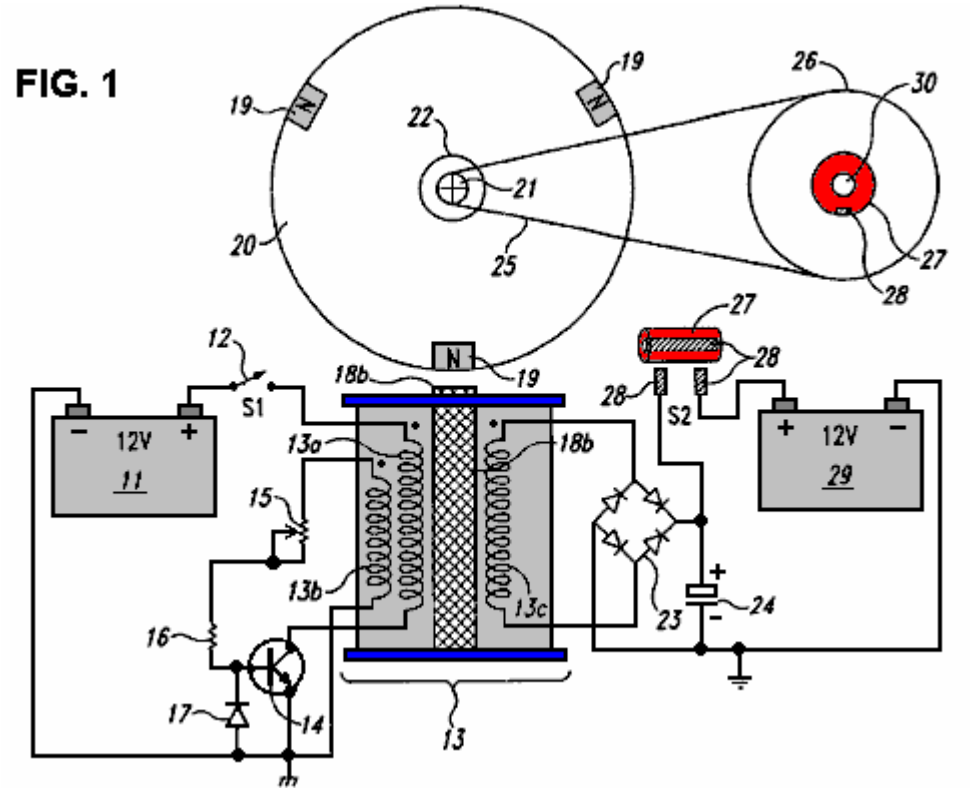


Fig.2 is a mechanical perspective top view of the monopole motor of the instant invention without electrical circuitry. Stator **18a** consists of coil **13**, which is comprised of three separate coil windings: power-coil winding **13a**, trigger-coil winding **13b** and recovery-coil winding **13c**. Pole piece **18b** is at the end of stator **18a**. As rotor **20**, (which is attached to rotor shaft **21**) rotates, each pole **19** respectively comes in a momentary monopole interface with pole piece **18b**. The polarity of pole piece **18b** is constant when electrically magnetised. Rotor shaft **21** has rotor shaft bearing blocks **31a,b** attached to it for stabilisation of rotor shaft **21**. Attached to rotor shaft **21** is drive pulley **22** with timing belt **25** engaged with it. Another means for timing may be a timing gear. Timing belt **25** engages with timing wheel **26** at its other end. Timing wheel **26** is attached to timing shaft **30**. Shaft **30** is stabilised with timing shaft bearing blocks **32a,b**. Attached to one end of timing shaft **30** is contact rotor **27** with brush **28a**, which, upon rotation of the timing shaft, comes into momentary contact with brushes **28b,c**.

Fig.3 is a block diagram detailing the circuitry of the monopole motor. Block **40** represents primary battery **11** with energy flowing to coil block **41**, which represents coil windings **13a,b,c**. From coil block **41** energy flows into three directions: to trigger-circuit block **42**, transistor-circuit block **43**, and rectifier-circuit block **44**. Energy flows from rectifier-block **44** to storage-capacitor block **45** with energy flowing from block **45** to both recovery-battery block **46** and rotor-switch block **47**.

Referring to **Fig.1**, the operation of the motor is described according to an embodiment of the invention. For purpose of explanation, assume that the rotor **20** is initially not moving, and one of the poles **19** is in the three o'clock position.

First, the switch **12** is closed. Because the transistor **14** is off, no current flows through the winding **13a**.

Next, the motor is started by rotating the rotor **20**, say, in a clockwise direction. The rotor may be rotated by hand, or by a conventional motor-starting device or circuit (not shown).

As the rotor **20** rotates, the pole **19** moves from the three o'clock position towards the pole piece **18b** and generates a magnetic flux in the windings **13a**,**13b** and**13c**. More specifically, the stator **18a** and the pole piece **18b** include a ferromagnetic material such as iron. Therefore, as the pole **19** moves nearer to the pole piece **18b**, it magnetises the pole piece **18b** to a polarity - South in this instance - that is opposite to the polarity of the pole **19** (which is North). This magnetisation of the pole piece **18b** generates a magnetic flux in the windings **13a-13c**. Furthermore, this magnetisation also causes a magnetic attraction between the pole **19** and the pole piece **18b**. This attraction pulls the pole **19** toward the pole piece **18b**, and thus reinforces the rotation of the rotor **20**.

The magnetic flux in the windings **13a-13c** generates voltages across their respective windings. More specifically, as the pole **19** rotates toward the pole piece **18b**, the magnetisation of the stator **18a** and the pole piece **18b**, and thus the magnetic flux in the windings **13a-13c**, increases. This increasing flux generates voltages across the windings **13a-13c** such that the dotted (top) end of each winding is more positive than the opposite end. These voltages are proportional to the rate at which the magnetic flux is increasing, and so, they are proportional to the velocity of the pole **19**.

At some point, the voltage across the winding **13b** becomes high enough to turn the transistor **14c** on. This turn-on, i.e., trigger, voltage depends on the combined serial resistance of the potentiometer **15** and the resistor **16**. The higher this combined resistance, the higher the trigger voltage, and vice-versa. Therefore, one can set the level of the trigger voltage by adjusting the potentiometer **15**.

In addition, depending on the level of voltage across the capacitor **24**, the voltage across the winding **13c** may be high enough to cause an energy recovery current to flow through the winding **13c**, the rectifier **23**, and the capacitor **24**. Thus, when the recovery current flows, the winding **13c** is converting magnetic energy from the rotating pole **19** into electrical energy, which is stored in the capacitor **24**.

Once turned on, the transistor **14** generates an opposing magnetic flux in the windings **13a-13c**. More specifically, the transistor **14** draws a current from the battery **11**, through the switch **12** and the winding **13b**. This current increases and generates an increasing magnetic flux that opposes the flux generated by the rotating pole **19**.

When the opposing magnetic flux exceeds the flux generated by the rotating pole **19**, the opposing flux reinforces the rotation of the rotor **20**. Specifically, when the opposing flux (which is generated by the increasing current

through winding **13a**) exceeds the flux generated by the pole **19**, the magnetisation of the pole piece **18** inverts to North pole. Therefore, the reverse-magnetic pole piece **18** repels the pole **19**, and thus imparts a rotating force to the rotor **20**. The pole piece **18** rotates the rotor **20** with maximum efficiency if the pole-piece magnetisation inverts to North when the centre of the pole **19** is aligned with the centre of the pole piece. Typically, the potentiometer **15** is adjusted to set the trigger voltage of the transistor **14** at a level which attains or approximates to this maximum efficiency.

The transistor **14** then turns off before the opposing flux can work against the rotation of the rotor **20**. Specifically, if the pole piece **18** remains magnetised to North pole, it will repel the next pole **19** in a direction (counterclockwise in this example) opposite to the rotational direction of the rotor **20**. Therefore, the motor turns transistor **14** off, and thus demagnetises the pole piece **18**, before this undesirable repulsion occurs. More specifically, when the opposing flux exceeds the flux generated by the pole **19**, the voltage across the winding **13b** reverses polarity such that the dotted end is less positive than the opposite end. The voltage across the winding **13b** decreases as the opposing flux increases. At some point, the voltage at the base of the transistor decreases to a level that turns transistor **14** off. This turn-off point depends on the combined resistance of potentiometer **15** and resistor **16** and the capacitance (not shown) at the transistor base. Therefore, potentiometer **15** can be adjusted, or other conventional techniques can be used to adjust the timing of this turn-off point.

The rectifier **23** and capacitor **24** recapture the energy that is released by the magnetic field (which energy would otherwise be lost) when the transistor **14** turns off. Specifically, turning transistor **14** off abruptly, cuts off the current flowing through winding **13a**. This generates voltage spikes across the windings **13a-13c** where the dotted ends are less positive than their respective opposite ends. These voltage spikes represent the energy released as the current-induced magnetisation of stator **18**a and pole piece **18b** collapses, and may have a magnitude of several hundred volts. But, as the voltage spike across the winding **13c** increases above the sum of the two diode drops of the rectifier **23**, it causes an energy-recovery current to flow through the rectifier **23** and the voltage across the capacitor **24** charge the capacitor **24**. Thus, a significant portion of the energy released upon collapse of the current-induced magnetic field is recaptured and stored as a voltage in the capacitor **24**. In addition, the diode **17** prevents damage to the transistor **14** by clamping the reverse base-emitter voltage caused by the voltage spike across the winding **13b**.

The recaptured energy can be used in a number of ways. For example, the energy can be used to charge a battery **29**. In one embodiment, the timing wheel **26** makes two revolutions for each revolution of the rotor **20**. The contact rotor **27** closes a switch **28**, and thus dumps the charge on the capacitor **24** into the battery **29**, once each revolution of the wheel **26**. Other energy-recapture devices and techniques may also be used. Rotor **20** may be stopped, either by applying a brake to it or by opening the switch **12**.

Other embodiments of the monopole motor are contemplated. For example, instead of remaining closed for the entire operation of the motor, the switch **12** may be a conventional optical switch or a Hall-effect switch that opens and closes automatically at the appropriate times. To increase the power of the motor, the number of stators **18a** and pole pieces **18b**, may be increased and/or the number of poles **19**. Furthermore, one can magnetise the stator **18a** and pole piece **18b** during the attraction of the pole **19** instead of or in addition to magnetising the stator and pole piece during the repulsion of the pole **19**.

Moreover, the stator **18a** may be omitted so that coil **13** becomes an air coil, or the stator **18a** and the pole piece **18b** may compose a permanent magnet. In addition, although the transistor **14** is described as being a bipolar transistor, a MOSFET transistor may also be used. Furthermore, the recaptured energy may be used to recharge the battery **11**. In addition, although described as rotating in a clockwise direction, the rotor **20** can rotate in a counterclockwise direction. Moreover, although described as attracting a rotor pole **19** when no current flows through winding **13a** and repelling the pole **19** when a current flows through winding **13a**, the pole piece **18b** may be constructed so that it attracts the pole **19** when a current flows through winding **13a** and repels the pole **19** when no current flows through winding **13a**.

In multiple stator/rotor systems, each individual stator may be energised one at a time or all of the stators may be energised simultaneously. Any number of stators and rotors may be incorporated into the design of such multiple stator/rotor monopole motor combinations. However, while there may be several stators per rotor, there can only be one rotor for a single stator. The number of stators and rotors that would comprise a particular motor is dependent upon the amount of power required in the form of watts. Any number of magnets, used in a monopole fashion, may comprise a single rotor. The number of magnets incorporated into a particular rotor is dependent upon the size of the rotor and power required of the motor. The desired size and horse power of the motor determines whether the stators will be in parallel or fired sequentially. Energy is made accessible through the capturing of available energy from the back EMF as a result of the unique circuitry and timing of the monopole motor. Individual motors may be connected in sequence with each motor having various combinations of stators and rotors or they may be connected in parallel. Each rotor may have any number of rotor magnets, all arranged without change of polarity. The number of stators for an individual motor may also be of a wide range.

One feature that distinguishes this motor from all others, is the use of monopole magnets in momentary apposition with the pole piece of the stator maintaining the same polarity when magnetised. In this particular embodiment, there are three magnets and one pole piece, the pole piece being an extension of a permanent-magnet stator. Finally, although the invention has been described with reference of particular means, materials and embodiments, it is to be understood that the invention is not limited to the particulars disclosed and extends to all equivalents within the scope of the claims.

CLAIMS

1. A back EMF monopole motor utilising a rotor wherein the magnets maintain a polarity when in apposition with a stator pole piece having the polarity, said motor to capture available back EMF energy for charging and storage in a recovery device, the motor comprising:
- **a.** A means for producing initial energy;
- **b.** A means for capturing energy in the form of back EMF, caused by a collapsing field in a coil comprised of multiple windings with a pole piece at one end of the stator of the coil, the pole piece having the correct polarity when magnetised and in aligned with the magnets of the rotor;
- **c.** A means for rectifying the back EMF energy, comprising of a voltage bridge for transferring the back EMF energy to a capacitor for storage;
- **d.** A means for discharging the stored voltage across a recovery battery; and
- **e**. A means for counting the revolutions of the rotor.

2. The back EMF monopole motor of Claim 1, where a battery is used to provide the initial energy.

3. The back EMF monopole motor of claim 1, where the rotor revolutions are counted by a timing gear.

4. The back EMF monopole motor of claim 1, where the rotor revolutions are counted by a timing belt.

5. The back EMF monopole motor of claim 1, where the means for discharging collected energy comprises a rotating switching commutator which discharges the collected energy into a recovery battery, the commutator switch having the same polarity as the recovery battery.

6. A back EMF monopole motor utilising a rotor in which the rotor magnets maintain a polarity when aligned with a magnetised stator pole piece, suited to capturing available back EMF energy for charging and storage in a recovery device, the motor comprising:
- **a.** A primary input battery and a means for switching the battery, namely, either a solid-state switching circuitry, a magnetic Reed switch, a commutator, an optical switch, or a Hall-effect switch;
- **b.** A means for capturing energy in the form of back EMF, created by a collapsing field in a coil comprised of multiple windings and a pole piece at one end of the stator coil;
- **c.** A means for rectifying the back EMF energy comprising a voltage bridge for transferring the energy to a capacitor for storage;
- **d.** A means for discharging the stored voltage across a recovery battery, the means being a rotating contact rotor switch;
- **e.** A means for counting the revolutions of the rotor via a timing gear or timing belt;

f. A rotating switching commutator for switching the rotating contact rotor switch.

DEVICE AND METHOD OF A BACK EMF PERMANENT ELECTROMAGNETIC MOTOR GENERATOR

ABSTRACT

This invention is a back EMF permanent electromagnetic motor generator and method using a regauging process for capturing available electromagnetic energy in the system. The device comprises a rotor with magnets of the same polarity; a timing wheel in apposition to a magnetic Hall-effect pickup switch semiconductor; and a stator comprised of two bars connected by a permanent magnet with magnetised pole pieces at one end of each bar. There are input and output coils created by wrapping each bar with a conducting material such as copper wire. Energy from the output coils is transferred to a recovery rectifier or diode. The magnets of the rotor, which is located on a shaft along with the timing wheel, are in apposition to the magnetised pole pieces of the two bars. The invention works through a process of regauging, that is, the flux fields created by the coils is collapsed because of a reversal of the magnetic field in the magnetised pole pieces thus allowing the capture of available back EMF energy. Additional available energy may be captured and used to re-energise the battery, and/or sent in another direction to be used for work. As an alternative, the available back EMF energy may be dissipated into the system.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The invention relates generally to the capturing of electromagnetic energy using a method and device to create back EMF (electromagnetic force) and re-phasing of the back EMF to recycle and capture the available back EMF energy. Back EMF is also referred to as regauging and may be defined as energy created by the magnetic field from coils, and only from coils, and not from magnets.

2. Background Information and Related Art

Operation of a normal magnetic motor has the rotor pole attracting the stator pole, resulting in the generation of power from the magnets to the rotor and flywheel. During this phase, energy flows from the magnetics to the rotor/flywheel and is stored in the increased rotation. A rotor pole leaving a stator pole and creating a condition of drag-back results in power having to be put back into the magnetic section by the rotor and flywheel to forcibly overcome the drag-back. In a perfect, friction-free motor, the nett force field is therefore referred to as most conservative. In other words, a most conservative EMF motor has maximum efficiency. Without extra energy continually fed to the motor, no nett work can be done by the magnetic field, since half the time the magnetic field adds energy to the load (the rotor and flywheel) and the other half of the time it subtracts energy from the load (the rotor and flywheel). Therefore the total nett energy output is zero in any such rotary process without additional energy input. To use a present day magnetic motor, continuous energy must be fed to the motor to overcome drag-back and to power the motor and its load.

Present EMF motors and generators all use such conservative fields and therefore, have internal losses. Hence, it is necessary to continually input all of the energy that the motor outputs to the load, plus more energy to cover losses inside the motor itself. EMF motors are rated for efficiency and performance by how much energy input into the motor actually results in output energy to the load. Normally, the Coefficient of Performance (COP) rating is used as a measure of efficiency. The COP is the actual output energy going into the load and powering it, divided by the energy that must be input into the device with its load. COP is the power out into the load, divided by the power input into the motor/load combination. If there were zero internal losses in a motor, that "perfect" motor would have a coefficient of performance (COP) equal to 1.0. That is, all energy fed into the motor would be output by the motor directly into the load, and none of the input energy would be lost or dissipated in the motor itself.

In magnetic motor generators presently in use, however, due to friction and design flaws, there are always internal losses and inefficiencies. Some of the energy input into the motor is dissipated in these internal losses. As a consequence, the energy that gets to the load is always less than the input energy. So a standard motor operates with a COP of less than 1.0 which is expressed as COP<1.0. An inefficient motor may have a COP of 0.4 or 0.45, while a specially designed, highly efficient motor may have a COP of 0.85.

The conservative field inside a motor itself can be divided into two phases. Producing a conservative field involves nett symmetry between the "power out" phase from the magnetics to the rotor/flywheel and the "power back in" phase from the rotor/flywheel back to the magnetics. That is, the two flows of energy (one from the

magnetics into the rotor and flywheel, and one from the rotor and flywheel back to the magnetics) are identical in magnitude but opposite in direction. Each phase alone is said to be "asymmetrical"; that is, it either has:
1) a nett energy flow out to the rotor/flywheel; or
2) a nett energy flow back into the magnetics from the rotor/flywheel.
In simplified terms, it is referred to as "power out" and "power back in" phases with respect to the motor magnetics. Hence, the two asymmetrical phases are:
1) the power-out phase; and
2) the "power back in" phase, with reference to the magnetics.

For the power-out phase, energy is derived from the EMF existing between the stator pole and incoming rotor pole in an attraction mode. In this phase, the rotary motion (angular momentum and kinetic energy) of the rotor and flywheel is increased. In short, power is added to the rotor/flywheel (and thus to the load) from the fields between stator pole and rotor pole (the electromagnetic aspects of the system).

For the "power back in" phase, energy must be fed back into the magnetics from the rotor and flywheel (and the load) to overcome the drag-back forces existing between stator pole and outgoing rotor pole. In this phase, energy is returned to the internal magnetic system from the rotary motion of the rotor and flywheel (the angular momentum, which is the rotational energy multiplied by time). As is well known in physics, a rotor/flywheel's angular momentum provides a convenient way to store energy with the spinning rotor/flywheel mass acting as an energy reservoir.

All present day conventional magnetic motors use various methods for overcoming, and partially reversing, back EMF. Back EMF is the out of phase return pulse from the coil and is also referred to as regauging. The back EMF is shorted out and the rotor is attracted back in, therefore eliminating back drag. This can be accomplished by pouring more energy in to overpower the back EMF, thereby producing a forward EMF in that region. The energy required for this method must be furnished by the operator.

The motor of the present invention uses only a small amount of energy to "trigger" a much larger input of available energy by supplying back EMF, thus increasing the potential energy of the system. It then utilises this excess potential energy to reduce or reverse back EMF, thereby increasing the efficiency of the motor and, therefore, the COP.

If the energy in phase 1 (the power-out phase) is increased by additional available energy in the electromagnetics themselves, then the energy in phase 1 can be made greater than the energy in phase 2 (the power-back-in phase) without the operator furnishing the energy utilised. This produces a non-conservative nett field. Nett power can then be taken from the rotating stator and flywheel, because the available energy transferred into the stator and flywheel by the additional effects, is transformed by the rotor/flywheel into additional angular momentum and stored as such. Angular momentum is conserved at all times; but now some of the angular momentum added to the flywheel is generated by additional effects in the electromagnetics rather than being provided by the operator.

Electrodynamicists assume that the potential available energy of any system can be changed at will and without cost. This is back EMF and is well-known in physics. It is also routinely employed by electrodynamicists in the theoretical aspects. However, to simplify the mathematics, electrodynamicists will create a back EMF twice simultaneously, each back EMF being carefully selected so that the two available forces which are produced, are equal and opposite and cancel each other "symmetrically". This is referred to as "symmetrical back EMF". A symmetrical back EMF system cannot produce a COP>1.0.
On the other hand, the motor of the present invention deliberately creates a back EMF itself and its potential energy only once at a time, thereby retaining each extra force for a period of time and applying it to increase the angular momentum and kinetic energy of the rotor and flywheel. Specifically, this back EMF energy with its nett force is deliberately applied in the motor of the present invention to overcome and even reverse the conventional drag-back (the back EMF). Hence less energy need be taken from the rotor and flywheel to overcome the reduced back EMF, and in the ideal case none is required since the back EMF has been overpowered and converted to forward EMF by the back EMF energy and force. In the motor of the present invention, the conventional back-drag section of the magnetics becomes a forward-EMF section and now adds energy to the rotor/flywheel instead of subtracting it. The important feature is that the operator only has to provide the small amount of energy necessary to trigger the back EMF, and does not have to furnish the much larger back EMF energy itself.

When the desired energy in phase 1 (the power out phase) is thus made greater than the undesired "drag-back" energy in phase 2, then part of the output power normally dragged back from the rotor and flywheel by the fields in phase 2 is not required. Hence, compared to a system without the special back EMF mechanisms, additional power is available from the rotor/flywheel. The rotor maintains additional angular momentum and kinetic energy, compared to a system which does not produce back EMF itself. Consequently, the excess angular momentum

retained by the rotor and flywheel can be utilised as additional shaft power to power an external load connected to the shaft.

A standard magnetic motor operates as the result of the motor being furnished with external energy input into the system by the operator to reduce phase 2 (power back into the magnetics from the rotor/flywheel) by any of several methods and mechanisms. The primary purpose of this external energy input into the system is to overcome the back EMF and also provide for the inevitable energy losses in the system. There is no input of energy separate from the operator input. Therefore, the COP of any standard magnetic motor is COP less than 1.0. The efficiency of a standard magnetic motor varies from less than 50% to a maximum of about 85%, and so has a COP<1.0. When nothing is done in the motor that will produce a reduction of the back EMF without the operator inputting all the energy for it, then for even a frictionless, ideal permanent magnet motor, the COP can never exceed 1.0.

Until the introduction of the motor of the present invention, it has been standard universal practice that the operator must furnish all energy used to reduce the back EMF, provide for the internal losses, and power the load. It is therefore a common belief by the scientific community that an ideal (loss-less) permanent magnet motor cannot exceed a COP of 1.0. That is true, so long as the operator himself must furnish all the energy. Furthermore, since real permanent magnetic motors have real internal losses, some of the input energy is always lost in the motor itself, and that lost energy is not available for powering the rotor/flywheel and load. Hence a real permanent magnetic motor of the conventional kind will always have a COP<1.0.

The common assumption that the COP of a motor is limited to less than 1.0 is not necessarily true, and that COP>1.0 is permitted without violating the laws of nature, physics, or thermodynamics. However, it can immediately be seen that any permanent magnet motor exhibiting a COP>1.0 must have some available energy input returning in the form of back EMF.

A problem relates to how back EMF energy can be obtained from a circuit's external environment for the specific task of reducing the back-drag EMF without the operator having to supply any input of that excess energy. In short, the ultimate challenge is to find a way to cause the system to:
1) become an open dissipative system, that is, a system receiving available excess energy from its environment, in other words, from an external source; and
2) use that available excess energy to reduce the drag-back EMF between stator and rotor poles as the rotor pole is leaving the stator pole.
If this objective can be accomplished, the system will be removed from thermodynamic equilibrium. Instead, it will be converted to a system out-of-thermodynamic equilibrium. Such a system is not obliged to obey classical equilibrium thermodynamics.

Instead, an out-of-equilibrium thermodynamic system must obey the thermodynamics of open systems far from the established and well-known parameters of thermodynamic equilibrium. As is well known in the physics of thermodynamics, such open systems can permissibly:
1) self-order;
2) self-oscillate;
3) output more back EMF energy than energy input by the operator (the available excess back EMF energy is received from an external source and some energy is input by the operator as well);
4) power itself as well as its loads and losses simultaneously (in that case, all the energy is received from the available external source and there is no input energy from the operator); and
5) exhibit negative entropy, that is, produce an increase of energy that is available in the system, and that is independent of the energy put into the system by the operator.

As a definition, entropy roughly corresponds to the energy of a system that has become unavailable for use. Negative entropy corresponds to additional energy of a system that has become available for use.

In the back EMF permanent magnet electromagnetic motor generator of the present invention, several known processes and methods are utilised which allow the invention to operate periodically as an open dissipative system (receiving available excess energy from back EMF) far from thermodynamic equilibrium, whereby it produces and receives its excess energy from a known external source.

A method is utilised to temporarily produce a much larger source of available external energy around an energised coil. Then the unique design features of this new motor provides a method and mechanism that can immediately produce a second increase in that energy, concurrently as the energy flow is reversed. Therefore, the motor is capable of producing two asymmetrical back EMFs, one after the other, of the energy within a single coil, which dramatically increases the energy available and causes that available excess energy to then enter the circuit as an impulse, being collected and utilised.

The present motor utilises this available excess back EMF energy to overcome and even reverse the back-drag EMF between stator pole and rotor pole, while furnishing only a small trigger pulse of energy necessary to control and activate the direction of the back EMF energy flow.

By using a number of such dual asymmetrical self back EMFs for every revolution of the rotor, the rotor and flywheel collectively focus all the excess impulsive inputs into increased angular momentum (expressed as energy multiplied by time), shaft torque, and shaft power.

Further, some of the excess energy deliberately generated in the coil by the utilisation of the dual process manifests itself in the form of excess electrical energy in the circuit and is utilised to power electrical loads, e.g., a lamp, fan, motor, or other electrical devices. The remainder of the excess energy generated in the coil can be used to power the rotor and flywheel, with the rotor/flywheel also furnishing shaft horsepower for powering mechanical loads.

This new and unique motor utilises a means to furnish the relatively small amount of energy to initiate the impulsive asymmetrical self back EMF actions. Then part of the available excess electrical power drawn off from the back EMFs is utilised to recharge the battery with dramatically increased over voltage pulses.

The unique design features of this motor utilise both north and south magnetic poles of each rotor and stator magnet. Therefore, the number of impulsive self back EMFs in a single rotation of the rotor is doubled. Advanced designs increase the number of self back EMFs in a single rotor rotation with the result that there is an increase in the number of impulses per rotation which increase the power output of this new motor.

The sharp voltage pulse produced in the coil of this new motor by the rapidly collapsing field in the back EMF coil is connected to a battery in charge mode and to an external electrical load. The nett result is that the coil asymmetrically creates back EMF itself in a manner adding available energy and impulse to the circuit. The excess available energy collected in the coil is used to reverse the back-EMF phase of the stator-rotor fields to a forward EMF condition, and through an impulse, adding acceleration and angular momentum to the rotor and flywheel. At the same time, a part of the excess energy collected in the coil is used to power electrical loads such as charging a battery and operating a lamp or such other device.

It is well known that changing the voltage alone, creates a back EMF and requires no work. This is because to change the potential energy does not require changing the form of that potential energy, but only its magnitude. Strictly speaking, work is the changing of the form of energy. Therefore, as long as the form of the potential energy is not changed, the magnitude can be changed without having to perform work in the process. The motor of the present invention takes advantage of this permissible operation to create back EMF asymmetrically, and thereby change its own usable available potential energy.

In an electric power system, the potential (voltage) is changed by inputting energy to do work on the internal charges of the generator or battery. This potential energy is expended within the generator (or battery) to force the internal charges apart, forming a source dipole. Then the external closed circuit system connected to that source dipole ineptly pumps the spent electrons in the ground line back through the back EMF of the source dipole, thereby scattering the charges and killing the dipole. This shuts off the energy flow from the source dipole to the external circuit. As a consequence of that conventional method, it is a requirement to input and replace additional energy to again restore the dipole. The circuits currently utilised in most electrical generators have been designed to keep on destroying the energy flow by continually scattering all of the dipole charges and terminating the dipole. Therefore, it is necessary to keep on inputting energy to the generator to keep restoring its source dipole.

An investigation of particle physics is required to see what furnishes the energy to the external circuit. Since neither a battery nor a generator furnishes energy to the external circuit, but only furnishes energy to form the source dipole, a better understanding of the electric power principle is required to fully understand how this new motor functions. A typical battery uses its stored chemical energy to form the source dipole. A generator utilises its input shaft energy of rotation to generate an internal magnetic field in which the positive charges are forced to move in one direction and the negative charges in the reverse direction, thereby forming the source dipole. In other words, the energy input into the generator does nothing except form the source dipole. None of the input energy goes to the external circuit. If increased current is drawn into the external load, there also is increased spent electron flow being rammed back through the source dipole, destroying it faster. Therefore, dipole-restoring-energy has to be inputted faster. The chemical energy of the battery also is expended only to separate its internal charges and form its source dipole. Again, if increased current and power is drawn into the external load, there is increased spent electron flow being rammed back through the source dipole, destroying it faster. This results in a depletion of the battery's stored energy faster, by forcing it to have to keep restoring the dipole faster.

Once the generator or battery source dipole is formed (the dipole is attached also to the external circuit), it is well known in particle physics that the dipole (same as any charge) is a broken symmetry in the vacuum energy flux.

By definition, this means that the source dipole extracts and orders part of that energy received from its vacuum interaction, and pours that energy out as the energy flowing through all space surrounding the external conductors in the attached circuit. Most of this enormous energy flow surging through space surrounding the external circuit does not strike the circuit at all, and does not get intercepted or utilised. Neither is it diverted into the circuit to power the electrons, but passes on out into space and is just "wasted". Only a small "sheath" of the energy flow along the surface of the conductors strikes the surface charges in those conductors and is thereby diverted into the circuit to power the electrons. Standard texts show the huge available but wasted energy flow component, but only calculate the small portion of the energy flow that strikes the circuit, is caught by it, and is utilised to power it.

In a typical circuit, the huge available but "wasted" component of the energy flow is about 10 to the power 13 times as large as the small component intercepted by the surface charges and diverted into the circuit to power it. Hence, around every circuit and circuit element such as a coil, there exists a huge non-intercepted, non-diverged energy flow that is far greater than the small energy flow being diverted and used by the circuit or element.

Thus there exists an enormous untapped energy flow immediately surrounding every EMF power circuit, from which available excess energy can be intercepted and collected by the circuit, if respective non-linear actions are initiated that sharply affect and increase the reaction cross section of the circuit (i.e., its ability to intercept this available but usually wasted energy flow).

The method in which the motor of the present invention alters the reaction cross section of the coils in the circuit, is by a novel use, which momentarily changes the reaction cross section of the coil in which it is invoked. Thus, by this new motor using only a small amount of current in the form of a triggering pulse, it is able to evoke and control the immediate change of the coil's reaction cross section to this normally wasted energy flow component. As a result, the motor captures and directs some of this usually wasted environmental energy, collecting the available excess energy in the coil and then releasing it for use in the motor. By timing and switching, the innovative gate design in this new motor directs the available excess energy so that it overcomes and reverses the return EMF of the rotor-stator pole combination during what would normally be the back EMF and demonstrates the creation of the second back EMF of the system. Now instead of an "equal retardation" force being produced in the back EMF region, a forward EMF is produced that is additive to the rotor/flywheel energy and not subtractive. In short, it further accelerates the rotor/flywheel.

This results in a non-conservative magnetic field along the rotor's path. The line integral of the field around that path (i.e., the nett work on the rotor/flywheel to increase its energy and angular momentum) is not zero but a significant amount. Hence, the creation of an asymmetrical back EMF impulse magnetic motor:
1) takes its available excess energy from a known external source, the huge usually non-intercepted portion of the energy flow around the coil;
2) further increases the source dipolarity by this back EMF energy; and
3) produces available excess energy flow directly from the source dipole's increased broken symmetry in its fierce energy exchange with the local vacuum.

No laws of physics or thermodynamics are violated in the method and device of the present invention, and conservation of energy rigorously applies at all times. Nonetheless, by operating as an open dissipative system not in thermodynamic equilibrium with the active vacuum, the system can permissibly receive available excess energy from a known environmental source and output more energy to a load than must be input by the operator alone. As an open system not in thermodynamic equilibrium, this new and unique motor can tap in to back EMF to energise itself, loads and losses simultaneously, fully complying with known laws of physics and thermodynamics.

A search of prior art failed to reveal any devices that recycle available energy from back EMF of a permanent electromagnetic motor generator as described in the present invention. However, the following prior art US patents were reviewed:

SUMMARY OF THE INVENTION

The device and method of the present invention is a new permanent electromagnetic motor generator that recycles back EMF energy (regauging) thus allowing the motor to produce an energy level of COP = 0.98, more or less, depending upon configuration, circuitry, switching elements and the number and size of stators, rotors and coils that comprise the motor. The rotor is fixed between two pole pieces of the stator. The motor generator is initially energised from a small starter battery means, analogous to a spark plug, that sends a small amount of energy to the motor, thus stimulating a rotating motion from the rotor. As the rotor rotates, energy is captured from the surrounding electromagnetic field containing an asymmetrical pulse wave of back EMF. The energy produced and captured can be directed in one of several directions, including returning energy to the initial starter battery, rotating a shaft for work and/or sending a current to energise a fan, light bulb or other such device.

DETAILED DESCRIPTION OF THE INVENTION

The present invention is a device and method for creating a back EMF permanent electromagnetic motor generator. As described in the Background Information, this new motor generator conforms to all applicable electrodynamic laws of physics and is in harmony with the law of the conservation of energy, the laws of electromagnetism and other related natural laws.

The back EMF permanent electromagnetic motor generator is comprised of a combination of electrical, material and magnetic elements, arranged to capture available electromagnetic energy (back EMF) in a recovery rectifier or single diode from output coils. The capturing of back EMF energy is also known as 'regauging'. As an arbitrary starting point in describing this invention, an input battery, as a means of energy, sends power through a power on-off switch and then to a timing mechanism, such as a magnetic timing switch (a semiconductor Hall-effect magnetic pickup switch) which is triggered by a magnet on a timing wheel. The timing wheel may contain any number of magnets (i.e. one or more), with the South poles facing outwards and aligned with the Hall-effect pickup switch.

The timing wheel is mounted at the end of a shaft which is located along the centreline of a rotor, which in turn, may contain any number of magnets (i.e. two or more). The rotor magnets are arranged so that they have the same polarity and are equidistant from each other. The shaft has the timing wheel mounted at one end, the rotor, and then some means for performing work, such as a power take off at the opposite end. However, there are other embodiments in which the position of the rotor, timing wheel and power take-off have other configurations. The rotor is mounted on a platform or housing which is fixed in a stationary position within a stator.

The stator is comprised of a permanent magnet connected to a means for conducting electromagnetic energy such as two parallel bars, each bar having a magnetised pole piece at one end. The conduction material of the bar may be ferrous, powdered iron, silicon steel, stainless magnetic steel, laminations of conductive material or any other magnetic conductive material. Each bar has an input coil placed around it. The coil may be constructed from copper, aluminium or any other suitable conductive material. The primary or input coil is connected to the switching circuit. A second coil on top of the input coil becomes a secondary or output coil. The secondary or output coil is connected to the recovery circuit. The rotor is located symmetrically between the pole pieces of the bars of the stator and it contains a series of magnets all having the same polarity, North or South, with each magnet in the rotor being in aligned with the pole piece as the rotor rotates.

When the rotor is energised from the battery of the switching circuit, there is an initial magnetic field that is instantly overcome as the magnetised pole pieces align with the rotor magnets. As the rotor begins to move, increasing electromagnetic energy is produced as a result of flux gaiting from the aligned magnets of the rotor and pole pieces. The coils surrounding the bars "buck" the permanent magnet connecting the bars. This is known as the "buck boosting" principle. When the permanent magnet is bucked by the coils, it reverses the polarity of the pole pieces which are aligned with the rotor magnets causing the rotor to increase its rate of rotation. The energy

available from the fields that are collapsing in the primary and secondary coils, (which creates the back EMF within the system), is now in non-equilibrium. Energy can now be put back into the system via the switching circuitry. Available energy captured from the back EMF, may be applied in different directions, including re-energising the input battery, storage in a capacitor, conversion by a recovery rectifier to be stored in the input battery, a capacitor or a secondary or recovery battery. Recovery rectifiers are used to convert this AC to DC. Available energy may be used to energise an electric bulb, fan or any other uses.

The shaft in the centre of the rotor can transfer energy in the form of work through a power take-off. The power take-off may be connected to any number of secondary shafts, wheels, gears and belts to increase or reduce torque.

This is a description of the basic invention, however, there are an innumerable number of combinations and embodiments of stators, rotors, Hall-effect magnetic pickup switches, coils, recovery rectifiers and electronic connecting modes that may be combined on a single shaft or several shafts connected in various combinations and sequences, and of various sizes. There may be any number of stators to one rotor, (however, there can be only one active rotor if there is a single stator). The number of Hall-effect pickup switches may vary, for example, in the case of multiple stators of high resistant coils, the coils may be parallel to form a low resistant coil so that one Hall-effect pickup with one circuit may fire all of the stators at the same time. The number of magnets in both the timing wheel and the rotor may also vary in number as well as the size and strength of the magnets. Any type of magnet may be used. The number of turns on both the input and output coils on each conducting bar may also vary in number and in conductive material.

The motor generator, as shown in **Fig.1**, a top perspective view of a single stator, single rotor back EMF motor and is comprised of a means of providing energy, such as input battery **10** connected to power switch **11** (shown in **Fig.2**) and Hall-effect magnetic pickup switch **13**. Magnetic pickup **13** interfaces with timing wheel **12** to form a timing switch. Timing wheel **12** contains four magnets **14** with the South pole of each said magnet facing outward towards magnetic pickup **13**. Timing wheel **12** is fixed at one end of shaft **15**. Located on shaft **15** is rotor **16**. Rotor **16** can be of any realistic size, and in this example the rotor contains four rotor magnets **17**. The rotor magnets **17** are arranged so all have the same polarity.

Opposite timing wheel **12** on shaft **15** is a means for performing work, such as a power take-off **18**. Rotor **16** is mounted in a fixed position with rotor magnets **17** in aligned with the magnetised pole pieces **19a** and **19b**. Each pole piece **19a** and **19b** is connected to iron bars **20a** and **20b**. These Iron bars are connected by a permanent magnet **21**. Wire is wrapped around iron bars **20a** and **20b** to form input coils **22a** and **22b**. Superimposed upon input coils **22a** and **22b** are output coils **23a** and **23b**. These output coils are connected to full wave bridge first recovery rectifier **24a** which then connects to battery **10**.

Fig.1a is a side view of the back EMF Motor Generator timing wheel **12** with Hall-effect magnetic pickup **13** positioned to be triggered by each of the four magnets **14** in turn as timing wheel **12** rotates. The magnets **14** have their South poles facing outward and they are spaced evenly with a 90 degree angular separation.

Fig.1b is a side view of rotor **16** with four rotor magnets **17** with 90 degree angular separation from each other and having the same polarity.

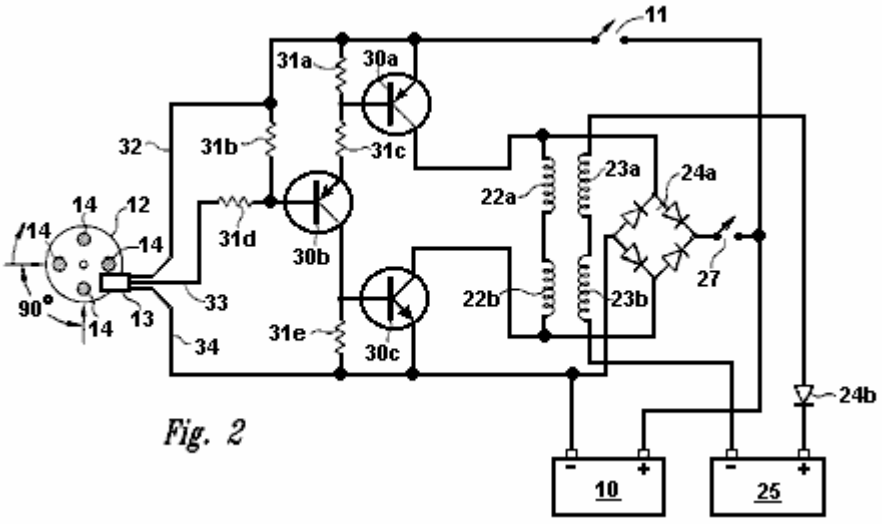

Fig. 2

Fig.2 is a schematic diagram of the motor generator circuitry showing input coil connections from input battery **10** through power switch **11**, transistors **30a,b,c** resistors **31a-e**, through power supply lead **32** ("VCC+") and to magnetic pickup **13**. Magnetic pickup **13** is in aligned with timing wheel magnets **14** located on timing wheel **12**.

Collector lead **33** and ground lead **34** carry the signals from magnetic pickup **13**. When current is reversed, it flows through resistor **31e** and transistor **30c** to input battery **10**. Input coils **22a,b** send power to full wave bridge first recovery rectifier **24a** which then sends power through switch recovery **27** back into the system, and/or to the input battery **10**. Output coils **23a** and **23b** send power through single diode second recovery rectifier **24b** to recovery battery **25**.

In this particular embodiment, the value and type number of the components are as follows:
Hall-effect magnetic pickup switch **13** is a No. 3020;
Transistor **30a** is a 2N2955;
Transistor **30b** is an **MPS8599**;
Transistor **30c** is a 2N3055;
Resistors **31a** and **31b** are 470 ohms
Resistor **31b** is 2.2 K ohms
Resistor **31c** is 220 ohms
Resistor **31d** is 1 K ohms
Recovery rectifier **24a** is a 10 Amp, 400 volts bridge rectifier.

Fig.3 is a box diagram showing the flow of voltage from input battery **A**, through recovery circuit **B**, switching circuit **C** and motor coils **D**. Motor coils **D** send available back EMF energy through recovery circuit **B**, and then on to recovery battery **E** and input battery **A**. Available back EMF energy can also flow from switching circuit **C** to recovery circuit **B**.

In multiple stator/rotor systems, each individual stator may be energised one at a time or all of the stators may be energised simultaneously. Any number of stators and rotors may be incorporated into the design of such multiple stator/rotor motor generator combinations. However, while there may be several stators per rotor, there can only be one rotor for a single stator. The number of stators and rotors that would comprise a particular motor generator is dependent upon the amount of power required in the form of watts. The desired size and horsepower of the motor determines whether the stators will be in parallel or fired sequentially by the magnetic Hall-effect pickup or pickups. The number of magnets incorporated into a particular rotor is dependent upon the size of the rotor and power required of the motor generator. In a multiple stator/rotor motor generator, the timing wheel may have one or more magnets, but must have one magnet Hall-effect pickup for each stator if the stators are not arranged in parallel. The back EMF energy is made available through the reversing of the polarity of the magnetised pole pieces thus collapsing the field around the coils and reversing the flow of energy to the recovery diodes, which are capturing the back EMF.

Individual motors may be connected in sequence, with each motor having various combinations of stators and rotors, or they may be connected in parallel. Each rotor may have any number of magnets ranging from a minimum of 2 to maximum of 60. The number of stators for an individual motor may range from 1 to 60 with the number of conducting bars ranging from 2 to 120.

What distinguishes this motor generator from all others is the presence of a permanent magnet connecting the two conducting bars which transfer magnetic energy through the pole pieces to the rotor, thereby attracting the rotor between the pole pieces. With the rotor attracted in between the two pole pieces, the coils switch the polarity of the magnetic field of the pole pieces so that the rotor is repelled out. Therefore there is no current and voltage being used to attract the rotor. The only current being used is the repulsion of the rotor between the two conductive bar pole pieces thereby requiring only a small amount of current to repel the rotor. This is known as ‘a regauging system’ and allows the capturing of available back EMF energy.

Finally, although the invention has been described with reference of particular means, materials and embodiments, it is to be understood that the invention is not limited to the particulars disclosed and extends to all equivalents within the scope of the claims.

JOHN BEDINI

US Patent Application 2003/117111 26th June 2003 Inventor: John C. Bedini

DEVICE AND METHOD FOR PULSE-CHARGING A BATTERY AND FOR DRIVING OTHER DEVICES WITH A PULSE

This is a slightly reworded copy of this patent application which shows a method of pulse-charging a battery bank or powering a heater and/or a motor. John Bedini is an intuitive genius with very considerable practical ability, so any information coming from him should be considered most carefully. At the end of this document there is some additional information not found in the patent.

ABSTRACT

This two-phase solid-state battery charger can receive input energy from a variety of sources including AC current, a battery, a DC generator, a DC-to-DC inverter, solar cells or any other compatible source of input energy. Phase 1 is the charging phase and Phase 2 is the discharge phase, where a signal, or current, passes through a dual timing switch which independently controls two channels, thus producing the two phases.

The dual timing switch is controlled by a logic chip, or pulse width modulator. A potential charge is allowed to build up in a capacitor bank. The capacitor bank is then disconnected from the energy input source and then a high voltage pulse is fed into the battery which is there to receive the charge. The momentary disconnection of the capacitor from the input energy source allows a free-floating potential charge in the capacitor. Once the capacitor has completed discharging the potential charge into the battery, the capacitor disconnects from the charging battery and re-connects to the energy source, thus completing the two-phase cycle.

TECHNICAL FIELD

This invention relates generally to a battery pulse-charger using a solid-state device and method where the current going to the battery is not constant. The signal or current is momentarily switch-interrupted as it flows through either the first channel, (the charging phase), or the second channel, (the discharging phase). This two-phase cycle alternates the signal in the two channels thereby allowing a potential charge in a capacitor to disconnect from its power source an instant before the capacitor discharges its stored potential energy into a battery set up to receive the capacitor's stored energy. The capacitor is then disconnected from the battery and re-connected to the power source upon completion of the discharge phase, thereby completing the charge-discharge cycle. The battery pulse-charger can also drive devices, such as a motor and a heating element, with pulses.

BACKGROUND AND PRIOR ART

Present day battery chargers use a constant charge current in their operation with no momentary disconnection of the signal or current as it flows either: (1) from a primary energy source to the charger; or (2) from the charger itself into a battery for receiving the charge. Some chargers are regulated to a constant current by any of several methods, while others are constant and are not regulated. There are no battery chargers currently in the art or available wherein there is a momentary signal or current disconnection between the primary energy source and the charger capacitors an instant before the capacitors discharge the stored potential energy into a battery receiving the pulse charge. Nor are there any chargers in the art that disconnect the charger from the battery receiving the charge when the charger capacitors receive energy from the primary source. The momentary current interruption allows the battery a short "rest period" and requires less energy from the primary energy source while putting more energy into the battery receiving the charge while requiring a shorter period of time to do it.

SUMMARY OF THE INVENTION

One aspect of the invention relates to a solid-state device and method for creating a pulse current to pulse-charge a battery or a bank of batteries in which a new and unique method is used to increase and preserve, for a longer period of time, the energy stored in the battery, as compared to constant-current battery chargers. The device uses a timed pulse to create a DC pulse waveform to be discharged into the battery receiving the charge.

One embodiment of the Invention uses a means for dual switching such as a pulse-width modulator (PWM), for example, a logic chip SG3524N PWM, and a means for optical coupling to a bank of high-energy capacitors to

store a timed initial pulse charge. This is the charge phase, or phase 1. The charged capacitor bank then discharges the stored high energy into the battery receiving the charge in timed pulses. Just prior to discharging the stored energy into the battery, the capacitor bank is momentarily disconnected from the power source, thus completing the charge phase, and thereby leaving the capacitor bank as a free-floating potential charge disconnected from the primary energy source to then be discharged into the battery. The transfer of energy from the capacitor bank to the battery completes the discharge phase, or phase 2. The two-phase cycle now repeats itself.

This embodiment of the battery pulse-charger works by transferring energy from a source, such as an AC source, to an unfiltered DC source of high voltage to be stored in a capacitor or a capacitor bank. A switching regulator is set to a timed pulse, for example, a one second pulse that is 180 degrees out of phase for each set of switching functions. The first function is to build the charge in the capacitor bank from the primary energy source; the second function is to disconnect the power source from the capacitor bank; the third function is to discharge the stored high voltage to the battery with a high voltage spike in a timed pulse, for example, a one second pulse; and the fourth function is to re-connect the capacitor bank to the primary energy source.

The device operates through a two-channel on/off switching mechanism or a gauging/re-gauging function wherein the charger is disconnected from its primary energy source an instant before the pulse-charger discharges the high-energy pulse into the battery to be charged. As the primary charging switch closes, the secondary discharging switch opens, and vise-versa in timed pulses to complete the two phase cycle.

The means for a power supply is varied with several options available as the primary energy source. For example, primary input energy may come from an AC source connected into the proper voltage (transformer); from an AC generator; from a primary input battery; from solar cells; from a DC-to-DC inverter; or from any other adaptable source of energy. If a transformer is the source of primary input energy, then it can be a standard rectifying transformer used in power supply applications or any other transformer applicable to the desired function. For example, it can be a 120-volt to 45-volt AC step-down transformer, and the rectifier can be a full-wave bridge of 200 volts at 20 amps, which is unfiltered when connected to the output of the transformer. The positive output terminal of the bridge rectifier is connected to the drains of the parallel connected field-effect transistors, and the negative terminal is connected to the negative side of the capacitor bank.

The Field Effect Transistor (FET) switches can be IRF260 FETs, or any other FET needed to accomplish this function. All the FETs are connected in parallel to achieve the proper current handling capacity for the pulses. Each FET may be connected through a 7-watt, 0.05-ohm resistor with a common bus connection at the source. All the FET gates may be connected through a 240-ohm resistor to a common bus. There may also be a 2 K-ohm resistor wired between the FET gates and the drain bus.

A transistor, for example an MJE15024, can be used as a driver for the gates, driving the bus, and in turn, an optical coupler powers the driver transistor through the first channel. A first charging switch is used to charge the capacitor bank, which acts as a DC potential source to the battery. The capacitor bank is then disconnected from the power rectifier circuit. The pulse battery charger is then transferred to a second field effect switch through the second channel for the discharge phase. The discharge phase is driven by a transistor, and that transistor is driven via an optical coupler. When the second (discharge) switch is turned on, the capacitor bank potential charge is discharged into the battery waiting to receive the charge. The battery receiving the charge is then disconnected from the pulse-charger capacitor bank in order to repeat the cycle. The pulse-charger may have any suitable source of input power including:

(1) solar panels to raise the voltage to the capacitor bank;
(2) a wind generator;
(3) a DC-to-DC inverter;
(4) an alternator;
(5) an AC motor generator;
(6) a static source such as a high voltage spark; and
(7) other devices which can raise the potential of the capacitor bank.

In another embodiment of the invention, one can use the pulse-charger to drive a device such as a motor or heating element with pulses of energy.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE INVENTION

An embodiment of the present invention is a device and method for a solid-state pulse-charger that uses a stored potential charge in a capacitor bank. The solid-state pulse-charger comprises a combination of elements and circuitry to capture and store available energy in a capacitor bank. The stored energy in the capacitors is then pulse-charged into the battery to be charged. In one version of this embodiment, there is a first momentary disconnection between the charger and the battery receiving the charge during the charge phase of the cycle, and a second momentary disconnection between the charger and the input energy source during the discharge phase of the cycle.

As a starting point, and an arbitrary method in describing this device and method, the flow of an electrical signal or current will be tracked from the primary input energy to final storage in the battery receiving the pulse charge.

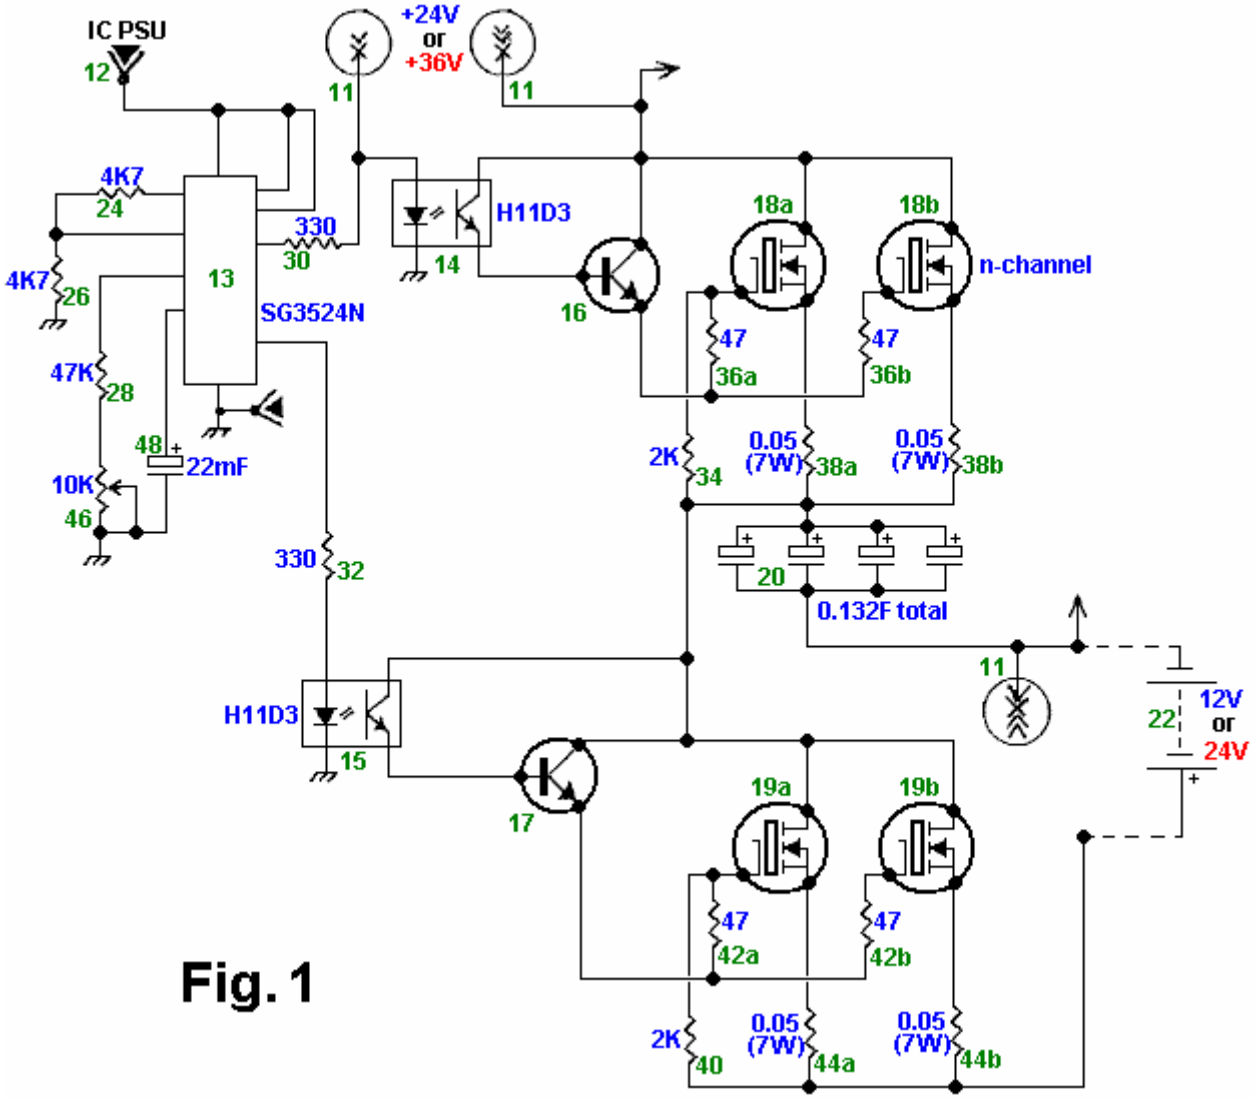

Fig. 1

Fig.1 is a schematic drawing of the solid-state pulse-charger according to an embodiment of the invention. As shown in **Fig.1**, the primary input energy source to the pulse-charger is a power supply **11**, examples of which are shown in **Fig.2**, **Fig.3**, and **Figs.4A-4D**. A 12-volt battery, as a low voltage energy source **12**, drives a dual switching means of control such as a logic chip or a pulse-width modulator (PWM) **13**.

Alternatively, the voltage from the power supply **11** may be converted to a voltage suitable to power the PWM **13**. The PWM **13** may be an SG3524N logic chip, and functions as an oscillator or timer to drive a 2-channel output with "on/off" switches that are connected when on to either a first optical isolator **14**, or alternatively, to a second optical isolator **15**. The first and second optical isolators **14** and **15** may be H11D3 optical isolators. When the logic chip **13** is connected to a first channel, it is disconnected from a second channel, thus resulting in two phases of signal direction; phase 1, a charge phase, and phase 2, a discharge phase.

When the logic chip **13** is switched to the charge phase, the signal flows to the first optical isolator **14**. From the optical isolator **14**, the signal continues its flow through a first NPN power transistor **16** that activates an N-channel MOSFET **18a** and an N-channel MOSFET **18b**. Current flowing through the MOSFETs **18a** and **18b** builds up a voltage across a capacitor bank **20**, thereby completing the charge phase of the switching activity.

The discharge phase begins when the logic chip **13** is switched to the second channel, with current flowing to the second optical isolator **15** and then through a second NPN power transistor **17**, which activates an N-channel MOSFET **19a** and an N-channel MOSFET **19b**. After the logic chip **13** closes the first channel and opens the second channel, the potential charge in the capacitor bank **20** is free floating between the power supply **11**, from which the capacitor bank **20** is now disconnected, and then connected to a battery **22** to receive the charge. It is at this point in time that the potential charge in the capacitor bank **20** is discharged through a high-energy pulse into the battery **22** or, a bank (not shown) of batteries. The discharge phase is completed once the battery **22** receives the charge. The logic chip **13** then switches the second channel closed and opens the first channel thus completing the charge-discharge cycle. The cycle is repetitive with the logic chip **13** controlling the signal

direction into either channel one to the capacitor bank, or to channel two to the battery **22** from the capacitor bank. The battery **22** is given a momentary rest period without a continuous current during the charge phase.

The component values for the described embodiment are as follows. The resistors **24**, **26**, . . . **44b** have the following respective values: 4.7K, 4.7K, 47K, 330, 330, 2K, 47, 47, 0.05(7W), 0.05(7W), 2K, 47, 47, 0.05(7 W), and 0.05(7W). The potentiometer **46** is 10K, the capacitor **48** is 22 mF, and the total capacitance of the capacitor bank **20** is 0.132F. The voltage of the battery **22** is between 12-24 V, and the voltage of the power supply **11** is 24-50 V such that the supply voltage is approximately 12-15 V higher than the battery voltage.

Other embodiments of the pulse-charger are contemplated. For example, the bipolar transistors **16** and **17** may be replaced with field-effect transistors, and the transistors **18a**, **18b**, **19a**, and **19b** may be replaced with bipolar or insulated-gate bipolar (IGBT) transistors. Furthermore, one can change the component values to change the cycle time, the peak pulse voltage, the amount of charge that the capacitor bank **20** delivers to the battery **22**, etc. In addition, the pulse-charger can have one or more than two transistors **18a** and **18b**, and one or more than two transistors **19a** and **19b**.

Still referring to **Fig.1**, the operation of the above-discussed embodiment of the pulse-charger is discussed. To begin the first phase of the cycle during which the capacitor bank **20** is charged, the logic circuit **13** deactivates the isolator **15** and activates the isolator **14**. Typically, the circuit **13** is configured to deactivate the isolator **15** before or at the same time that it activates the isolator **14**, although the circuit **13** may be configured to deactivate the isolator **15** after it activates the isolator **14**.

Next, the activated isolator **14** generates a base current that activates the transistor **16**, which in turn generates a current that activates the transistors **18a** and **18b**. The activated transistors **18a** and **18b** charge the capacitors in the bank **20** to a charge voltage equal or approximately equal to the voltage of the power supply **11** less the lowest threshold voltage of the transistors **18a** and **18b**. To begin the second phase of the cycle during which the capacitor bank **20** pulse charges the battery **22**, the logic circuit **13** deactivates the isolator **14** and activates the isolator **15**. Typically, the circuit **13** is configured to deactivate the isolator **14** before or at the same time that it activates the isolator **15**, although the circuit **13** may be configured to deactivate the isolator **14** after it activates the isolator **15**.

Next, the activated isolator **15** generates a base current that activates the transistor **17**, which in turn generates a current that activates the transistors **19a** and **19b**. The activated transistors **19a** and **19b** discharge the capacitors in the bank **20** into the battery **22** until the voltage across the bank **20** is or is approximately equal to the voltage across the battery **22** plus the lowest threshold voltage of the transistors **19a** and **19b**. Alternatively, the circuit **13** can deactivate the isolator **15** at a time before the bank **20** reaches this level of discharge. Because the resistances of the transistors **19a** and **19b**, the resistors **44a** and **44b**, and the battery **22** are relatively low, the capacitors in the bank **20** discharge rather rapidly, thus delivering a pulse of current to charge the battery **22**. For example, where the pulse-charger includes components having the values listed above, the bank **20** delivers a pulse of current having a duration of about 100 ms and a peak of about 250 A.

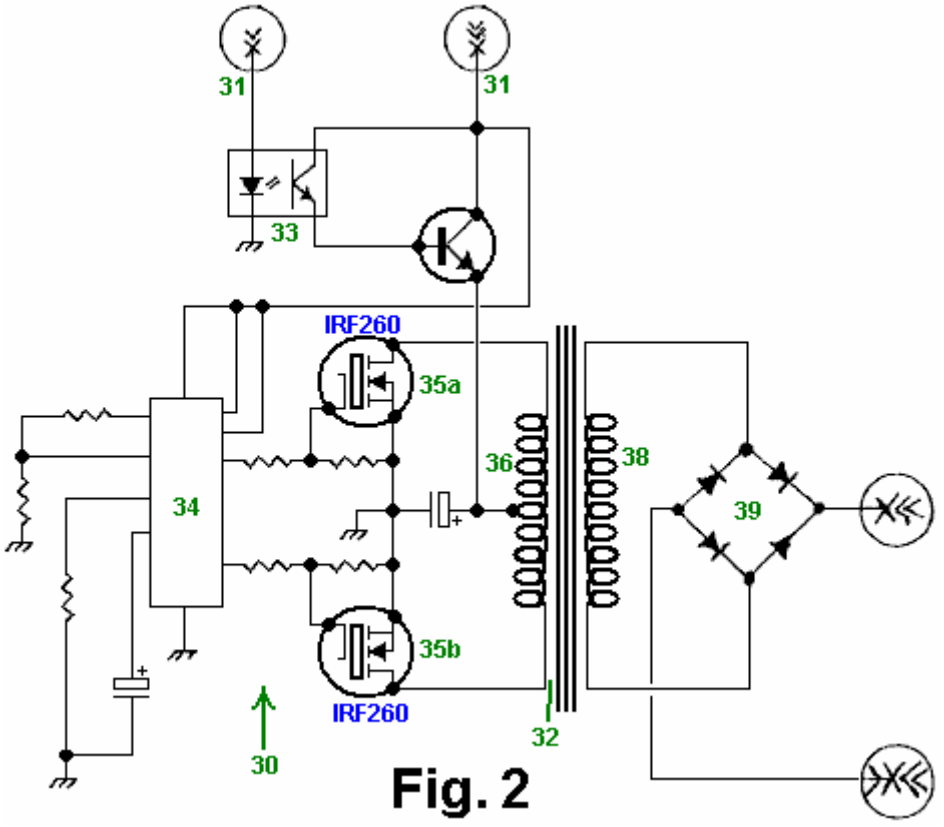

Fig. 2

Fig.2 is a schematic drawing of a conventional DC-to-DC converter **30** that can be used as the power supply **11** of **Fig.1** according to an embodiment of the invention. A DC-to-DC converter converts a low DC voltage to a higher DC voltage or vice-versa. Therefore, such a converter can convert a low voltage into a higher voltage that the pulse-charger of **Fig.1** can use to charge the capacitor bank **20** (**Fig.1**). More specifically, the converter **30** receives energy from a source **31** such as a 12-volt battery. An optical isolator sensor **33** controls an NPN power transistor which provides a current to a primary coil **36** of a power transformer **32**. A logic chip or pulse width modulator (PWM) **34** alternately switches on and off an IRF260 first N-channel MOSFET **35a** and an IRF260 second N-channel MOFSET **35b** such that when the MOSFET **35a** is on the MOSFET **35b** is off and vice-versa. Consequently, the switching MOSFETs **35a** and **35b** drive respective sections of the primary coil **36** to generate an output voltage across a secondary coil **38**. A full-wave bridge rectifier **39** rectifies the voltage across the secondary coil **38**, and this rectified voltage is provided to the pulse-charger of **Fig.1**. Furthermore, the secondary coil **38** can be tapped to provide a lower voltage for the PWM **13** of **Fig.1** such that the DC-to-DC converter **30** can be used as both the power supply **11** and the low-voltage supply **12** of **Fig.1**.

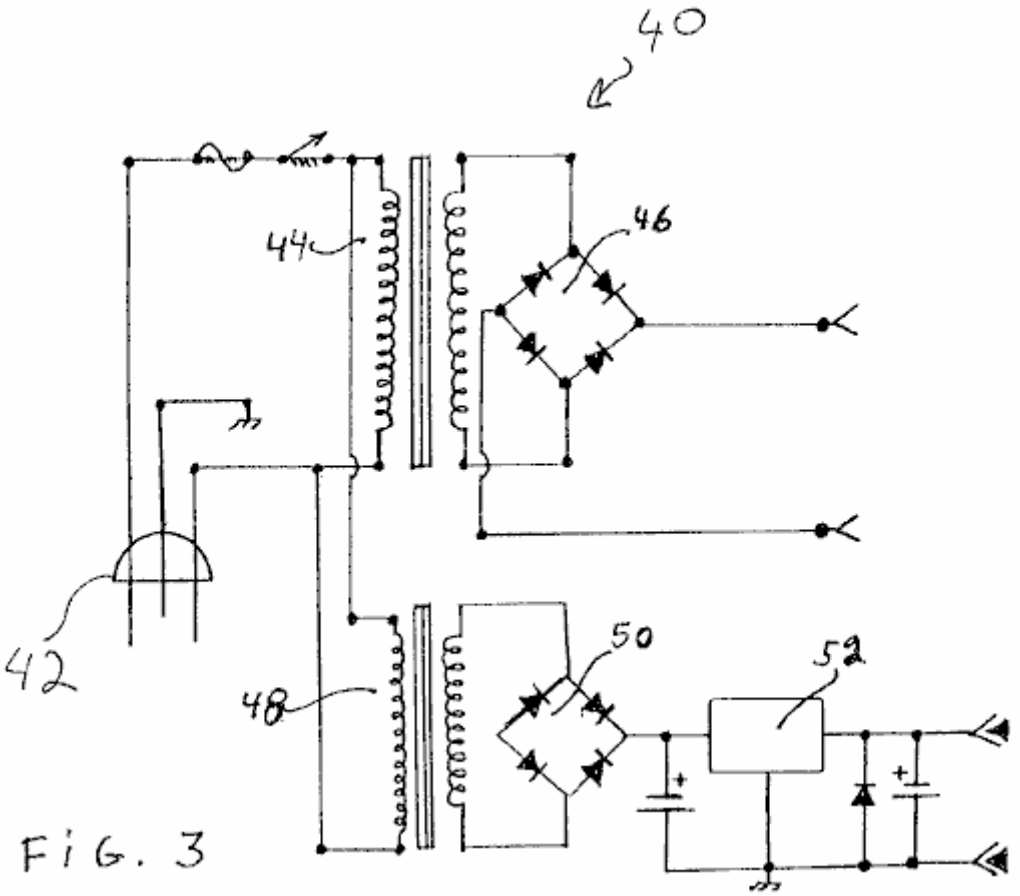

Fig.3 is a schematic drawing of an AC power supply **40** that can be used as both the power supply **11** and the power supply **12** of **Fig.1** according to an embodiment of the invention. The power input **42** to the supply **40** is 120V AC. A first transformer **44** and full-wave rectifier **46** compose the supply **11**, and a second transformer **48**, full-wave rectifier **50**, and voltage regulator **52** compose the supply **12**.

Fig.4A to **Fig.4D** are schematic drawings of various conventional primary energy input sources which can be used as the supply **11** and/or the supply **12** of **Fig.1** according to an embodiment of the invention. **Fig.4A** is a schematic drawing of serially coupled batteries. **Fig.4B** is a schematic drawing of serially-coupled solar cells. **Fig.4C** is a schematic drawing of an AC generator, and **Fig.4D** is a schematic drawing of a DC generator.

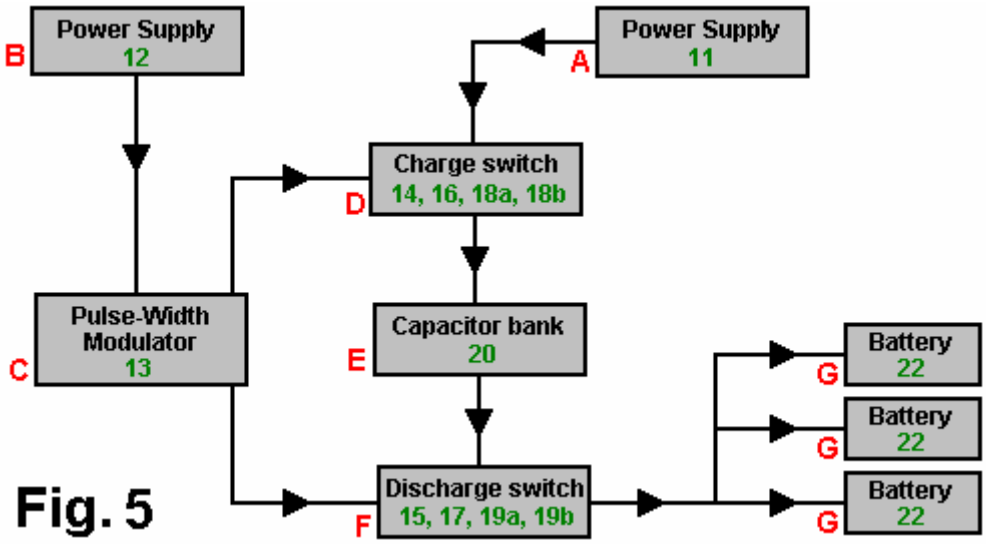

Fig. 5

Fig.5 is a block diagram of the solid-state pulse-charger of **Fig.1** according to an embodiment of the invention. Block **A** is the power supply **11**, which can be any suitable power supply such as those shown in **Fig.2**, **Fig.3**, **Figs.4A-4D**. Block **B** is the power supply **12**, which can be any suitable power supply such as a 12V DC supply or the supply shown in **Fig.3**. Block **C** is the PWM **13** and its peripheral components. Block **D** is the charge switch that includes the first optical isolator chip **14**, the first NPN power transistor **16**, the first set of two N-

channel MOSFETs **18a** and **18b**, and their peripheral resistors. Block **E** is the capacitor bank **20**. Block **F** is the discharge switch that includes the second optical isolator chip **15**, the second NPN power transistor **17**, the second set of two N-channel MOSFETs **19a** and **19b**, and their peripheral resistors. Block **G** is the battery or battery bank **22** which is being pulse-charged.

A unique feature that distinguishes one embodiment of the pulse-charger described above, from conventional chargers is the method charging the battery with pulses of current instead of with a continuous current. Consequently, the battery is given a reset period between pulses.

Fig.6 is a diagram of a DC motor **60** that the pulse-charger of **Fig.1** can drive according to an embodiment of the invention. Specifically, one can connect the motor **60** in place of the battery **22** (**Fig.1**) such that the pulse-charger drives the motor with pulses of current. Although one need not modify the pulse-charger to drive the motor **60**, one can modify it to make it more efficient for driving the motor. For example, one can modify the values of the resistors peripheral to the PWM **13** (**Fig.1**) to vary the width and peak of the drive pulses from the capacitor bank **20** (**Fig.1**).

Fig.7 is a diagram of a heating element **70**, such as a dryer or water-heating element, that the pulse-charger of **Fig.1** can drive according to an embodiment of the invention. Specifically, one can connect the heating element **70** in place of the battery **22** (**Fig.1**) such that the pulse-charger drives the element with pulses of current. Although one need not modify the pulse-charger to drive the element **70**, one can modify it to make it more efficient for driving the element. For example, one can modify the values of the resistors peripheral to the PWM **13** (**Fig.1**) to vary the width and peak of the drive pulses from the capacitor bank **20** (**Fig.1**).

In the embodiments discussed above, specific electronic elements and components are used. However, it is known that a variety of available transistors, resistors, capacitors, transformers, timing components, optical isolators, pulse width modulators, MOSFETs, and other electronic components may be used in a variety of combinations to achieve an equivalent result. Finally, although the invention has been described with reference of particular means, materials and embodiments, it is to be understood that the invention is not limited to the particulars disclosed and extends to all equivalents within the scope of the claims.

CLAIMS

1. A solid-state pulse battery charger wherein input power from a primary source is stored as a potential charge in a capacitor bank, said capacitor bank then disconnected from said input power source through a dual timing means, said capacitor then connected to a battery to receive the potential charge, the charge then discharged into said battery from said capacitor, said battery then disconnected from said capacitor through said dual timing means, said capacitor then re-connected to said input power source completing a two phase switching cycle comprising:

a. a means for providing input power;

b. a means for timing a signal and a current flow in two phases, a charge phase and a discharge phase, through either a first channel output for charging said capacitor bank, or a second channel output for discharging stored energy from said capacitor into said battery, the current flowing from said first channel output through a first optical isolator and through a first NPN power transistor, said first transistor activating a first pair of N-channel MOSFETs with voltage stored as the potential charge in said capacitor bank, said capacitor disconnecting from said input power means by said timing means;

c. said means for timing current flow connecting to said second channel output, current flowing from said second channel through a second optical isolator and through a second NPN power transistor, said second transistor activating a second pair of N-channel MOSFETs, said capacitor connecting to said battery, the potential charge discharging into said battery, said timing means disconnecting said capacitor from said battery, and connecting said capacitor to said power means.

2. The pulse-charger of claim 1 wherein the means for providing input power is an AC voltage current.

3. The pulse-charger of claim 1 wherein the means for providing input power is a battery.

4. The pulse-charger of claim 1 wherein the means for providing input power is a DC generator.

5. The pulse-charger of claim 1 wherein the means for providing input power is an AC generator.

6. The pulse-charger of claim 1 wherein the means for providing input power is a solar cell.

7. The pulse-charger of claim 1 wherein the means for providing input power is a DC-to-DC inverter.

8. The pulse-charger of claim 1 wherein the means for timing a signal is a pulse width modulator, said modulator an SG3524N logic chip.

9. The pulse-charger of claim 1 wherein the optical isolator is an H11D3 isolator.

10. The pulse-charger of claim 1 wherein the NPN power transistor is an MJE15024 transistor.

11. The pulse-charger of claim 1 wherein the N-channel MOSFET is a IRF260 MOSFET.

12. A solid-state pulsed battery charger wherein input power from a primary source is stored as a potential charge in a capacitor bank, said capacitor then disconnected from said input power source through a dual timing means, said capacitor then connected to a battery to receive the potential charge, the charge then discharged into said battery from said capacitor, said battery then disconnected from said capacitor through said dual timing means, said capacitor then reconnected to said input power source completing a two phase cycle comprising:

a. a means for providing said input power, said means either an AC voltage current, or a battery, or a DC generator, or an AC generator, or a solar cell, or a DC-to-DC inverter;

b. a means for timing a signal and a current flow, said timing means a pulse width modulator, logic chip SG3524N, the current flowing through either a first channel output, or a second channel output, the current flowing from said first channel output through a first optical isolator, said isolator an H11D3, and through a first NPN power transistor, said transistor an MJE15024, said first transistor activating a first pair of N-channel MOSFETs, said MOSFETs an IRF260, with current voltage stored as the potential charge in said capacitor bank, said capacitor disconnecting from said input power means by said logic chip;

c. said timing logic chip connecting to said second channel output, current flowing from said second channel through a second optical isolator, said isolator an H11D3, and through a second NPN power transistor, said second transistor an MJE15024, and activating a second pair of N-channel MOSFETs, said MOSFETs an IRF260, with current voltage stored as the potential charge in said capacitor bank, said capacitor disconnecting from said input power means by said logic chip, said capacitor connecting to said battery, the potential charge discharging into said battery, said timing means disconnecting said capacitor from said battery and connecting said capacitor to said power means.

13. A method of making a solid-state pulse battery charger wherein input power from a primary source is stored as a potential charge in a capacitor bank, said capacitor disconnected from said input power source through a dual timing means, said capacitor connected to a battery to receive the potential charge, said charge discharged into said battery from said capacitor, said battery disconnected from said capacitor through said dual timing means, said capacitor reconnected to said input power source completing a two phase cycle comprising the steps of:

a. providing a source of input power;

b. connecting a means for dual-timing said charger to control a signal or current flow through a first channel output comprising a first optical isolator, a first NPN power transistor and a first pair of N-channel MOSFETs;

c. capturing energy from said current and storing said energy in said capacitor bank thereby charging said capacitor;

d. switching the flow of said current using said timing device to a second channel comprising a second optical isolator, a second NPN power transistor and a second pair of N-channel MOSFETs, thus disconnecting said capacitor from said power source and connecting said capacitor to said battery;

e. discharging the potential charge into said battery;

f. switching the flow of the current using said timing device to said power source and said first channel to complete said cycle.

14. The pulse-charger of claim 13 wherein the means for providing input power is an AC voltage current.

15. The pulse-charger of claim 13 wherein the means for providing input power is a battery.

16. The pulse-charger of claim 13 wherein the means for providing input power is a DC generator.

17. The pulse-charger of claim 13 wherein the means for providing input power is an AC generator.

18. The pulse-charger of claim 13 wherein the means for providing input power is a solar cell.

19. The pulse-charger of claim 13 wherein the means for providing input power is a DC-to-DC inverter.

20. The pulse-charger of claim 13 wherein the means for timing a signal is a pulse width modulator, said modulator an SG3524N logic chip.

21. The pulse-charger of claim 13 wherein the optical isolator is an H11D3 isolator.

22. The pulse-charger of claim 13 wherein the NPN power transistor is an MJE15024 transistor.

23. The pulse-charger of claim 13 wherein the N-channel MOSFET is a IRF260 MOSFET.

24. A battery charger, comprising:
a supply node;
a charge node;
a switch circuit coupled to the supply and the charge nodes and operable to, allow a battery-charge current to flow into the charge node during a
battery-charge period, and prohibit the battery-charge current from flowing into the charge node during
a battery-rest period.

25. The battery charger of claim 24, further comprising:
a charge-storage device coupled to the switch circuit; and
wherein the switch circuit is operable to, allow the battery-charge current to flow from the charge-storage device into the charge node during the battery-charge period, and charge the charge-storage device during the battery-rest period.

26. The battery charger of claim 24, further comprising:
a capacitor coupled to the switch circuit; and
wherein the switch circuit is operable to, allow the battery-charge current to from the capacitor into the charge node
during the battery-charge period, and charge the capacitor during the battery-rest period.

27. A method, comprising:
charging a battery during a first period of a charge cycle; and
prohibiting the charging of the battery during a second period of the charge cycle.

28. The method of claim 27 wherein:
charging the battery comprises charging the battery with a charge current during the first period of the charge cycle; and
prohibiting the charging of the battery comprises prohibiting the charge current from flowing into the battery during the second period of the charge cycle.

29. The method of claim 27 wherein:
charging the battery comprises discharging a capacitor into the battery during the first period of the charge cycle; and
prohibiting the charging of the battery comprises uncoupling the capacitor from the battery during the second period of the charge cycle.

30. The method of claim 27, further comprising:
wherein charging the battery comprises discharging a capacitor into the battery during the first period of the charge cycle;
wherein prohibiting the charging of the battery comprises uncoupling the capacitor from the battery during the second period of the charge cycle; and
charging the capacitor during the second period of the charge cycle.

31. A method, comprising:
discharging a charge-storage device into a battery during a first period of a battery-charge cycle; and
uncoupling the charge-storage device from the battery and charging the charge-storage device during a second period of the battery-charge cycle.

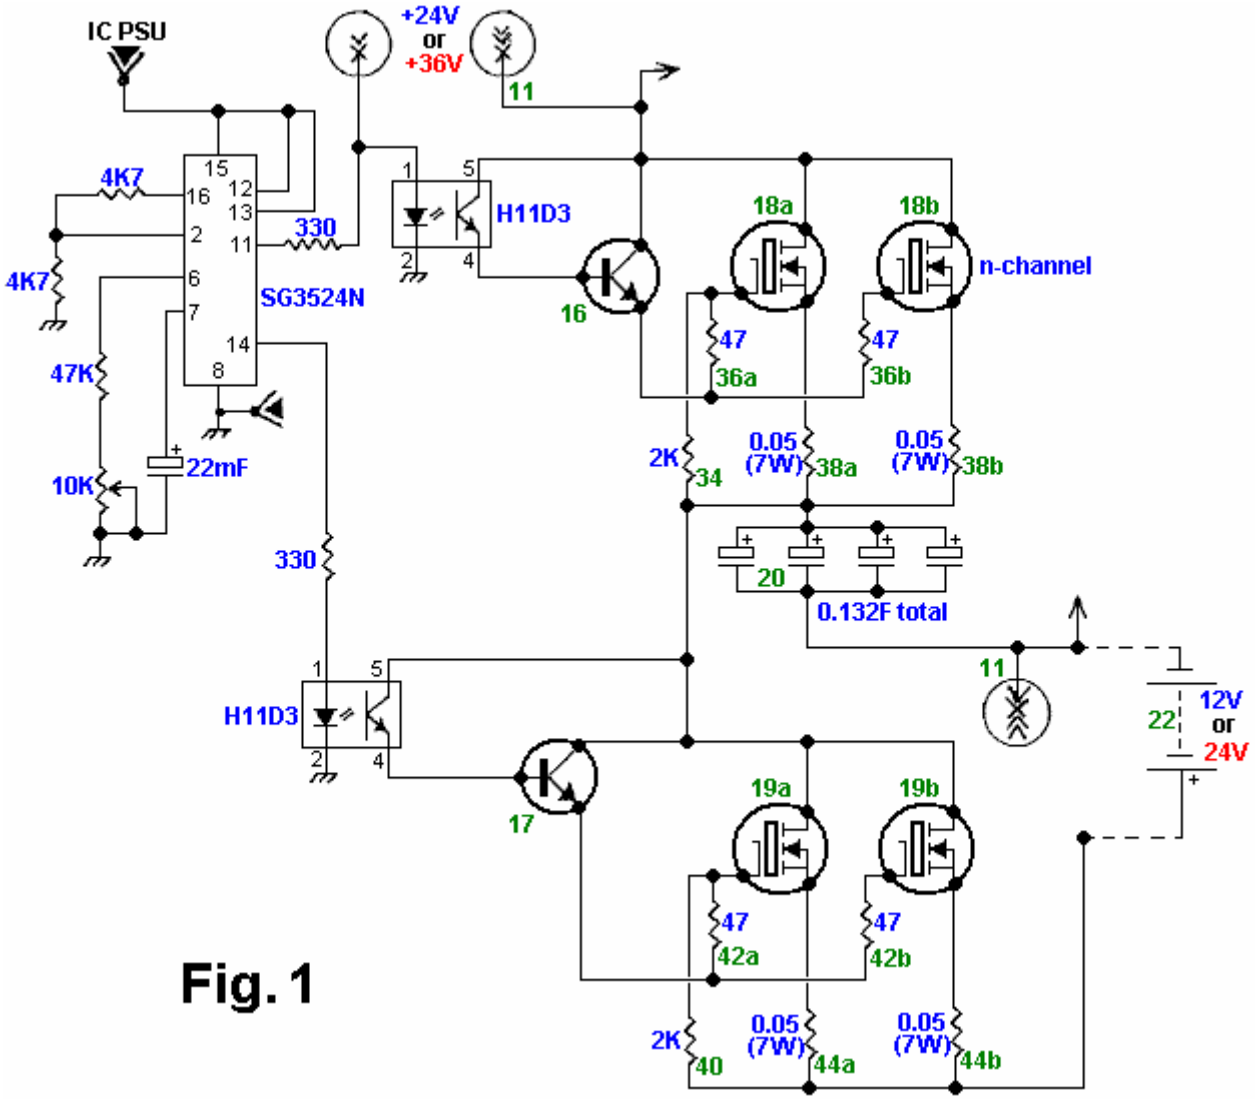
32. The method of claim 31 wherein uncoupling the charge-storage device comprises uncoupling the charge-storage device from the battery before commencing charging of the charge-storage device.

33. The method of claim 31 wherein uncoupling the charge-storage device comprises uncoupling the charge-storage device from the battery after commencing charging of the charge-storage device.

34. The method of claim 31 wherein uncoupling the charge-storage device comprises simultaneously uncoupling the charge-storage device from the battery and commencing charging of the charge-storage device.

Notes:

The following information is NOT part of John's patent. It is information intended to be helpful, but as it is not coming from John it must be considered to be opinion and not fact. In the above diagrams, the SG3524N integrated circuit is likely to be unfamiliar to many readers, and an examination of the specification sheet does not make it obvious which pin connections are used in John's circuit. The following pin connections are believed to be correct, but cannot be guaranteed.



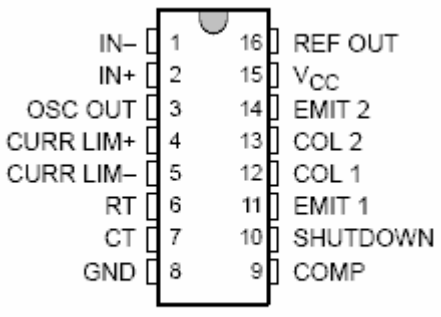


Fig. 1

In addition to these SG3524N pin connections, it is suggested that pins 1, 4 and 5 be connected to ground instead of just pin 8, and that a 100nF capacitor be connected from pin 9 to ground. Pins 3 and 10 are left unconnected. The pinouts for the chip are:

SG3524N

RICHARD WEIR and CARL NELSON

US Patent 7,033,406 25th April 2006 Inventors: Richard Weir and Carl Nelson

ELECTRICAL-ENERGY-STORAGE UNIT UTILISING CERAMIC AND INTEGRATED-CIRCUIT TECHNOLOGIES FOR REPLACEMENT OF ELECTROCHEMICAL BATTERIES

This patent shows an electrical storage method which is reputed to power an electric car for a 500 mile trip on a charge taking only five minutes to complete. This document is a very slightly re-worded copy of the original. It has been pointed out by Mike Furness that while a five minute recharge is feasible, it is not practical, calling for cables with a six-inch diameter. Also, the concept of recharging stations as suggested is also rather improbable as the electrical supply needed would rival that of a power station. However, if the charging time were extended to night time, then it would allow substantial driving range during the day time.

ABSTRACT

An Electrical-Energy-Storage Unit (EESU) has as a basis material a high-permittivity, composition-modified barium titanate ceramic powder. This powder is double coated with the first coating being aluminium oxide and the second coating calcium magnesium aluminosilicate glass. The components of the EESU are manufactured with the use of classical ceramic fabrication techniques which include screen printing alternating multi-layers of nickel electrodes and high-permittivity composition-modified barium titanate powder, sintering to a closed-pore porous body, followed by hot-isostatic pressing to a void-free body. The components are configured into a multi-layer array with the use of a solder-bump technique as the enabling technology so as to provide a parallel configuration of components that has the capability to store electrical energy in the range of 52 kWH. The total weight of an EESU with this range of electrical energy storage is about 336 pounds.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates generally to energy-storage devices, and relates more particularly to high-permittivity ceramic components utilised in an array configuration for application in ultra high electrical-energy storage devices.

2. Description of the Relevant Art

The internal-combustion-engine (ICE) powered vehicles have as their electrical energy sources a generator and battery system. This electrical system powers the vehicle accessories, which include the radio, lights, heating, and air conditioning. The generator is driven by a belt and pulley system and some of its power is also used to recharge the battery when the ICE is in operation. The battery initially provides the required electrical power to operate an electrical motor that is used to turn the ICE during the starting operation and the ignition system.

The most common batteries in use today are:
Flooded lead-acid,
Sealed gel lead-acid,
Nickel-Cadmium (Ni-Cad),
Nickel Metal Hydride (NiMH), and
Nickel-Zinc (Ni-Z).

References on the subject of electrolchemical batteries include the following:

Guardian, Inc., "Product Specification": Feb. 2, 2001;
K. A. Nishimura, "NiCd Battery", Science Electronics FAQ V1.00: Nov. 20, 1996;
Ovonics, Inc., "Product Data Sheet": no date;
Evercel, Inc., "Battery Data Sheet—Model 100": no date;

B. Dickinson et al., "Issues and Benefits with Fast Charging Industrial Batteries", AeroVeronment, Inc. article: no date.

Each specific type of battery has characteristics, which make it either more or less desirable to use in a specific application. Cost is always a major factor and the NiMH battery tops the list in price with the flooded lead-acid battery being the most inexpensive. Evercel manufactures the Ni-Z battery and by a patented process, with the

claim to have the highest power-per-pound ratio of any battery. See Table 1 below for comparisons among the various batteries. What is lost in the cost translation is the fact that NiMH batteries yield nearly twice the performance (energy density per weight of the battery) than do conventional lead-acid batteries. A major drawback to the NiMH battery is the very high self-discharge rate of approximately 5% to 10% per day. This would make the battery useless in a few weeks. The Ni-Cad battery and the lead-acid battery also have self-discharge but it is in the range of about 1% per day and both contain hazardous materials such as acid or highly toxic cadmium. The Ni-Z and the NiMH batteries contain potassium hydroxide and this electrolyte in moderate and high concentrations is very caustic and will cause severe burns to tissue and corrosion to many metals such as beryllium, magnesium, aluminium, zinc, and tin.

Another factor that must be considered when making a battery comparison is the recharge time. Lead-acid batteries require a very long recharge period, as long as 6 to 8 hours. Lead-acid batteries, because of their chemical makeup, cannot sustain high current or voltage continuously during charging. The lead plates within the battery heat rapidly and cool very slowly. Too much heat results in a condition known as "gassing" where hydrogen and oxygen gases are released from the battery's vent cap. Over time, gassing reduces the effectiveness of the battery and also increases the need for battery maintenance, i.e., requiring periodic de-ionised or distilled water addition. Batteries such as Ni-Cad and NiMH are not as susceptible to heat and can be recharged in less time, allowing for high current or voltage changes which can bring the battery from a 20% state of charge to an 80% state of charge in just 20 minutes. The time to fully recharge these batteries can be more than an hour. Common to all present day batteries is a finite life, and if they are fully discharged and recharged on a regular basis their life is reduced considerably.

SUMMARY OF THE INVENTION

In accordance with the illustrated preferred embodiment, the present invention provides a unique electrical-energy-storage unit that has the capability to store ultra high amounts of energy.

One aspect of the present invention is that the materials used to produce the energy-storage unit, EESU, are not explosive, corrosive, or hazardous. The basis material, a high-permittivity calcined composition-modified barium titanate powder is an inert powder and is described in the following references: S. A. Bruno, D. K. Swanson, and I. Burn, J. Am Ceram. Soc. 76, 1233 (1993); P. Hansen, U.S. Pat. No. 6,078,494, issued Jun. 20, 2000. The most cost-effective metal that can be used for the conduction paths is nickel. Nickel as a metal is not hazardous and only becomes a problem if it is in solution such as in deposition of electroless nickel. None of the EESU materials will explode when being recharged or impacted. Thus the EESU is a safe product when used in electric vehicles, buses, bicycles, tractors, or any device that is used for transportation or to perform work. It could also be used for storing electrical power generated from solar voltaic cells or other alternative sources for residential, commercial, or industrial applications. The EESU will also allow power averaging of power plants utilising SPVC or wind technology and will have the capability to provide this function by storing sufficient electrical energy so that when the sun is not shinning or the wind is not blowing they can meet the energy requirements of residential, commercial, and industrial sites.

Another aspect of the present invention is that the EESU initial specifications will not degrade due to being fully discharged or recharged. Deep cycling the EESU through the life of any commercial product that may use it will not cause the EESU specifications to be degraded. The EESU can also be rapidly charged without damaging the material or reducing its life. The cycle time to fully charge a 52 kWH EESU would be in the range of 4 to 6 minutes with sufficient cooling of the power cables and connections. This and the ability of a bank of EESUs to store sufficient energy to supply 400 electric vehicles or more with a single charge will allow electrical energy stations that have the same features as the present day gasoline stations for the ICE cars. The bank of EESUs will store the energy being delivered to it from the present day utility power grid during the night when demand is low and then deliver the energy when the demand hits a peak. The EESU energy bank will be charging during the peak times but at a rate that is sufficient to provide a full charge of the bank over a 24-hour period or less. This method of electrical power averaging would reduce the number of power generating stations required and the charging energy could also come from alternative sources. These electrical-energy-delivery stations will not have the hazards of the explosive gasoline.

Yet another aspect of the present invention is that the coating of aluminium oxide and calcium magnesium aluminosilicate glass on calcined composition-modified barium titanate powder provides many enhancement features and manufacturing capabilities to the basis material. These coating materials have exceptional high voltage breakdown and when coated on to the above material will increase the breakdown voltage of ceramics comprised of the coated particles from 3×10^6 V/cm of the uncoated basis material to around 5×10^6 V/cm or higher. The following reference indicates the dielectric breakdown strength in V/cm of such materials: J. Kuwata et al., "Electrical Properties of Perovskite-Type Oxide Thin-Films Prepared by RF Sputtering", Jpn. J. Appl. Phys., Part 1, 1985, 24(Suppl. 24-2, Proc. Int. Meet. Ferroelectr., 6th), 413-15. This very high voltage breakdown assists in allowing the ceramic EESU to store a large amount of energy due to the following: Stored energy $E = CV^2 / 2$,

Formula 1, as indicated in F. Sears et al., "Capacitance-Properties of Dielectrics", University Physics, Addison-Wesley Publishing Company, Inc.: Dec. 1957: pp 468-486, where C is the capacitance, V is the voltage across the EESU terminals, and E is the stored energy. This indicates that the energy of the EESU increases with the square of the voltage. **Fig.1** indicates that a double array of 2230 energy storage components 9 in a parallel configuration that contain the calcined composition-modified barium titanate powder. Fully densified ceramic components of this powder coated with 100 Angstrom units of aluminium oxide as the first coating 8 and a 100 Angstrom units of calcium magnesium aluminosilicate glass as the second coating 8 can be safely charged to 3500 V. The number of components used in the double array depends on the electrical energy storage requirements of the application. The components used in the array can vary from 2 to 10,000 or more. The total capacitance of this particular array 9 is 31 F which will allow 52,220 W·h of energy to be stored as derived by Formula 1.

These coatings also assist in significantly lowering the leakage and ageing of ceramic components comprised of the calcined composition-modified barium titanate powder to a point where they will not effect the performance of the EESU. In fact, the discharge rate of the ceramic EESU will be lower than 0.1% per 30 days which is approximately an order of magnitude lower than the best electrochemical battery.

A significant advantage of the present invention is that the calcium magnesium aluminosilicate glass coating assists in lowering the sintering and hot-isostatic-pressing temperatures to 800^{O}C. This lower temperature eliminates the need to use expensive platinum, palladium, or palladium-silver alloy as the terminal metal. In fact, this temperature is in a safe range that allows nickel to be used, providing a major cost saving in material expense and also power usage during the hot-isostatic-pressing process. Also, since the glass becomes easily deformable and flowable at these temperatures it will assist in removing the voids from the EESU material during the hot-isostatic-pressing process. The manufacturer of such systems is Flow Autoclave Systems, Inc. For this product to be successful it is mandatory that all voids be removed to assist in ensuring that the high voltage breakdown can be obtained. Also, the method described in this patent of coating the calcium magnesium aluminosilicate glass ensures that the hot-isostatic-pressed double-coated composition-modified barium titanate high-relative-permittivity layer is uniform and homogeneous.

Yet another aspect of the present invention is that each component of the EESU is produced by screen-printing multiple layers of nickel electrodes with screening ink from nickel powder. Interleaved between nickel electrodes are dielectric layers with screening ink from calcined double-coated high-permittivity calcined composition-modified barium titanate powder. A unique independent dual screen-printing and layer-drying system is used for this procedure. Each screening ink contains appropriate plastic resins, surfactants, lubricants, and solvents, resulting in a proper rheology (the study of the deformation and flow of matter) for screen printing. The number of these layers can vary depending on the electrical energy storage requirements. Each layer is dried before the next layer is screen printed. Each nickel electrode layer **12** is alternately preferentially aligned to each of two opposite sides of the component automatically during this process as indicated in **Fig.2**. These layers are screen printed on top of one another in a continuous manner. When the specified number of layers is achieved, the component layers are then baked to obtain by further drying sufficient handling strength of the green plastic body. Then the array is cut into individual components to the specified sizes.

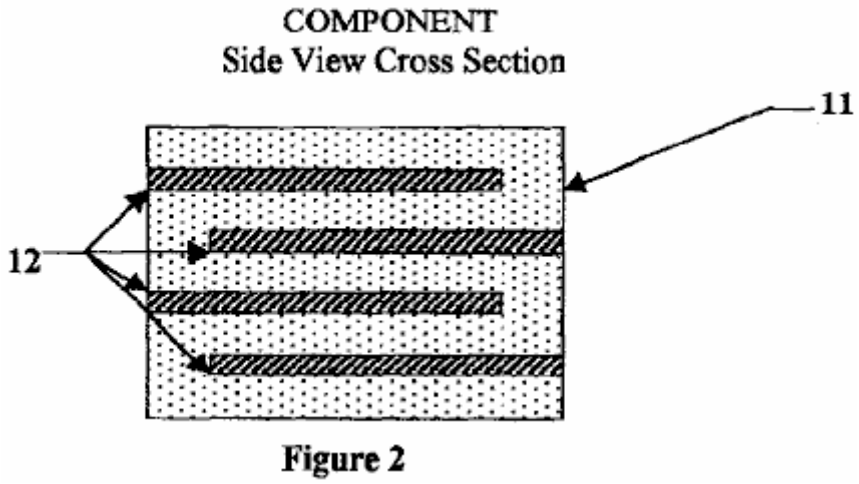

Figure 2

Alternatively, the dielectric powder is prepared by blending with plastic binders, surfactants, lubricants, and solvents to obtain a slurry with the proper rheology for tape casting. In tape casting, the powder-binder mixture is extruded by pressure through a narrow slit of appropriate aperture height for the thickness desired of the green plastic ceramic layer on to a moving plastic-tape carrier, known as a doctor-blade web coater. After drying, to develop sufficient handling strength of the green plastic ceramic layer, this layer is peeled away from the plastic-tape carrier. The green plastic ceramic layer is cut into sheets to fit the screen-printing frame in which the

electrode pattern is applied with nickel ink. After drying of the electrode pattern, the sheets are stacked and then pressed together to assure a well-bonded lamination. The laminate is then cut into components of the desired shape and size.

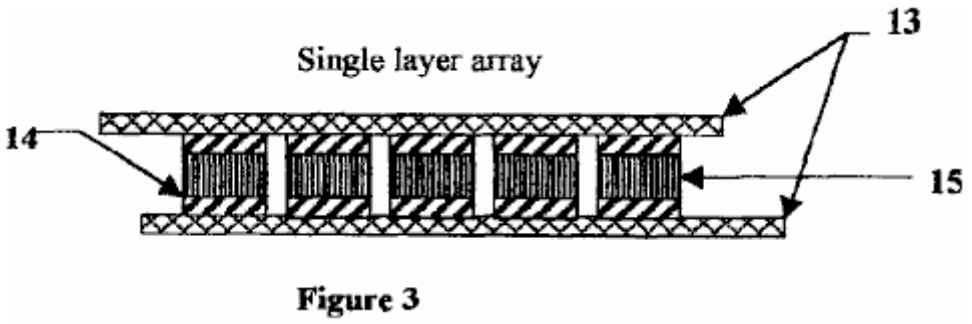

Figure 3

The components are treated for the binder-burnout and sintering steps. The furnace temperature is slowly ramped up to 350^{O}C and held for a specified length of time. This heating is accomplished over a period of several hours so as to avoid any cracking and delamination of the body. Then the temperature is ramped up to 850^{O}C and held for a specified length of time. After this process is completed the components are then properly prepared for the hot isostatic pressing at 700^{O}C and the specified pressure. This process will eliminate voids. After this process, the components are then side-lapped on the connection side to expose the preferentially aligned nickel electrodes **12**. Then these sides are dipped into ink from nickel powder that has been prepared to have the desired rheology. Then side conductors of nickel **14** are dipped into the same ink and then are clamped on to each side of the components **15** that have been dipped into the nickel powder ink. The components are then fired at 800^{O}C for 20 minutes to bond the nickel bars to the components as indicated in **Fig.3**. The components are then assembled into a first-level array, **Fig.3**, with the use of the proper tooling and solder-bump technology. Then the first-level arrays are assembled to form a second-level array, **Fig.4**, by stacking the first array layers on top of one another in a preferential mode. Then nickel bars **18** are attached on each side of the second array as indicated in **Fig.4**. Then the EESU is packaged to form its final assembly configuration.

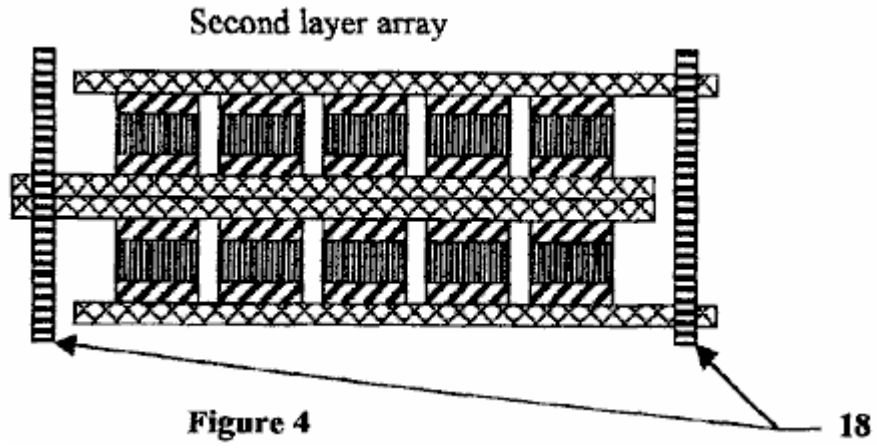

Figure 4

The features of this patent indicate that the ceramic EESU, as indicated in Table 1, outperforms the electrochemical battery in every parameter. This technology will provide mission-critical capability to many sections of the energy-storage industry.

TABLE 1
The parameters of each technology to store 52.2 kW · h of electrical energy
are indicated-(data as of February 2001 from manufacturer's specification sheets).

	NiMH	LA(Gel)	Ceramic EESU	Ni—Z
Weight (pounds)	1,716	3,646	336	1,920
Volume (cu. inch)	17,881	43,045	2,005	34,780
Discharge rate	5% in 30 days	1% in 30 days	0.1% in 30 days	1% in 30 days
Charging time (full)	1.5 hours	8.0 hours	3 to 6 minutes	1.5 hours
Life reduced with deep cycle use	moderate	high	none	moderate
Hazardous materials	Yes	Yes	None	Yes

This EESU will have the potential to revolutionise the electric vehicle (EV) industry, the storage and use of electrical energy generated from alternative sources with the present utility grid system as a backup source for residential, commercial, and industrial sites, and the electric energy point of sales to EVs. The EESU will replace the electrochemical battery in any of the applications that are associated with the above business areas or in any business area where its features are required.

The features and advantages described in the specifications are not all inclusive, and particularly, many additional features and advantages will be apparent to one of ordinary skill in the art in view of the description, specification and claims made here. Moreover, it should be noted that the language used in the specification has been principally selected for readability and instructional purposes, and may not have been selected to delineate or circumscribe the inventive subject matter, resort to the claims being necessary to determine such inventive subject matter.

BRIEF DESCRIPTION OF THE DRAWINGS

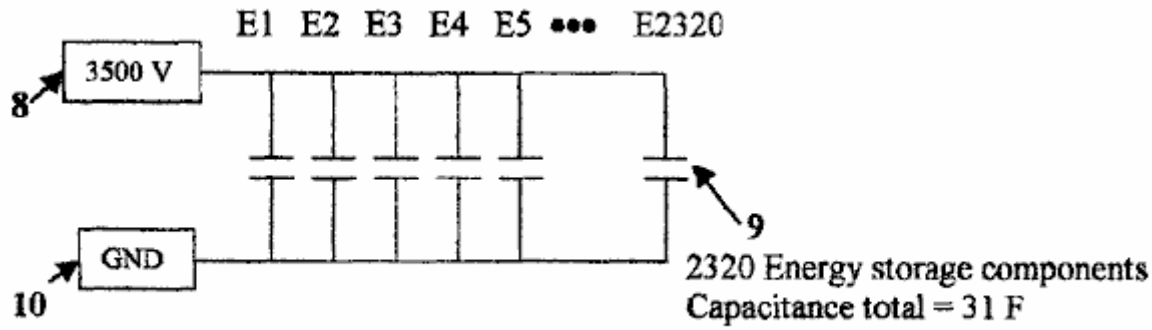

Figure 1

Fig.1 indicates a schematic of 2320 energy storage components **9** hooked up in parallel with a total capacitance of 31 Farads. The maximum charge voltage **8** of 3500 V is indicated with the cathode end of the energy storage components **9** hooked to system ground **10**.

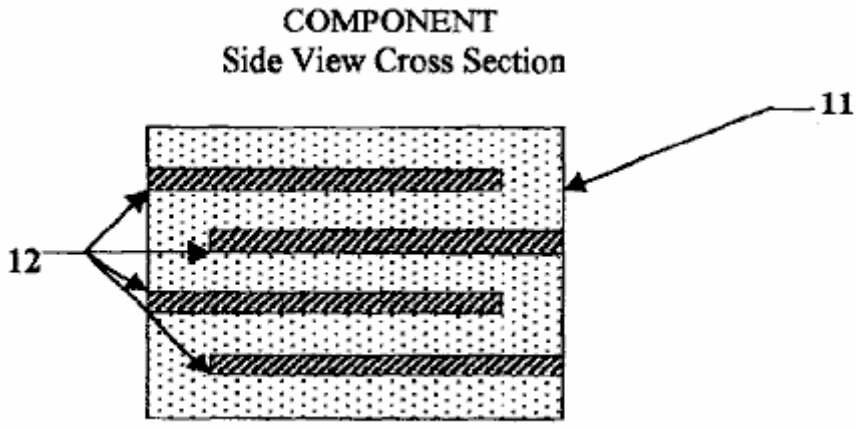

Figure 2

Fig.2 is a cross-section side view of the electrical-energy-storage unit component. This figure indicates the alternating layers of nickel electrode layers **12** and high-permittivity composition-modified barium titanate dielectric layers **11**. This figure also indicate the preferentially aligning concept of the nickel electrode layers **12** so that each storage layer can be hooked up in parallel.

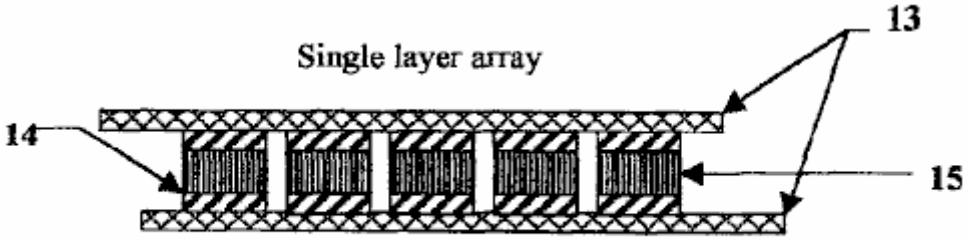

Figure 3

Fig.3 is side view of a single-layer array indicating the attachment of individual components **15** with the nickel side bars **14** attached to two preferentially aligned copper conducting sheets **13**.

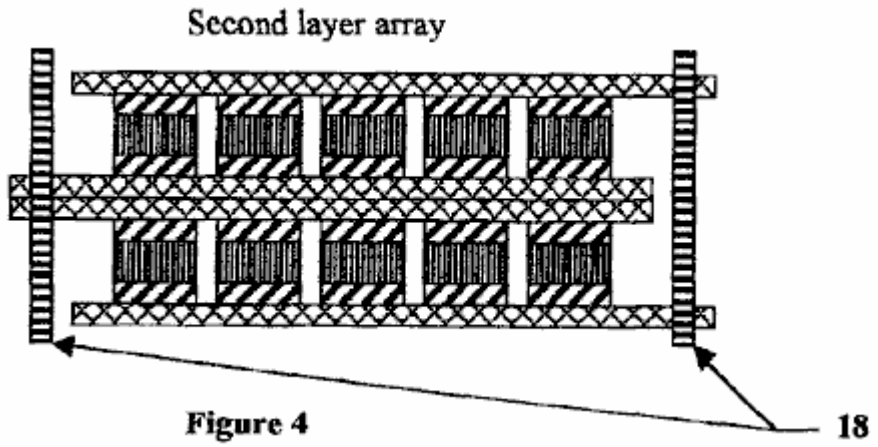

Figure 4

Fig.4 is a side view of a double-layer array with copper array connecting nickel bars **16** attaching the two arrays via the edges of the preferentially aligned copper conductor sheets **13**. This figure indicates the method of attaching the components in a multi-layer array to provide the required energy storage.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Fig.1, **Fig.2**, **Fig.3**, and **Fig.4** of the drawings and the following description depict various preferred embodiments of the present invention for purposes of illustration only. One skilled in the art will readily recognise from the following discussion those alternative embodiments of the structures and methods illustrated herein may be employed without departing from the principles of the invention described here. While the invention will be described in conjunction with the preferred embodiments, it will be understood that they are not intended to limit the invention to those embodiments. On the contrary, the invention is intended to cover alternatives, modifications, and equivalents, which may be included within the spirit and scope of the invention as defined by the claims.

Preparation of the high-permittivity calcined composition-modified barium titanate powder that is used to fabricate the EESU is explained as follows. Wet-chemical-prepared powders of high-purity as well as composition-modified barium titanate with narrow particle-size distribution have been produced with clear advantages over those prepared by solid-state reaction of mechanically mixed, ball-milled, and calcined powdered ingredients. The

compositional and particle-size uniformity attained with a coprecipitated-prepared powder is vastly superior to that with a conventional-prepared powder. The microstructures of ceramics formed from these calcined wet-chemical-prepared powders are uniform in grain size and can also result in smaller grain size. Electrical properties are improved so that higher relative permittivities and increased dielectric breakdown strengths can be obtained. Further improvement can be obtained by the elimination of voids within the sintered ceramic body with subsequent hot isostatic pressing.

High-relative-permittivity dielectrics have inherent problems, namely ageing, fatigue, degradation, and decay of the electrical properties, which limit their application. The use of surface-coated powders in which the surface region is comprised of one or two materials different in composition from that of the powder overcomes these problems provided that the compositions are appropriately chosen.

Among ceramics, alumina [aluminium oxide (Al_2O_3)], and among glasses, calcium magnesium aluminosilicate ($CaO.MgO.Al_2O_3.SiO_2$) glasses are the best dielectrics in terms of having the highest dielectric breakdown strengths and to seal the high-relative-permittivity dielectric powder particles so as to eliminate or significantly reduce their inherent problems.

A glass with a given composition at temperatures below its glass transition temperature range, which is in the neighbourhood of its strain-point temperature, is in a fully rigid condition, but at temperatures above this range is in a viscous-flow condition, its viscosity decreasing with increasing temperature. The application of hot isostatic pressing to a sintered closed-pore porous ceramic body comprised of sufficient-thickness glass-coated powder will lead to void elimination provided the glass is in the viscous-flow condition where it is easily deformable and flowable.

The wet-chemical-prepared and calcined composition-modified barium titanate powder is accordingly coated with these layers of, first, alumina, and second, a calcium magnesium aluminosilicate glass. After the first layer has been applied by wet-chemical means, the powder is calcined at $1050^{O}C$ to convert the precursor, aluminium nitrate nonahydrate [$Al(NO_3)_3.9H_2O$] to aluminium oxide (corundum) [α-Al_2O_3]. Then the second layer is applied by wet-chemical means with the use of the precursors in the appropriate amounts of each, and in absolute ethanol (CH_3CH_2OH) as the solvent, shown in the accompanying table. After drying, the powder is calcined at $500^{O}C$ to convert the precursor mixture to a calcium magnesium aluminosilicate glass. It is important that the calcining temperature is not higher than the strain point of the selected glass composition to prevent sticking together of the powder. The glass coating has the further advantage of acting as a sintering aid and allowing a substantially lower firing temperature for densification of the ceramic body particularly during the hot-isostatic-pressing step.

Another significant advantage of the calcium magnesium aluminosilicate glass coating is that sintering and densification temperatures are sufficiently lowered to allow the use of nickel conductor electrodes in place of the conventional expensive platinum, palladium, or palladium-silver alloy ones.

Preparation of the Calcined Composition-Modified Barium Titanate Powder is Indicated by the Following Process Steps.

A solution of the precursors: $Ba(NO_3)_2$, $Ca(NO_3)_2.4H_2O$, $Nd(NO_3)_3.6H_2O$, $Y(NO_3)_3.4H_2O$, $Mn(CH_3COO)_2.4H_2O$, $ZrO(NO_3)_2$, and $[CH_3CH(O—)COONH_4]2Ti(OH)_2$, as selected from the reference; Sigma-Aldrich, Corp., "Handbook of Fine Chemicals and Laboratory Equipment", 2000-2001, in de-ionised water heated to $80^{O}C$ is made in the proportionate amount in weight percent for each of the seven precursors as shown in the most right-hand column of Table 3. A separate solution of $(CH_3)4NOH$ somewhat in excess amount than required, as shown in Table 4, is made in de-ionised water, free of dissolved carbon dioxide (CO_2) and heated to 80^{O}-$85^{O}C$. The two solutions are mixed by pumping the heated ingredient streams simultaneously through a coaxial fluid jet mixer. A slurry of the co-precipitated powder is produced and collected in a drown-out vessel. The co-precipitated powder is refluxed in the drown-out vessel at 90°-95° C. for 12 hr and then filtered, de-ionised-water washed, and dried. Alternatively, the powder may be collected by centrifugal sedimentation. An advantage of $(CH_3)4NOH$ as the strong base reactant is that there are no metal element ion residuals to wash away anyway. Any residual $(CH_3)4NOH$, like any residual anions from the precursors, is harmless, because removal by volatilisation and decomposition occurs during the calcining step. The powder contained in a silica glass tray or tube is calcined at $1050^{O}C$ in air. Alternatively, an alumina ceramic tray can be used as the container for the powder during calcining.

(0.738105 mol) (91.15 g/mol) = 67.278 g for 100 g of the precursor mixture.
Tetramethylammonium hydroxide (CH3)4NOH is a strong base.

Coating of Aluminium Oxide on Calcined Modified Barium Titanate Powder

Barium titanate $BaTiO_3$	FW 233.19	d 6.080 g/cm3
Aluminium oxide Al_2O_3	FW 101.96	d 3.980 g/cm3

Precursor, aluminium nitrate nonahydrate, as selected from the reference: Sigma-Aldrich Corp., "Handbook of Fine Chemicals and Laboratory Equipment", 2000-2001. $Al(NO_3)_3.9H_2O$ FW 3.75.13

For Calcined Aluminium Oxide (Al_2O_3) Coating of 100 Angstrom units Thickness on Calcined Modified Barium Titanate Powder 100 Angstrom units = 10-6 cm 1.0 m^2 = 104 cm^2

area thickness of Al_2O_3 coating volume $(10^4\ cm^2/g)(10^{-6}\ cm) = 10^{-2}\ cm^3/g$ - - - of calcined powder

$$\frac{(10^{-2}\ \text{cm}^3\ \text{volume}\ Al_2O_3\ \text{coating}) \times (3.98\ \text{g/cm}^3\ \text{density of}\ Al_2O_3)}{\text{g of calcined powder}} = \frac{39.8 \times 10^{-3}\ \text{g of}\ Al_2O_3\ \text{coating}}{\text{g of calcined powder}}\ \text{or}$$

$$= \frac{39.8\ \text{mg of}\ Al_2O_3\ \text{coating}}{\text{g of calcined powder}}$$

$Al(NO_3)_3.9H_2O$ (FW 375.13)(2)=750.26

Al_2O_3 FW 101.96=101.96

750.26/101.96=7.358

$$\frac{(7.358)(39.8\ \text{mg of}\ Al_2O_3\ \text{coating})}{\text{g of calcined powder}} = \frac{292.848\ \text{mg of}\ Al(NO_3)_3 \cdot 9H_2O}{\text{g of calcined powder}}$$

For an aluminium oxide (Al_2O_3) coating of 100 Angstrom units thickness on calcined modified barium titanate powder with particle volume of 1.0 μm^3, 39.8 mg of Al_2O_3 are required per g of this powder, corresponding to 292.848 mg of the aluminium nitrate nonahydrate [$Al(NO_3)_3.9H_2O$] precursor required per g of this powder.

Coating of Calcium Magnesium Aluminosilicate Glass on Aluminium Oxide Coated
Calcined Modified Barium Titanate Powder

	FW g/mol	d g/cm^3
Barium titanate $BaTiO_3$	233.19	6.080

Calcium magnesium aluminosilicate (CaO.MgO.Al2O3.SiO2) glass precursors, as selected from the reference: Sigma-Aldrich, Corp., "Handbook of Fine Chemicals and Laboratory Equipment", 2000-2001.

Calcium methoxide	$(CH_3O)2Ca$	101.15
Calcium isopropoxide	$[(CH_3)_2CHO]_2Ca$	158.25
Magnesium methoxide	$(CH_3O)_2Mg$	86.37
Magnesium ethoxide	$(CH_3CH_2O)_2Mg$	114.43
Aluminium ethoxide	$(CH_3CH_2O)_3Al$	162.16
Aluminium isopropoxide	$[(CH_3)_2CHO]_3Al$	204.25
Aluminium butoxide	$[CH_3(CH_2)_3O]_3Al$	246.33
Tetraethyl orthosilicate	$Si(OCH_2CH_3)_4$	208.33

Select glass composition, e.g.,

$CaO.MgO.2Al_2O_3.8SiO_2$ and accordingly the precursors:

1 mol	(158.25 g) calcium isopropoxide
1 mol	(114.43 g) magnesium ethoxide
4 mol	(817.00 g) aluminum isopropoxide
8 mol	(1666.64 g) tetraethyl orthosilicate
	2756.32 g for 1.0 mol glass

Prepare Mixture of these Precursors in Absolute Ethanol (to Avoid Hydrolysis) and in Dry-Air Environment (Dry Box) (also to Avoid Hydrolysis).

Glass Composition: $CaO.MgO.2Al_2O_3.8SiO_2$ or $CaMgAl_4Si_8O_{24}$

1 mol (56.08 g)	CaO
1 mol (40.30 g)	MgO
2 mol (101.96 g × 2 = 203.92 g)	Al_2O_3
8 mol (60.08 g × 8 = 480.64 g)	SiO_2

glass FW total 780.98 g/mol
Density of glass: about 2.50 g/cm^3

Calcined modified barium titanate powder
Particle volume: 1.0 μm^3 or $1.0(10^{-4}\ cm)^3 = 10^{-12}\ cm^3$;
so there are 10^{12} particles/cm^3 (assumption of no voids)
Particle area: 6 μm^2 or $(6)(10^{-4}\ cm)^2 = 6\times10^{-8}\ cm^3$;
Particle area/cm3 (no voids):
$(6\times10^{-8}\ cm^2/particle)(10^{12}\ particles/cm^3) = 6\times10^4\ cm^2/cm^3$ or 6 m^2/cm^3.

Then for density of 6 g/cm^3, the result is:

$$\frac{6\ m^2/cm^3}{6\ g/cm^3} = 1.0\ m^2/g$$

For Calcined Glass Coating of 100 Angstrom units Thickness on Calcined Powder:

100 Angstrom units = 10^{-6} cm 1.0 m^2 = 10^4 cm^2

(10^4 cm^2/g)(10^{-6} cm) = 10^{-2} cm^3/g of calcined powder of glass coating and then

$$\frac{(10^{-2}\ \text{cm}^3\ \text{of glass coating})}{\text{g of calcined powder}} \times (2.50\ \text{g/cm}^3\ \text{density of glass}) =$$

$$\frac{25.0\times10^{-3}\ \text{g of glass coating}}{\text{g of calcined powder}} \quad \text{or} \quad \frac{25.0\ \text{mg of glass coating}}{\text{g of calcined powder}}$$

Precursor mixture FW 2756.32 = 3.529
Glass FW 780.98

$$\frac{(3.529)(25.0\ \text{mg of glass coating})}{(\text{g of calcined powder})} = 88.228\ \text{mg of precursor mixture}$$

For a $CaMgAl_4Si_8O_{24}$ glass coating of 100 Angstrom units thickness on calcined modified barium titanate powder with particle volume of 1.0 μm3, 25.0 mg of this glass are required per g of this powder, corresponding to 88.228 mg of the precursor mixture required per g of this powder.

Particle Volume and Area

V particle = a^3 for cube
If a = 1.0 μm, V = 1.0 μm^3
A particle = $6a^2$ for cube
If a = 1.0 μm, A = 6 μm^2

Particle coating volume

($6\ a^2$)(t), if t = 100 Angstrom units = 10×10^3 μm, and 6 a^2=6.0 μm^2,
then (6.082 m^2)(10×10^{-3} μm) = 60×10^{-3} μm^3 = V coating

Ratio of particle coating volume to particle volume 60×10^{-3} μm^3/1.0 μm^3 = 60×10^{-3} = 0.06 or 6%

With the assumption of no voids and absolutely smooth surface, for an ideal cubic particle with volume of 1.0 μm3 and for a particle coating of 100 Angstrom units thickness, the coating volume is 60×10^{-3} μm3 or 6.0% that of the particle volume.

Calculations of the Electrical-Energy-Storage Unit's Weight, Stored Energy, Volume, and Configuration.

Assumptions:

The relative permittivity of the high-permittivity powder is nominally 33,500, as given in the reference: P. Hansen, U.S. Pat. No. 6,078,494, issued Jan. 20, 2000.

- The 100 ? coating of Al2O3 and 100 ? of calcium magnesium aluminosilicate glass will reduce the relative permittivity by 12%.
- K = 29,480

Energy stored by a capacitor: E = CV^2/(2×3600 s/h) = W·h

- C = capacitance in farads
- V = voltage across the terminals of the capacitor

It is estimated that is takes 14 hp, 746 watts per hp, to power an electric vehicle running at 60 mph with the lights, radio, and air conditioning on. The energy-storage unit must supply 52,220 W·h or 10,444 W for 5 hours to sustain this speed and energy usage and during this period the EV will have travelled 300 miles. Each energy-storage component has 1000 layers.

C = ε_oKA/t

* ε_o = permittivity of free space
* K = relative permittivity of the material
* A = area of the energy-storage component layers
* t = thickness of the energy-storage component layers

Voltage breakdown of the energy-storage components material after coating with Al_2O_3 and calcium magnesium aluminosilicate glass will be in the range of 1.0×10^6 V/cm to 5×10^6 V/cm or higher. Using the proper voltage breakdown selected from this range could allow the voltage of the energy-storage unit to be 3500 V or higher.
One hp = 746 W

EXAMPLE

Capacitance of one layer = 8.854×10^{-12} F / m × 2.948×10^4 × $6.45 \times 10^{-4} m^2$ / 12.7×10^{-6} m

C = 0.000013235 F

With 1000 layers:

C = 0.013235 F

The required energy storage is

E_t = 14 hp × 746 W /hp × 5 h = 52,220 W·h

The total required capacitance of the energy-storage unit:

CT = E_t × 2 × 3600 s/h / V^2 = 52,220 W·h × 2 × 3600 s/h/(3500 V)^2 C_T = 31 F

Number of capacitance components required:

N_c = 31 F / 0.013235 F = 2320

Volume and weight of energy-storage unit:

Volume of the dielectric material:

Volume = area x thickness x number of layers
= 6.45 cm^2 x 12.72 x 10^{-4} cm x 1000
= 8.2 cm^3

Total volume = 8.2 cm^3 × number of components (2320) = 19,024 cm^3
Density of the dielectric material = 6.5 g/cm^3
Weight of each component = density × volume = 53.3 g
Total weight of the dielectric material = 53.3 g × 2320 / 454 g per pound = 272 pounds

Volume of the nickel conductor layers:
Thickness of the nickel layer is 1×10-6 m
Volume of each layer = 6.45 cm2×1.0×10-4 cm × 1000 = 0.645 cm3
Density of nickel = 8.902 g/cm3
Weight of nickel layers for each component = 5.742 g
Total weight of nickel = 34 pounds

Total number of capacitance layers and volume of the EESU:
Area required for each component to solder bump = 1.1 $inch^2$
A 12 × 12 array will allow 144 components for each layer of the first array
19 layers of the second array will provide 2736 components which are more than enough to meet the required 2320 components. The distance between the components will be adjusted so that 2320 components will be in each EESU. The second array area will remain the same.

The total weight of the EESU (est.) = 336 pounds
The total volume of the EESU (est.) = 13.5 inches × 13.5 inches × 11 inches = 2005 $inches^3$ which includes the weight of the container and connecting material.
The total stored energy of the EESU = 52,220 W·h

From the above description, it will be apparent that the invention disclosed herein provides a novel and advantageous electrical-energy-storage unit composed of unique materials and processes. The foregoing discussion discloses and describes merely exemplary methods and embodiments of the present invention. As will be understood by those familiar with the art, the invention may be embodied in other specific forms and utilise other materials without departing from the spirit or essential characteristics thereof. Accordingly, the disclosure of the present invention is intended to be illustrative, but not limiting, of the scope of the invention, which is set forth in the following claims.

CLAIMS

1. A method for making an electrical-energy-storage unit comprising components fabricated by the method steps as follow;

a) preparing a wet-chemical-prepared calcined composition-modified barium titanate powder derived from a solution of precursors: $Ba(NO_3)_2$, $Ca(NO_3)_2.4H_2O$, $Nd(NO_3)_3.6H_2O$, $Y(NO_3)_3.4H_2O$, $Mn(CH_3COO)_2.4H_2O$, $ZrO(N_3O)_2$, and $[CH_3CH(O—)COONH_4]_2Ti(OH)_2$ in de-ionised water heated to 80^OC, and a separate solution of $(CH_3)_4NOH$ made in de-ionised water and heated to 80^O-85^OC, then mixing the solutions by pumping the heated ingredient streams simultaneously through a coaxial fluid mixer producing co-precipitated powder, then collecting the co-precipitated powder in a drown-out vessel and refluxing at a temperature of 90^O-95^OC for 12 hours, then filtering, washing with de-ionised water, drying, and then calcining 1050^OC in air;

b) fabricating an aluminium oxide (Al_2O_3) coating of 100 Angstrom units thickness on to the wet-chemical-prepared calcined composition-modified barium titanate powder, with the use of aluminium nitrate nonahydrate precursor applied by wet chemical means, then calcining at 1050^OC, resulting in a single-coated calcined composition-modified barium titanate powder;

c) fabricating on to the alumina-coated composition-modified barium titanate powder, a second uniform coating of 100 Angstrom units of calcium magnesium aluminosilicate glass derived from alcohol-soluble precursors: calcium methoxide or calcium isopropoxide, magnesium methoxide or magnesium ethoxide, aluminium ethoxide or aluminium isopropoxide or aluminium isopropoxide, and tetraethyl orthosilicate are applied by wet chemical means which upon calcining at 500^OC results in a double-coated composition-modified barium titanate powder;

d) blending, this double-coated composition-modified barium titanate powder with a screen-printing ink containing appropriate plastic resins surfactants, lubricants, and solvents to provide a suitable rheology for screen printing;

e) screen-printing into interleaved multi-layers of alternating offset nickel electrode layers **12** and double-coated calcined composition-modified barium titanate high-relative-permittivity layers **11** with the use of screening inks having the proper rheology for each of the layers;

f) drying and cutting the screen-punted multi-layer components **15** into a specified rectangular area;

g) sintering the screen-printed multi-layer components **15**, first at a temperature of 350^OC for a specified length of time, then at 850^OC for a specified length of time, to form closed-pore porous ceramic bodies; and

h) hot isostatically pressing the closed-pore porous ceramic bodies, at a temperature of 700^OC with a specified pressure, into a void-free condition;

i) grinding and each side of the component to expose the alternating offset interleaved nickel electrodes **12**;

j) connecting nickel side bars **14** to each side of the components **15**, that have the interleaved and alternating offset nickel electrodes **12** exposed, by applying nickel ink with the proper rheology to each side and clamping the combinations together;

k) heating the components and side nickel bar combination **14-15** 800^OC, and time duration of 20 minutes to bond them together;

l) wave soldering each side of the conducting bars;

m) assembling the components **15** with the connected nickel side bars **14** into the first array, utilising unique tooling and solder-bump technology;

n) assembling the first arrays into the second array;

o) assembling the second arrays into the EESU final assembly.

2. The method of claim 1 wherein a second coating of glass is provided on to the double-coated composition-modified barium titanate powder being in contact with the nickel electrodes and having an applied working voltage of 3500 V across the parallel electrodes.

3. The method of claim 1 wherein a dielectric voltage breakdown strength of 5.0×10^6 V/cm was achieved across the electrodes of the components.

4. The method of claim 1 wherein the method provides an ease of manufacturing due to the softening temperature of the calcium magnesium aluminosilicate glass allowing the relatively low hot-isostatic-pressing temperatures of 700^{O}C which in turn provides a void-free ceramic body.

5. The method of claim 1 wherein the method provides an ease of fabrication due to the softening temperature of the calcium magnesium aluminosilicate glass allowing the relatively low hot-isostatic-pressing temperatures of 700^{O}C which in turn allows the use of nickel for the conduction-path electrodes rather than expensive platinum, palladium, or palladium-silver alloy.

6. The method of claim 1 wherein the method provides an ease of fabrication due to the softening temperature of the calcium magnesium aluminosilicate lass allowing the relatively low hot-isostatic-pressing temperatures of 700^{O}C, which feature along with the coating method provided a uniform-thickness shell of the calcium magnesium aluminosilicate glass and in turn provides hot-isostatic-pressed double-coated composition-modified barium titanate high-relative-permittivity layers that are uniform and homogeneous in microstructure.

7. The method of claim 1 wherein the method provides the double coating of the basis particles of the composition-modified barium titanate powder thereby reducing the leakage and ageing of this material by an order of magnitude of the specification of this basis material, thus reducing the discharge rate to 0.1% per 30 days.

8. The method of claim 1 wherein the method provides a double coating of the composition-modified barium titanate powder, the hot-isostatic-pressing process, the high-density solder-bump packaging, and along with the double-layered array configuration stored 52,220 W·h of electrical energy in a 2005 $inches^3$ container.

9. The method of claim 1 wherein the method provides materials used: water-soluble precursors of barium (Ba), calcium (Ca), titanium (Ti), zirconium (Zr), manganese (Mn), yttrium (Y), neodymium (Nd), forming the composition-modified barium titanate powder, and the metals: nickel (Ni), and copper (Cu), which are not explosive, corrosive, or hazardous.

10. The method of claim 1 wherein the method provides an EESU that is not explosive, corrosive, or hazardous and therefore is a safe product when used in electrical vehicles, which include bicycles, tractors, buses, cars, or any device used for transportation or to perform work.

11. The method of claim 1 wherein the method provides an EESU which can store electrical energy generated from solar voltaic cells or other alternative sources for residential, commercial, or industrial applications.

12. The method of claim 1 wherein the method provides an EESU which can store electrical energy from the present utility grid during the night when the demand for electrical power is low and then deliver the electrical energy during the peak power demand times and thus provide an effective power averaging function.

13. The method of claim 1 wherein the method provides a double coating of the composition-modified barium titanate powder and a hot-isostatic-pressing process which together assists in allowing an applied voltage of 3500 V to a dielectric thickness of 12.76×10-6 m to be achieved.

14. The method of claim 1 wherein the method provides a EESU which when fully discharged and recharged, the EESU's initial specifications are not degraded.

15. The method of claim 1 wherein the method provides a EESU which can be safely charged to 3500 V and store at least 52.22 kW·h of electrical energy.

16. The method of claim 1 wherein the method provides a EESU at has a total capacitance of at least 31 F.

17. The method of claim 1 wherein the method provides a EESU that can be rapidly charged without damaging the material or reducing its life.

HERMANN PLAUSTON

US Patent 1,540,998 9th June 1925 Inventor: Hermann Plauson

CONVERSION OF ATMOSPHERIC ELECTRIC ENERGY

Please note that this is a re-worded excerpt from this patent. It describes in considerable detail, different methods for abstracting useable electrical power from passive aerial systems. He describes a system with 100 kilowatt output as a “small” system.

Be it known that I, Hermann Plauson, Estonian subject, residing in Hamburg, Germany, have invented certain new and useful improvements in the Conversion of atmospheric Electric Energy, of which the following is a specification.

According to this invention, charges of atmospheric electricity are not directly converted into mechanical energy, and this forms the main difference from previous inventions, but the static electricity which runs to earth through aerial conductors in the form of direct current of very high voltage and low current strength is converted into electro-dynamic energy in the form of high frequency vibrations. Many advantages are thereby obtained and all disadvantages avoided.

The very high voltage of static electricity of a low current strength can be converted by this invention to voltages more suitable for technical purposes and of greater current strength. By the use of closed oscillatory circuits it is possible to obtain electromagnetic waves of various amplitudes and thereby to increase the degree of resonance of such current. Such resonance allows various values of inductance to be chosen which, by tuning the resonance between a motor and the transformer circuit, allows the control of machines driven by this system. Further, such currents have the property of being directly available for various uses, other than driving motors, including lighting, heating and use in electro-chemistry.

Further, with such currents, a series of apparatus may be fed without a direct current supply through conductors and the electro-magnetic high frequency currents may be converted by means of special motors, adapted for electro-magnetic oscillations, into alternating current of low frequency or even into high voltage direct current.

DESCRIPTION OF THE DRAWINGS

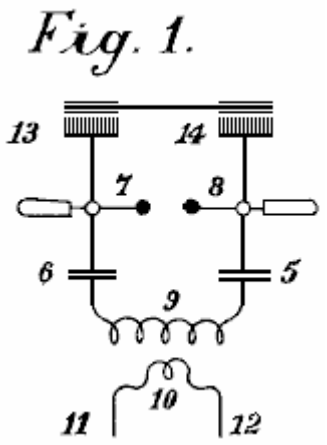

Fig.1 is an explanatory figure

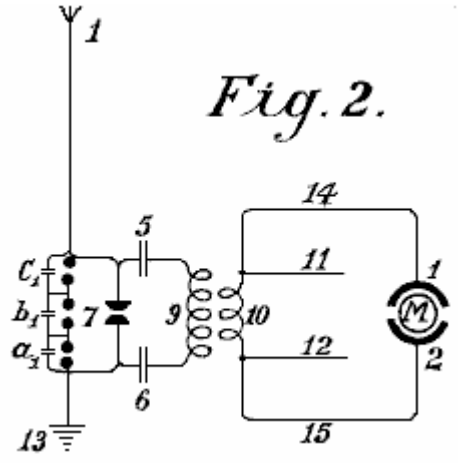

Fig.2 is a diagrammatic view of the most simple form.

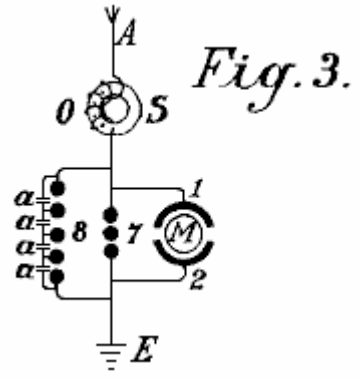

Fig.3 shows a method of converting atmospheric electrical energy into a form suitable for use with motors.

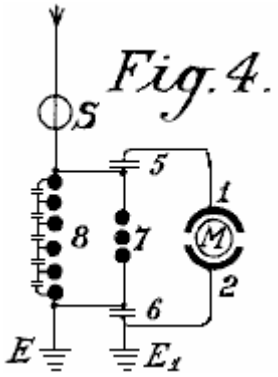

Fig.4 is a diagram showing the protective circuitry.

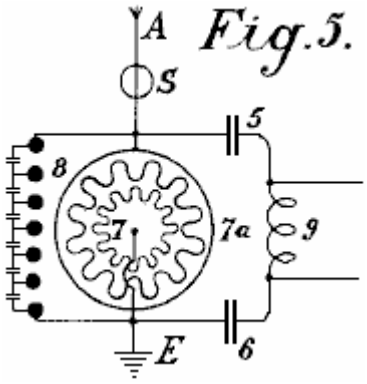

Fig.5.

Fig.5 is a diagram of an arrangement for providing control

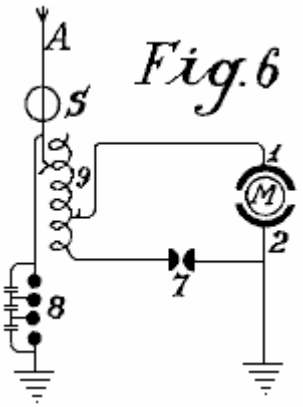

Fig.6

Fig.6 is an arrangement including a method of control

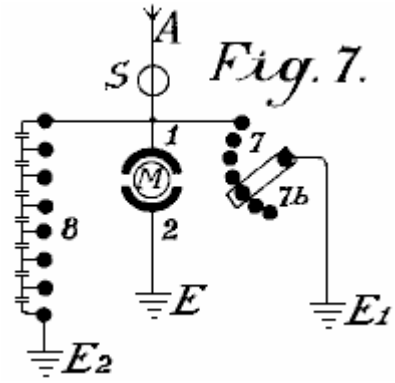

Fig. 7.

Fig.7 shows how the spark gap can be adjusted

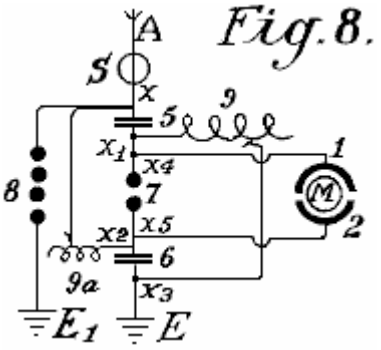

Fig.8 shows a unipolar connection for the motor

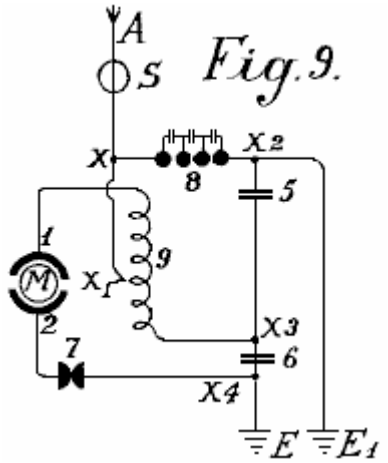

Fig.9 shows a weak coupled system suitable for use with small power motors

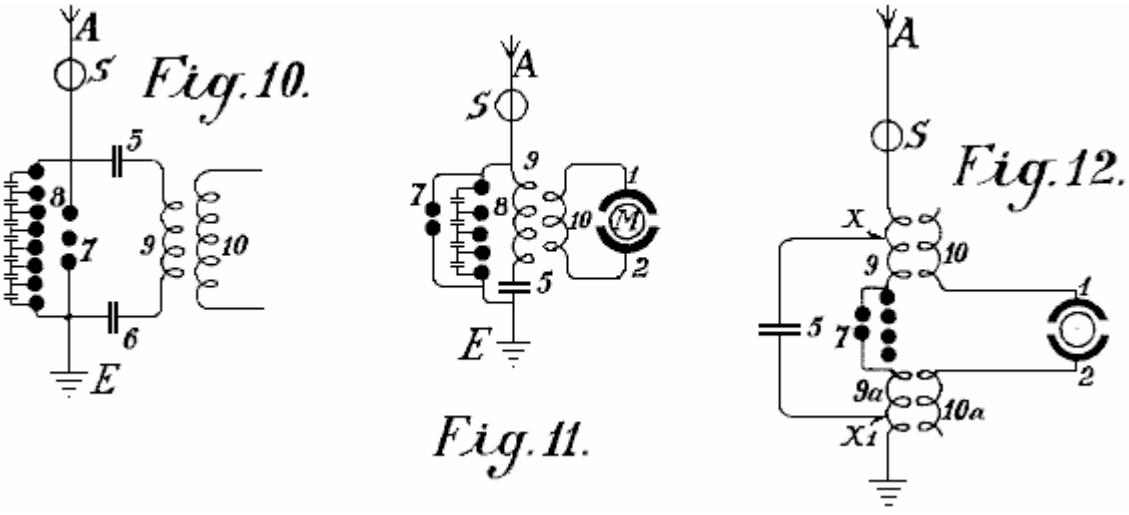

Fig.10, Fig.11 and Fig.12 show modified arrangements

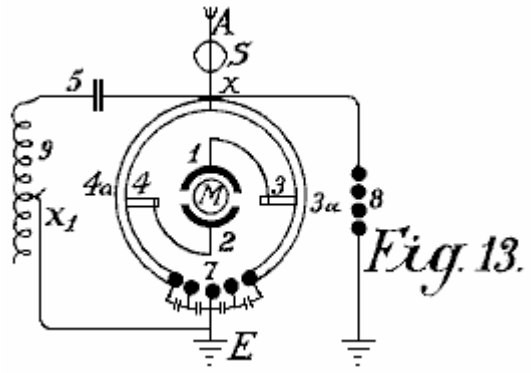

Fig. 13.

Fig.13 shows a form of inductive coupling for the motor circuit

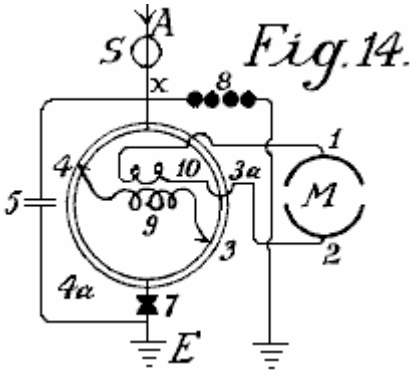

Fig. 14.

Fig.14 is a modified form of Fig.13 with inductive coupling.

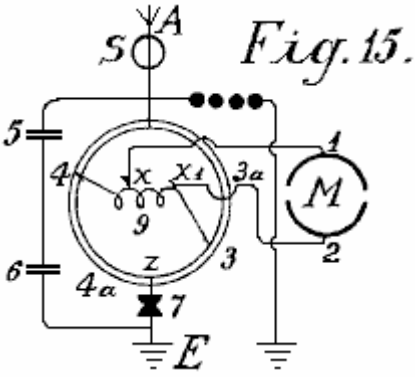

Fig. 15.

Fig.15 is an arrangement with non-inductive motor

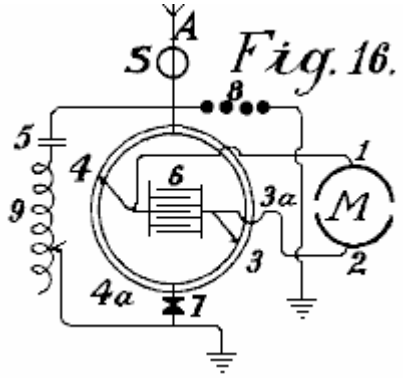

Fig. 16.

Fig.16 is an arrangement with coupling by capacitor.

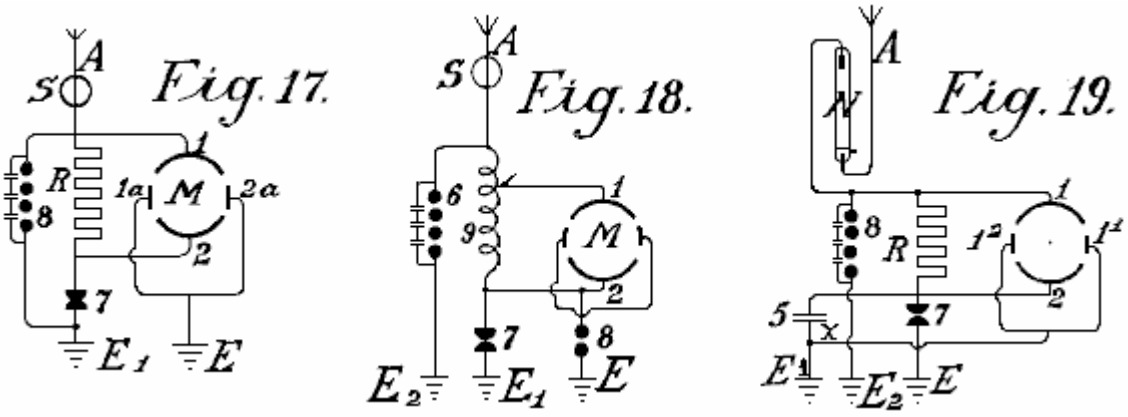

Fig.17, **Fig.18** and **Fig.19** are diagrams showing further modifications

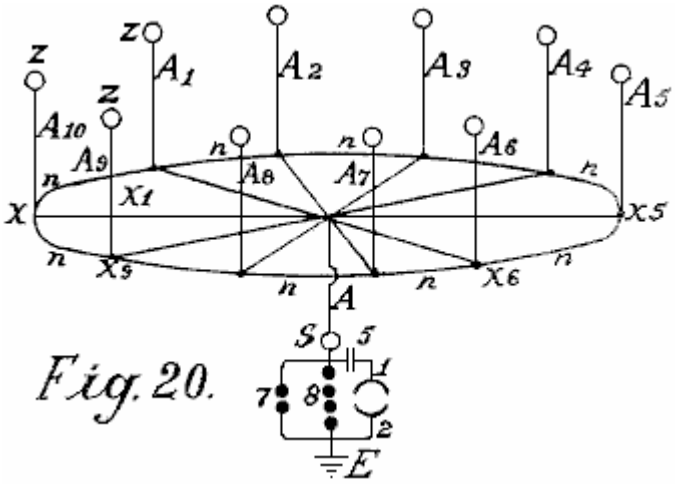

Fig.20 shows a simple form in which the aerial network is combined with special collectors

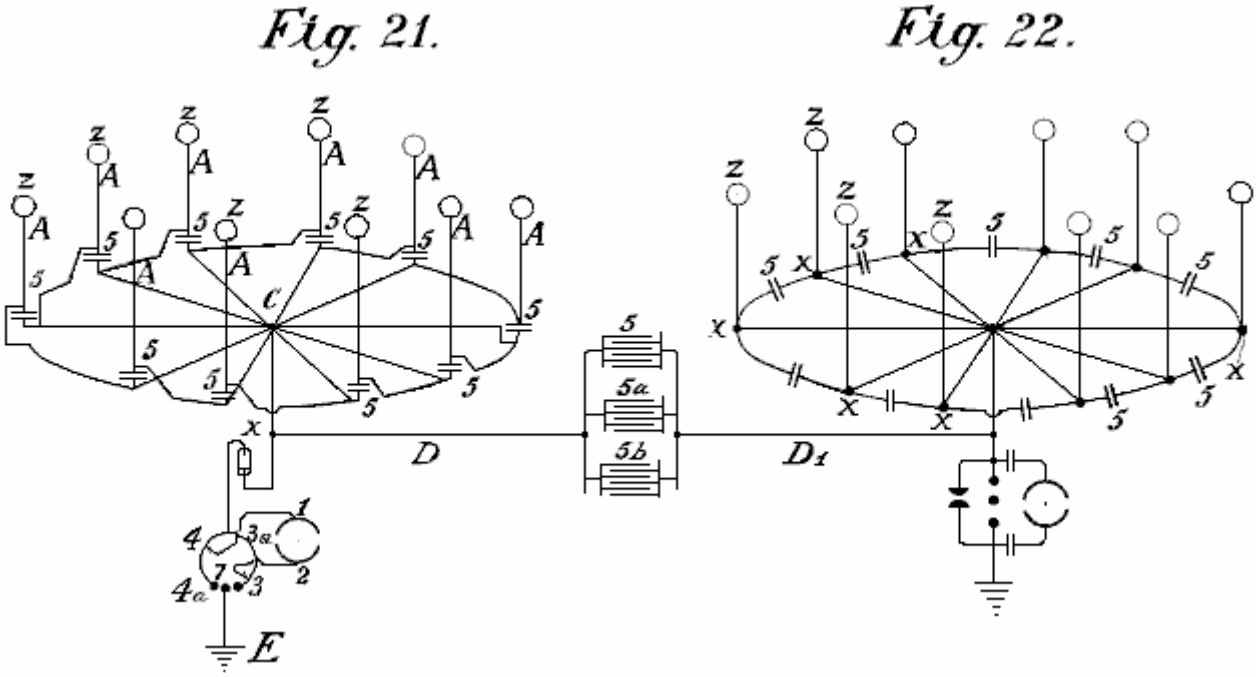

Fig.21 shows diagramatically, an arrangement suitable for collecting large quantities of energy.
Fig.22 is a modified arrangement having two rings of collectors

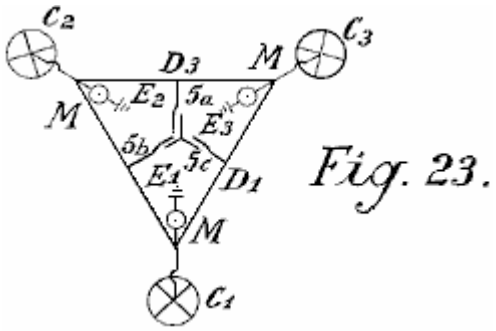

Fig. 23.

Fig.23 shows the connections for three rings of collectors

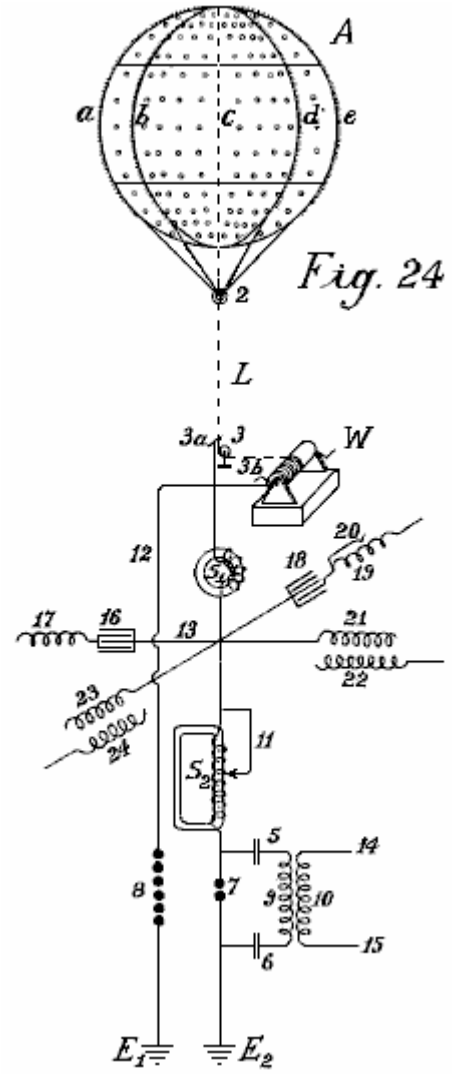

Fig. 24

Fig.24 shows a collecting balloon and diagram of its battery of capacitors

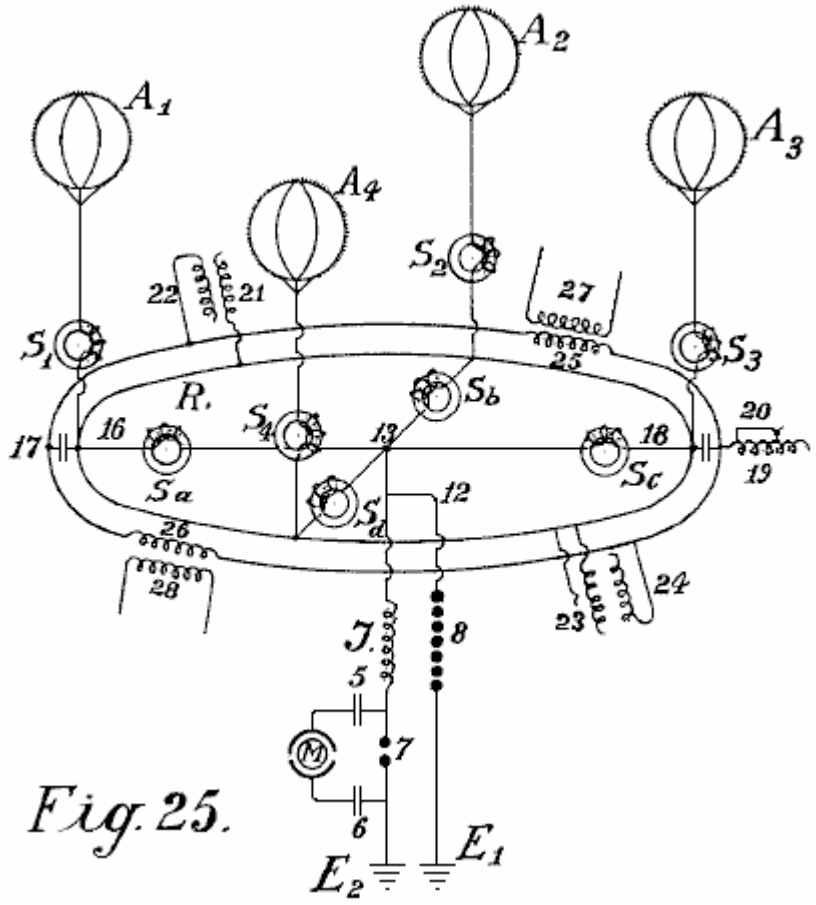

Fig. 25.

Fig.25 and Fig.26 show modified collector balloon arrangements.

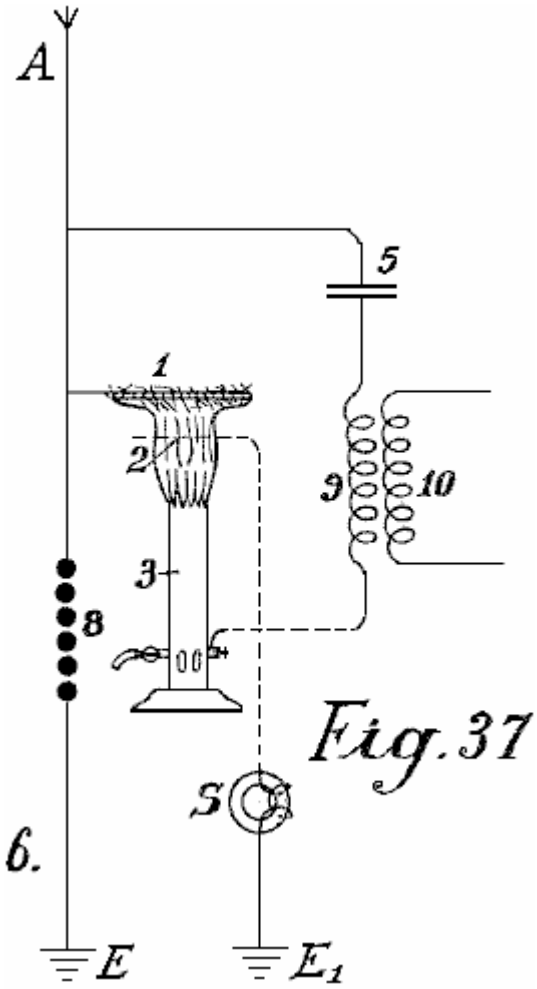

Fig.37 shows a form with a gas flame.

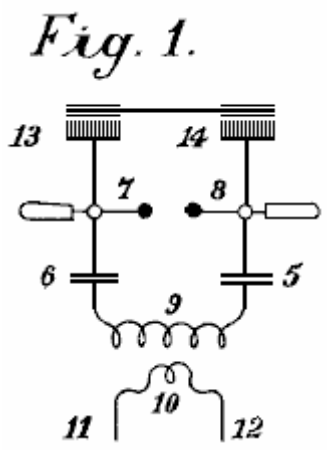

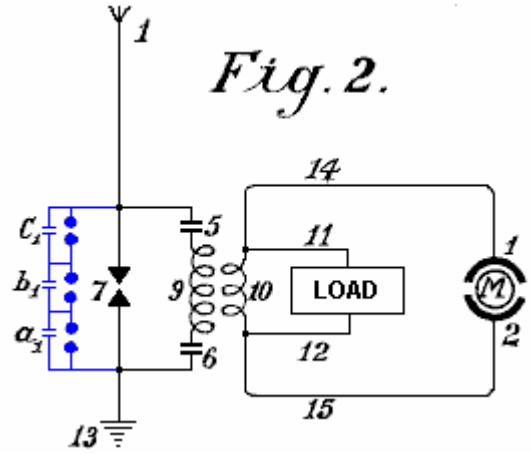

Fig.1 illustrates a simple diagram for converting static electricity into dynamic energy of a high number of oscillations. For the sake of clarity, a Wimshurst machine is assumed to be employed and not an aerial antenna. Items **13** and **14** are combs for collecting the static electricity of the influence machine. Items **7** and **8** are spark-discharging electrodes. Items **5** and **6** are capacitors, **9** is the primary winding of an inductive coil, **10** is the secondary winding whose ends are **11** and **12**. When the disc of the static influence machine is rotated by mechanical means, the combs collect the electric charges, one being positive and one negative and these charge the capacitors **5** and **6** until such a high voltage is developed across the spark gap **7-- 8** that the spark gap is jumped. As the spark gap forms a closed circuit with capacitors **5** and **6**, and inductive resistance **9**, as is well known, waves of high frequency electromagnetic oscillations will pass in this circuit.

The high frequency of the oscillations produced in the primary circuit induces waves of the same frequency in the secondary circuit. Thus, in the primary circuit, electromagnetic oscillations are formed by the spark and these oscillations are maintained by fresh charges of static electricity.

By suitably selecting the ratio between the number of turns in the primary and secondary windings, with regard to a correct application of the coefficients of resonance (capacitance, inductance and resistance) the high voltage of the primary circuit may be suitably converted into a low voltage high current output.

When the oscillatory discharges in the primary circuit become weaker or cease entirely, the capacitors are charged again by the static electricity until the accumulated charge again breaks down across the spark gap. All this is repeated as long as electricity is produced by the static machine through the application of mechanical energy to it.

An elementary form of the invention is shown in **Fig.2** in which two spark gaps in parallel are used, one of which may be termed the working gap **7** while the second serves as a safety device for excess voltage and consists of a larger number of spark gaps than the working section, the gaps being arranged in series and which are bridged by very small capacitors a_1, b_1, c_1, which allow uniform sparking in the safety section.

1 is the aerial antenna for collecting charges of atmospheric electricity, **13** is the earth connection of the second part of the spark gap, **5** and **6** are capacitors and **9** is the primary coil winding. When the positive atmospheric electricity seeks to combine with the negative earth charge via aerial **1**, this is prevented by the air gap between the spark gaps. The resistance of spark gap **7** is lower than that of the safety spark gap set of three spark gaps connected in series a which consequently has three times greater air resistance.

Therefore, so long as the resistance of spark gap **7** is not overloaded, discharges take place only through it. However, if the voltage is increased by any influence to such a level that it might be dangerous for charging the capacitors **5** and **6**, or for the coil insulation of windings 9 and 10, the safety spark gap set will, if correctly set, discharge the voltage directly to earth without endangering the machine. Without this second spark gap arrangement, it is impossible to collect and render available large quantities of electrical energy.

The action of this closed oscillation circuit consisting of spark gap **7**, two capacitors **5** and **6**, primary coil **9** and secondary coil **10**, is exactly the same as that of **Fig.1** which uses a Wimshurst machine, the only difference being the provision of the safety spark gap. The high frequency electromagnetic alternating current can be tapped off through the conductors **11** and **12** for lighting and heating purposes. Special motors adapted for working with static electricity or high frequency oscillations may be connected at **14** and **15**.

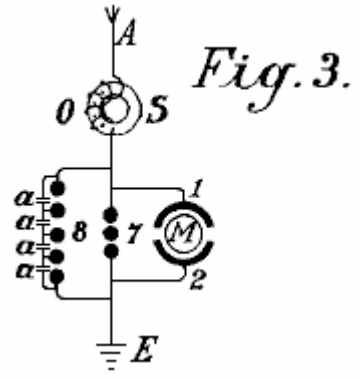

Fig. 3.

In addition to the use of spark gaps in parallel, a second measure of security is also necessary for taking the current from this circuit. This is the introduction of protective electromagnets or choking coils in the aerial circuit as shown by **S** in **Fig.3**. A single electromagnet having a core of the thinnest possible separate laminations is connected with the aerial. In the case of high voltages in the aerial network or at places where there are frequent thunderstorms, several such magnets may be connected in series.

In the case of large units, several such magnets can be employed in parallel or in series parallel. The windings of these electromagnets may be simply connected in series with the aerials. In this case, the winding preferably consists of several thin parallel wires, which together, make up the necessary cross-sectional area of wire. The winding may be made of primary and secondary windings in the form of a transformer. The primary winding will then be connected in series with the aerial network, and the secondary winding more or less short-circuited through a regulating resistor or an induction coil. In the latter case it is possible to regulate, to a certain extent, the effect of the choking coils. In the following circuit and constructional diagrams , the aerial electromagnet choke coil is indicated by a simple ring **S**.

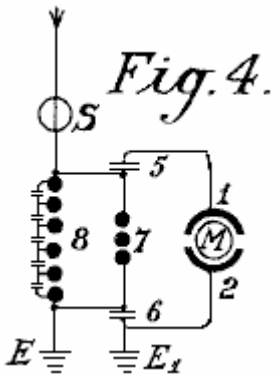

Fig.3 shows the most simple way of converting atmospheric electricity into electromagnetic wave energy by the use of special motors adapted for high oscillatory currents or static charges of electrical energy. Recent improvements in motors for working with static energy and motors working by resonance, that is to say, having groups of tuned electromagnetic co-operating circuits render this possible but such do not form part of the present invention.

A motor adapted to operate with static charges, will for the sake of simplicity, be shown in the diagrams as two semi-circles **1** and **2** and the rotor of the motor by a ring **M** (**Fig.3**). **A** is a vertical aerial or aerial network. **S** is the safety choke or electromagnet with coil **O** as may be seen is connected with the aerial **A**. Adjacent to the electromagnet **S**, the aerial conductor is divided into three circuits, circuit **8** containing the safety spark gap, circuit **7** containing the working spark gap, and then a circuit containing the stator terminal **1**, the rotor and stator terminal **2** at which a connection is made to the earth wire. The two spark gaps are also connected metallically with the earth wire. The method of working in these diagrams is as follows:

The positive atmospheric electric charge collected tends to combine with the negative electricity (or earth electricity) connected via the earth wire. It travels along the aerial **A** through the electromagnet **S** without being checked as it flows in the same direction as the direct current. Further, its progress is arrested by two spark gaps placed in the way and the stator capacitors. These capacitors charge until their voltage exceeds that needed to jump the spark gap **7** when a spark occurs and an oscillatory charge is obtained via the closed oscillation circuit containing motor **M**. The motor here forms the capacity and the necessary inductance and resistance, which as is well known, are necessary for converting static electricity into electromagnetic wave energy.

The discharges are converted into mechanical energy in special motors and cannot reach the aerial network because of the electromagnet or choke. If, however, when a spark occurs at spark gap **7**, a greater quantity of atmospheric electricity tends to flow to earth, then a counter voltage is induced in the electromagnet, which is greater the more rapidly and strongly the flow of current direct to earth is. This opposing voltage causes the circuit to exhibit a sufficiently high resistance to prevent a short circuit between the atmospheric electricity and the earth.

The circuit containing spark gap **8**, having a different wave length which is not in resonance with the natural frequency of the motor, does not endanger the motor and serves as security against excess voltage, which, as practical experiments have shown, may still arise in certain cases.

In **Fig.4**, spark gap **7** is shunted across capacitors **5** and **6** from the motor **M**. This arrangement provides improved over-voltage protection for the motor and it gives a uniform excitation through the spark gap **7**.

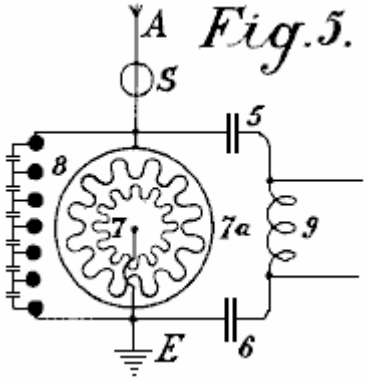

Fig.5 shows an arrangement for producing large currents which can be used direct without motors, to provide heating and lighting. The main difference here is that the spark gap consists of a star-shaped disc **7** which can rotate on its own axis and is rotated by a motor opposite similarly fitted electrodes **7a**. When separate points of starts face one another, discharges take place, thus forming an oscillation circuit with capacitors **5** and **6** and inductor **9**. It is evident that a motor may also be connected directly to the ends of inductor **9**.

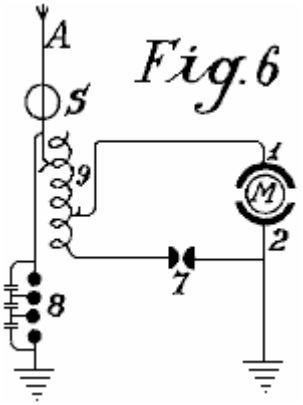

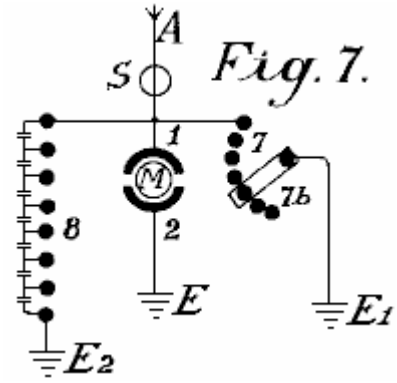

Fig.6 shows how the oscillation circuit may have a motor connected via a variable inductor which opposes any excess voltages which might be applied to the motor. By cutting the separate coils **9** (coupled inductively to the aerial) in or out, the inductive action on the motor may be more or less increased, or variable aerial action may be exerted on the oscillation circuit.

In **Fig.7** the oscillation circuit is closed through the earth (**E** and $\mathbf{E_1}$). The spark gap **7** may be increased or reduced by means of a contact arm **7b**.

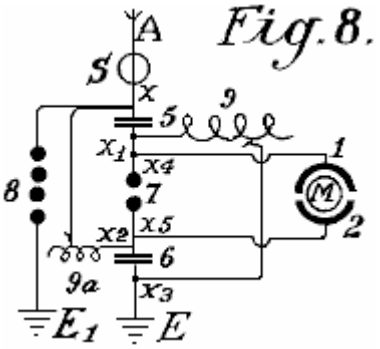

Fig.8 shows a unipolar connection of the motor with the aerial network. Here, two oscillation circuits are closed through the same motor. The first oscillation circuit passes from aerial **A** through electromagnet **S**, point **x**, inductance **9a** to the earth capacitor **6**, across spark gap **7** to the aerial capacitor **5** and back to point **x**. The second oscillation circuit starts from the aerial **5** at the point **x1** through inductor **9** to the earth capacitor **6** at the point **x3**, through capacitor **6**, across spark gap **7** back to point **x1**. The motor itself, is inserted between the two points of spark gap **7**. This arrangement produces slightly dampened oscillation wave currents.

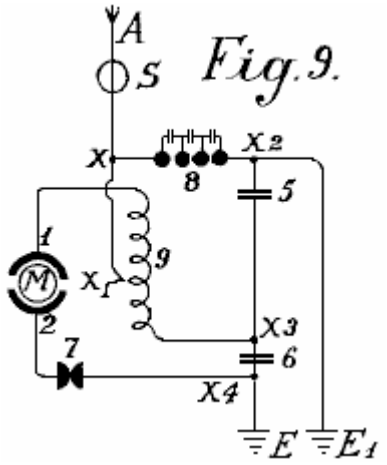

Fig.9 shows a loosely coupled system intended for small motors for measuring purposes. **A** is the serial, **S** is the electromagnet or aerial inductor, **9** the inductor, **7** the spark gap, **5** and **6** capacitors, **E** the earth, **M** the motor, and **1** and **2** the stator connections of the motor which is directly connected to the oscillator circuit.

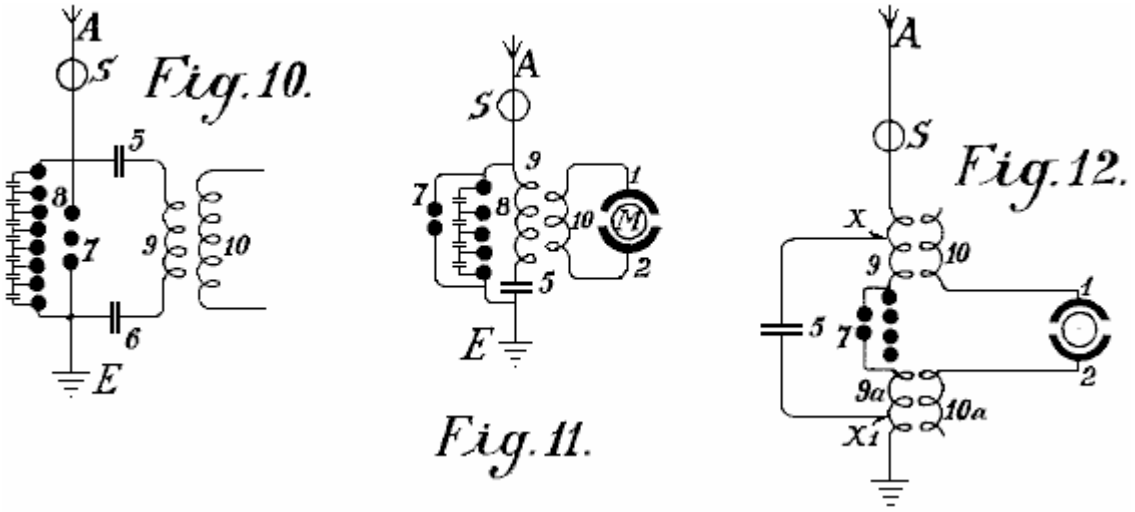

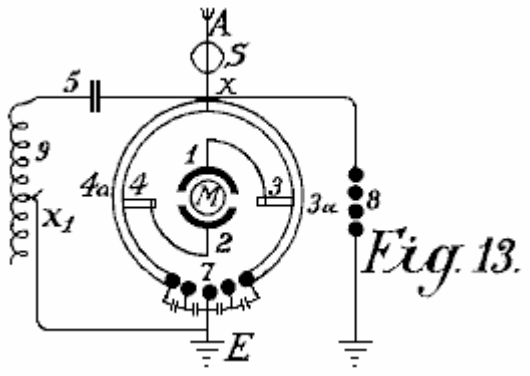

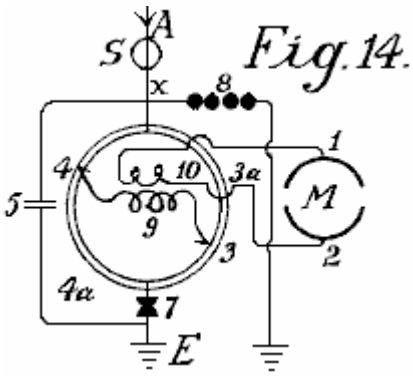

Fig.10 shows a motor circuit with purely inductive coupling. The motor is connected with the secondary wire **10** as may be seen in **Fig.11** in a somewhat modified circuit. The same applies to the circuit of **Fig.12**.

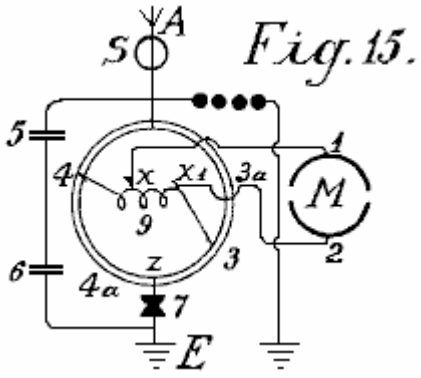
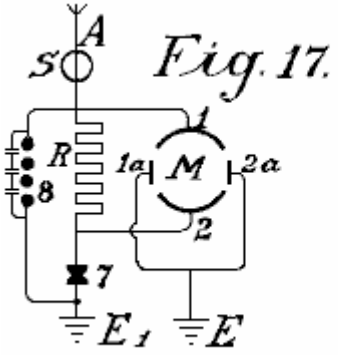
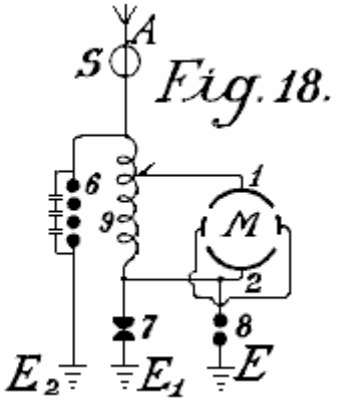
The circuit diagrams shown so far, allow motors of small to medium strength to be operated. For large aggregates, however, they are too inconvenient as the construction of two or more oscillation circuits for large amounts of energy is difficult; the governing is still more difficult and the danger in switching on or off is greater.

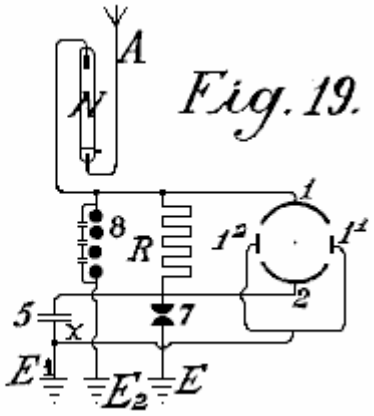


A means for overcoming such difficulties is shown in **Fig.13**. The oscillation circuit shown here, runs from point **x** over capacitor **5**, variable inductor **9**, spark gap **7** and the two segments **3a** and **3b** forming arms of a Wheatstone bridge, back to **x**. If the motor is connected by brushes **3** and **4** transversely to the two arms of the bridge as shown in the drawing, electromagnetic oscillations of equal sign are induced in the stator surfaces **1** and **2** and the motor does not revolve. If however, the brushes **3** and **4** are moved in common with the conducting wires **1** and **2** which connect the brushes with the stator poles, a certain alteration or displacement of the polarity is obtained and the motor commences to revolve.



The maximum action will result if one brush **3** comes on the central sparking contact **7** and the other brush **4** on the part **x**. In practice however, they are usually brought on to the central contact **7** but only held in the path of the bridge segments **4a** and **3a** in order to avoid connecting the spark gaps with the motor oscillation circuit.





As this prevents the whole of the oscillation energy acting on the motor, it is better to adopt the modification shown in **Fig.14**. The only difference here is that the motor is not wired directly to the segments of the commutator, but instead it is wired to secondary coil **10** which receives induced current from primary coil **9**. This arrangement provides a good transforming action, a loose coupling and an oscillation circuit without a spark gap.

In **Fig.15**, the motor is wired directly to the primary coil at **x** and **x1** after the principle of the auto-transformer. In **Fig.16**, instead of an inductor, capacitor **6** replaces the inductance and is inserted between the segments **3a** and **4a**. This has the advantage that the segments **3a** and **4a** need not be made of solid metal, but may consist of spiral coils which allow a more exact regulation, and high inductance motors may be used.

The circuits shown in **Fig.17**, **Fig.18** and **Fig.19** may be used with resonance and particularly with induction capacitor motors; between the large stator induction capacitor surfaces, small reversing pole capacitors are connected which are lead together to earth. Such reversing poles have the advantage that, with large quantities of electrical energy, the spark formation between the separate oscillation circuits ceases.

Fig.19 shows another method which prevents high frequency electromagnetic oscillations formed in the oscillation circuit, feeding back to the aerial. It is based on the well known principle that a mercury lamp, one electrode of which is formed of mercury, the other of solid metal such as steel, allows an electric charge to pass in only one direction: from the mercury to the steel and not vice versa. The mercury electrode of the vacuum tube **N** is therefore connected with the aerial conductor and the steel electrode with the oscillation circuit. Charges can then only pass from the aerial through the vacuum tube to the oscillation circuit and no flow occurs in the opposite direction. In practice, these vacuum tubes must be connected behind an electromagnet as the latter alone provides no protection against the danger of lightning.

As regards the use of spark gaps, all arrangements as used for wireless telegraphy may be used. Of course, the spark gaps in large machines must have a sufficiently large surface. In very large stations they are cooled in liquid carbonic acid or better still, in liquid nitrogen or hydrogen; in most cases the cooling may also take place by means of liquefied low homologues of the metal series or by means of hydrocarbons, the freezing point of which lies between -90^{o}C and -40^{0}C. The spark gap casing must also be insulated and be of sufficient strength to be able to resist any pressure which may arise. Any undesirable excess super-pressure which may be formed must

be let off automatically. I have employed with very good results, mercury electrodes which were frozen in liquid carbonic acid, the cooling being maintained during the operation from the outside, through the walls.

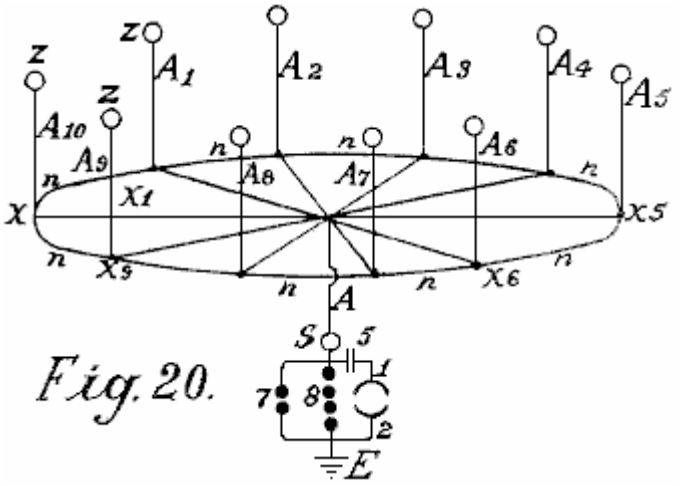


Fig. 20.

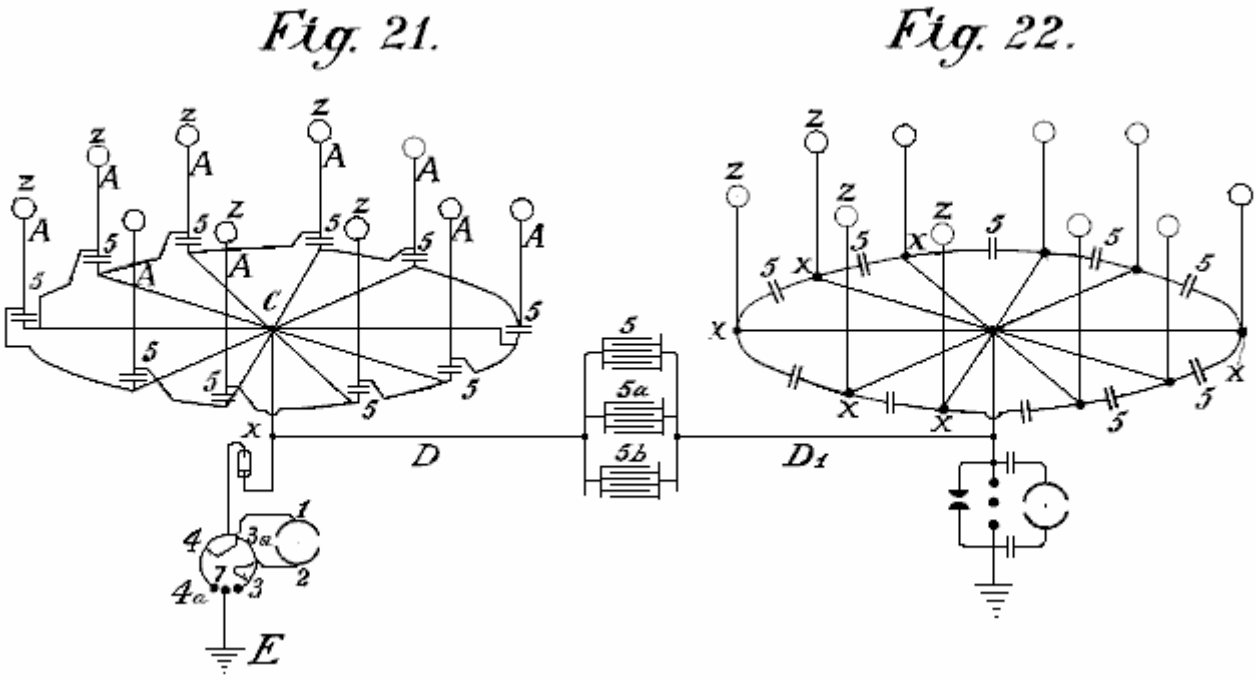
Fig.20 shows one of the most simple forms of construction of an aerial network in combination with collectors, transformers and the like. **E** is the earth wire, **8** the safety spark gap, **7** the working spark gap, **1** and **2** the stator surfaces of the motor, **5** a capacitor battery, **S** the protective magnet which is connected with the coil in the aerial conductor, $\mathbf{A^1}$ to $\mathbf{A^{10}}$ aerial antennae with collecting balloons, **N** horizontal collecting or connecting wires, from which, a number of connections run to the centre.



The actual collectors consist of metal sheaths, preferably made of an aluminium magnesium alloy, and are filled with hydrogen or helium, and are attached to copper-plated steel wires. The size of the balloon is selected so that the actual weight of the balloon and its conducting wire is supported by it. Aluminium spikes, made and gilded as described below, are arranged on top of the balloons in order to produce a conductor action. Small quantities of radium preparations, more particularly, polonium-ionium or mesothorium preparations, considerably increase the ionisation, and the performance of these collectors.

In addition to metal balloons, fabric balloons which are sprayed with a metallic coating according to Schoop's metal-spraying process may also be used. A metallic surface may also be produced by lacquering with metallic bronzes, preferably according to Schoop's spraying process, or lacquering with metallic bronze powders in two electrical series of widely different metals, because this produces a considerably increased collecting effect.

Instead of the ordinary round balloons, elongated cigar-shaped ones may be employed. In order also to utilise the frictional energy of the wind, patches or strips of non-conducting substances which produce electricity by friction, may be attached to the metallised balloon surfaces. The wind will impart a portion of its energy in the form of frictional electricity, to the balloon casing, thus substantially increasing the collection effect.

In practice however, very high towers of up to 300 metres may be employed as antennae. In these towers, copper tubes rise freely further above the top of the tower. A gas lamp secured against the wind is then lit at the point of the copper tube and a netting is secured to the copper tube over the flame of this lamp to form a collector. The gas is conveyed through the interior of the tube, up to the summit. The copper tube must be absolutely protected from moisture at the place where it enters the tower, and rain must be prevented from running down the walls of the tower, which might lead to a bad catastrophe. This is done by bell-shaped enlargements which expand downwards, being arranged in the tower in the form of high voltage insulators of Siamese pagodas.

Special attention must be devoted to the foundations of such towers. They must be well insulated from the ground, which may be achieved by first embedding a layer of concrete in a box form to a sufficient depth in the ground, and inserting in this, an asphalt lining and then glass bricks cast about 1 or 2 metres in thickness. Over this in turn, there is a ferro-concrete layer in which alone the metal foot of the tube is secured. This concrete block must be at least 2 metres from the ground and at the sides, be fully protected from moisture by a wooden covering. In the lower part of the tower, a wood or glass housing should be constructed to protect the capacitors and/or motors. In order to ensure that the ground lead connects to the water-table, a well insulated pit lined with vitreous bricks must be provided. Several such towers are erected at equal distances apart and connected with a horizontal conductor. The horizontal connecting wires may either run directly from tower to tower or be carried on bell-shaped insulators similar to those in use for high voltage electricity transmission lines. The width of the aerial tower network may be of any suitable size and the connection of the motors can take place at any convenient location.

In order to collect large quantities of electricity with few aerials, it is as well to provide the aerial conductor with sets of capacitors as shown in the two methods of construction illustrated in **Fig.21** and **Fig.22**. In **Fig.21** the set of capacitors **5** is connected between the aerials **Z** via lead **A** and an annular conductor from which horizontal run to the connecting points **C** to which the earth wire is connected. **Fig.22** shows a similar arrangement.

Should two such series of antenna rings be shown by a voltmeter to have a large voltage difference (for example, one in the mountains and one on the plain) or even of a different polarity, these differences may be compensated for by connecting sufficiently large capacitor sets (**5, 5a, 5b**) by means of Maji star conductors **D** and **D[1]**. **Fig.23**, shows a connection of three such rings of collectors are positioned in a triangle with a central set of capacitors.

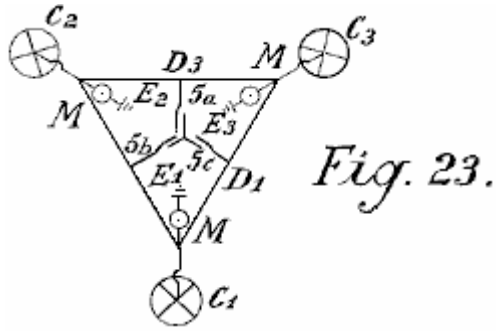


Fig. 23.

The capacitor sets of such large installations must be embedded in liquefied gasses or in liquids freezing at very low temperatures. In such cases, a portion of the atmospheric energy must be employed for liquefying these gasses. It is also preferable to employ pressure. By this means, the capacitor surfaces may be reduced in area and still allow the storage of large quantities of energy to be stored, secure against breakdown. For the smaller installations, the immersing of the capacitors in well insulated oil or the like, is sufficient. Solid substances, on the other hand, cannot be employed as insulators.

The arrangement in the diagrams shown earlier has always shown both poles of the capacitors connected to the aerial conductors. An improved method of connection has been found to be very advantageous. In this method, only one pole of each capacitor is connected to the collecting network. Such a method of connection is very important, as by means of it, a constant current and an increase in the normal working voltage is obtained. If, for example, a collecting balloon aerial which is allowed to rise to a height of 300 metres, shows 40,000 volts above earth voltage, in practice it has been found that the working voltage (with a withdrawal of the power as described earlier by means of oscillating spark gaps and the like) is only about 400 volts. If however, the capacity of the capacitor surfaces be increased, which capacity in the above mentioned case was equal to that of the collecting surface of the balloon aerials, to double the amount, by connecting the capacitors with only one pole, the voltage rises under an equal withdrawal of current up to and beyond 500 volts. This can only be ascribed to the favourable action of the connecting method.

In addition to this substantial improvement it has also been found preferable to insert double inductances with electromagnets and to place the capacitors preferably between two such electromagnets. It has also been found that the useful action of such capacitors can be further increased if an induction coil is connected as an inductive resistance to the unconnected pole of the capacitor, or still better if the capacitor itself be made as an induction capacitor. Such a capacitor may be compared to a spring, which when compressed, carries in itself accumulated force, which it gives off again when released. In charging, a charge with reversed sign is formed at the other free capacitor pole, and if a short circuit occurs through the spark gap, the accumulated energy is again given back since now new quantities of energy are induced at the capacitor pole connected to the conductor network, which in fact, charges with opposite sign to that at the free capacitor pole. The new induced charges have of course, the same sign as the collector network. The whole voltage energy in the aerial is thereby increased. In the same time interval, larger quantities of energy are accumulated than is the case without such capacitor sets being inserted.

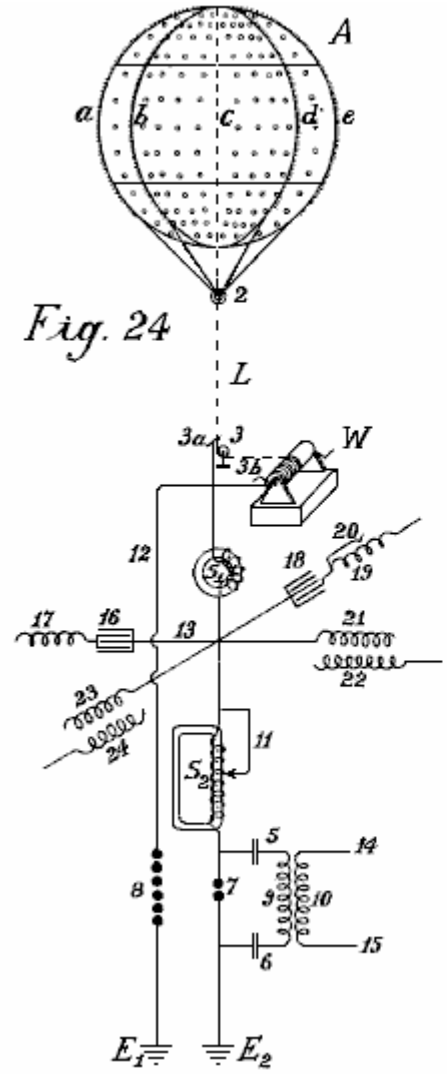

Fig. 24

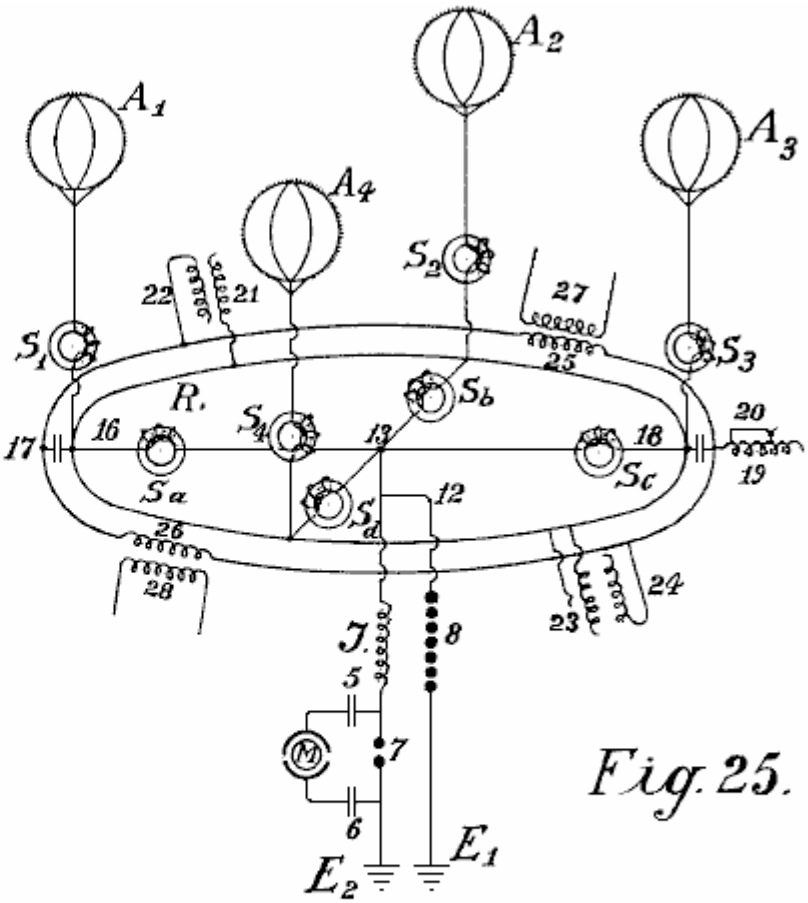

Fig. 25.

In **Fig.24** and **Fig.25**, two different connection diagrams are illustrated in more detail. **Fig.24** shows a collecting balloon along with its earth connections. **Fig.25** shows four collecting balloons and the parallel connection of their capacitor sets.

A is the collecting balloon made of an aluminium magnesium alloy (electron metal magnalium) of a specific gravity of 1.8 and a plate thickness of 0.1 mm to 0.2 mm. Inside, there are eight strong vertical ribs of T-shaped section of about 10 mm to 20 mm in height and about 3 mm in thickness, with the projecting part directed inwards (indicated by **a, b, c, d** and so forth). They are riveted together to form a firm skeleton and are stiffened in a horizontal direction by two cross ribs. The ribs are further connected to one another internally and transversely by means of thin steel wires, whereby the balloon obtains great strength and elasticity. Rolled plates of 0.1 mm to 0.2 mm in thickness made of magnalium alloy are then either soldered or riveted on to this skeleton so that a fully metallic casing with a smooth external surface is created. Well silvered or coppered aluminium plated steel wires run from each rib to the fastening ring **2**. Further, the coppered steel hawser **L**, preferably twisted out of separate thin wires (shown as dotted lines in **Fig.24**) and which must be long enough to allow the balloon to rise to the

desired height, leads to a metal roller or pulley **3** and on to a winch **W**, which must be well insulated from the earth. By means of this winch, the balloon which is filled with hydrogen or helium, can be allowed to rise to a suitable height of 300 to 5,000 metres, and brought to the ground for recharging or repairs.

The actual current is taken directly through a friction contact from the metal roller **3** or from the wire or even from the winch, or simultaneously from all three by means of brushes (**3**, **3a** and **3b**). Beyond the brushes, the conductor is divided, the paths being:- firstly, over **12** to the safety spark gap **8**, on to the earth conductor $\mathbf{E^1}$, and secondly over electromagnet $\mathbf{S^1}$, point **13**, to a second loose electromagnet having an adjustable coil $\mathbf{S^2}$, then to the spark gap **7** and to the second earth conductor $\mathbf{E^2}$. The actual working circuit is formed through the spark gap **7**, capacitors **5** and **6**, and through the primary coil **9**; here the static electricity formed by oscillatory discharges is accumulated and converted into high frequency electromagnetic oscillations. Between the electromagnets $\mathbf{S^1}$ and $\mathbf{S^2}$ at the crossing point **13**, four capacitor sets are introduced which are only indicated diagramatically in the drawings by a single capacitor. Two of these sets of capacitors (**16** and **18**) are made as plate capacitors and prolonged by regulating induction coils or spirals **17** and **19** while the two others (**21** and **23**) are induction capacitors. As may be seen from the drawings, each of the four capacitor sets, **16**, **18**, **21** and **23** is connected by only one pole to either the aerial or to the collector conductor. The second poles **17**, **19**, **22** and **24** are open. In the case of plate capacitors having no inductive resistance, an induction coil is inserted. The object of such a spiral or coil is the displacement of phase of the induction current by $^1/_4$ periods, whilst the charging current of the capacitor poles which lie free in the air, works back to the collector aerial. The consequence of this is that in discharges in the collector aerial, the back-inductive action of the free poles allows a higher voltage to be maintained in the aerial collecting conductor than would otherwise be the case. It has also been found that such a back action has an extremely favourable effect on the wear of the contacts. Of course, the inductive effect may be regulated at will within the limits of the size of the induction coil, the length of the coil in action being adjustable by means of wire connection without induction (see **Fig.24** No. **20**).

$\mathbf{S^1}$ and $\mathbf{S^2}$ may also be provided with such regulating devices, in the case of $\mathbf{S^2}$ illustrated by **11**. If excess voltage be formed, it is conducted to earth through wire **12** and spark gap **8**, or through any other suitable apparatus, since this voltage would be dangerous for the other components. The action of these capacitor sets has already been described.

The small circles on the collector balloon indicate places where small patches of extremely thin layers (0.01 to 0.05 mm thick) of zinc amalgam, gold amalgam or other photoelectric acting metals, are applied to the balloon casing of light metal. Such metallic patches may also be applied to the entire balloon as well as in greater thickness to the conducting network. The capacity of the collector is thereby considerably strengthened at the surface. The greatest possible effect in collecting may be obtained by polonium amalgams and the like. On the surface of the collector balloon, metal points or spikes are also fixed along the ribs. These spikes enhance the charge collection operation. Since it is well known that the sharper the spikes, the less the resistance of the spikes, it is therefore extremely important to use spikes which are as sharp as possible. Experiments have shown that the formation of the body of the spike or point also play a large part, for example, spikes made of bars or rollers with smooth surfaces, have point resistance many times greater than those with rough surfaces. Various kinds of spike bodies have been experimented with for the collector balloons and the best results were given with spikes which were made in the following way: Fine points made of steel, copper, nickel or copper and nickel alloys, were fastened together in bundles and then placed as anode with the points placed in a suitable electrolyte (preferably in hydrochloric acid or muriate of iron solutions) and so treated with weak current driven by 2 to 3 volts. After 2 to 3 hours, according to the thickness of the spikes, the points become extremely sharp and the bodies of the spikes have a rough surface. The bundle can then be removed and the acid washed off with water. The spikes are then placed as cathode in a bath containing a solution of gold, platinum, iridium, palladium or wolfram salts or their compounds, and coated at the cathode galvanically with a thin layer of precious metal, which mush however be sufficiently firm to protect them from atmospheric oxidation.

Such spikes act at a 20 fold lower voltage almost as well as the best and finest points made by mechanical means. Still better results are obtained if polonium or radium salts are added to the galvanic bath when forming the protective layer or coating. Such pins have low resistance at their points and have excellent collector action even at one volt or lower.

In **Fig.24**, the three unconnected poles are not connected with one another in parallel. That is quite possible in practice without altering the principle of the free pole. It is also preferable to interconnect a series of collecting aerials in parallel to a common collector network. **Fig.25** shows such an arrangement. $\mathbf{A^1, A^2, A^3, A^4}$ are four metal collector balloons with gold or platinum coated spikes which are electrolytically mad in the presence of polonium emanations or radium salts, the spikes being connected over four electromagnets $\mathbf{S^1, S^2, S^3, S^4}$, through an annular conductor **R**. From this annular conductor, four wires run over four further electromagnets $\mathbf{S^a, S^b, S^c, S^d}$, to the connecting point **13**. There, the conductor is divided, one branch passing over **12** and the safety spark gap **7** to the earth at $\mathbf{E^1}$, the other over inductive resistance **J** and working spark gap **7** to the earth at

E^2. The working circuit, consisting of the capacitors **5** and **6** and a resonance motor or a capacitor motor **M**, such as already described, is connected in proximity around the sparking gap section **7**. Of course, instead of connecting the capacitor motor directly, the primary circuit for high frequency oscillatory current may also be inserted.

The capacitor sets are connected by one pole to the annular conductor **R** and can be either inductionless (**16** and **18**) or made as induction capacitors as shown by **21** and **23**. The free poles of the inductionless capacitors are indicated by **17** and **19**, and those of the induction capacitors by **22** and **24**. As may be seen from the drawings, all of these poles **17, 22, 19** and **24** may be interconnected in parallel through a second annular conductor without any fear that thereby the principle of the free pole connection will be lost. In addition to the advantages already mentioned, the parallel connection also allows an equalisation of the working voltage in the entire collector network. Suitably calculated and constructed induction coils **25** and **26** may also be inserted in the annular conductor of the free poles, by means of which, a circuit may be formed in the secondary coils **27** and **28** which allows current produced in this annular conductor by fluctuations of the charges, to be measured or otherwise utilised.

According to what has already been stated, separate collector balloons may be connected at equidistant stations distributed over the whole country, either connected directly with one another metallically or by means of intermediate suitably connected capacitor sets through high voltage conductors insulated from earth. The static electricity is converted through a spark gap, into high frequency dynamic electricity which may be utilised as a source of energy by means of a suitable connection method, various precautions being observed, and with special regulations. The wires leading from the collector balloons, have up to now been connected through an annular conductor without this endless connection, which can be regarded as an endless induction coil, being able to exert any action on the whole conductor system.

It has now been found that if the network conductor connecting the aerial collector balloons with one another, is not made as a simple annular conductor, but preferably short-circuited in the form of coils over a capacitor set or spark gap or through thermionic valves, then the total collecting network exhibits quite new properties. The collection of atmospheric electricity is thereby not only increased but an alternating field may easily be produced in the collector network. Further, the atmospheric electrical forces showing themselves in the higher regions, may also be obtained directly by induction. In **Fig.26** and **Fig.28**, a form of construction is shown, on the basis of which, the further foundations of the method will be explained in more detail.

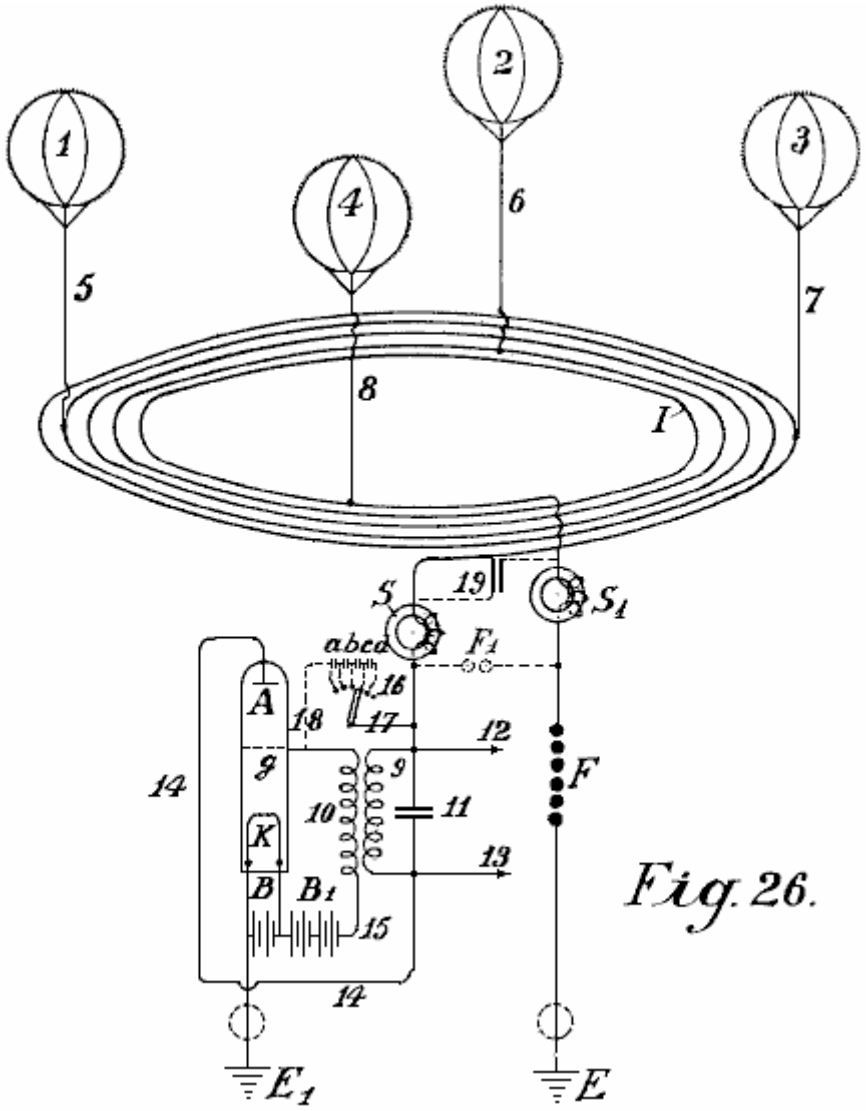

Fig. 26.

In **Fig.26, 1,2,3** and **4** are metallic collector balloons, with **5, 6, 7** and **8** their metallic aerial conductors and **I** the actual collector network. This consists of five coils and is mounted on high voltage insulators in the air, on high voltage masts (or with a suitable construction of cable, embedded in the earth). One coil has a diameter of 1 to 100 km. or more. **S** and **S^1** are two protective electromagnets, **F** is the second safety section against excess voltage, **E** its earth conductor and **E^1** the earth conductor of the working section. When an absorption of static atmospheric electricity is effected through the four balloon collectors, in order to reach the earth connection **E^1**, the current must flow spirally through the collector network, over the electromagnet **S**, primary induction coil **9**, conductor **14**, anode **A** of the audion tube, incandescent cathode **K**, as the way over the electromagnet and safety spark gap **F** offers considerably greater resistance. Owing to the fact that the accumulated current flows in one direction, an electromagnetic alternating field is produced in the interior of the collector network coil, whereby all of the free electrons are directed more or less into the interior of the coil. An increased ionisation of the atmosphere is therefore produced. Consequently, the points mounted on the collector balloon, show a considerably reduced resistance and therefore increased static charges are produced between the points on the balloon and the surrounding atmosphere. This results in a considerably increased collector effect.

A second effect, which could not be achieved in any other way, is obtained by the alternating electromagnetic field running parallel to the earth's surface, which acts more or less with a diminishing or increasing effect on the earth's magnetic field, whereby in the case of fluctuations in the current, a return induction current of reversed sign is always produced in the collector coil by earth magnetism. Now if a constantly pulsating, continuous alternating field is produced as stated in the collector network **I**, an alternating current of the same frequency is also produced in the collecting network coil. As the same alternating field is further transmitted to the aerial balloon, the resistance of its points is thereby considerably reduced, while the collector action is considerably increased. A further advantage is that positive charges which collect on the metal surfaces during the conversion into dynamic current, produce a so-called voltage drop in the collector area. As an alternating field is present, when discharge of the collector surfaces takes place, the negative ions surrounding the collector surfaces produce, by the law of induction, an induction of reversed sign on the collector surface - that is, a positive charge. In addition to the advantages already stated, the construction of connecting conductors in coil form, when of

sufficiently large diameter, allows a utilisation of energy arising in higher regions, also in the most simple way. As is well known, electric discharges frequently take place at very great elevations which may be observed, such as 'St. Elmo's fires' or 'northern lights'. These energy quantities have not been able to have been utilised before now. By this invention, all of these kinds of energy, as they are of electromagnetic nature and since the axis of the collector coils is at right angles to the earth's surface, can be absorbed in the same way as a radio absorbs distant radio signals. With a large diameter of the spiral, it is possible to connect large surfaces and thereby take up large quantities of energy.

It is well known that in the summer months and in the tropics, large radio stations are very frequently unable to receive signals due to interruptions caused by atmospheric electricity, and this takes place with vertical coils of only 40 to 100 metres in diameter. If, on the contrary, horizontal coils of 1 to 100 kilometres in diameter are used, very strong currents may be obtained through discharges which are constantly taking place in the atmosphere. Particularly in the tropics, or still better in the polar regions where the northern lights are constantly present, large quantities of energy may probably be obtained in this way. A coil with several windings should perform the best. In a similar manner, any alteration of the earth's magnetic field should act inductively on such a coil.

It is not at all unlikely that earthquakes and sunspots will also produce an induction in collector coils of that size. In similar manner, this collector conductor will react to earth currents more particularly when they are near the surface of the earth or even embedded in the earth. By combining the previous kind of current collectors, so far as they are adapted for the improved system with the improved possibilities of obtaining current, the quantities of free natural energy which are to be obtained in the form of electricity are considerably increased.

In order to produce uniform undamped current oscillations in the improved collector coil, so-called audion high vacuum or thermionic valves are used instead of the previous described spark gaps (**Fig.26, 9-18**). The main aerial current flows through electromagnet **S** (which in the case of a high number of alternations is not connected here but in the earth conductor $\mathbf{E^1}$) and may be conveyed over the primary coils in the induction winding through wire **14** to the anode **A** of the high vacuum grid valve. Parallel with the induction resistance **9**, a regulating capacity of suitable size, such as capacitor **11**, is inserted. In the lower part of the vacuum grid valve is the incandescent filament cathode **K** which is fed through a battery **B**. From the battery, two branches run, one to the earth conductor $\mathbf{E^1}$ and the other through battery $\mathbf{B^1}$ and secondary coil **10** to the grid anode **g** of the vacuum tube. By the method of connections shown in dotted lines, a desired voltage may also be produced at the grid electrode **g** through wire **17** which is branched off from the main current conductor through switches **16** and some small capacitors (**a, b, c, d**) connected in series, and conductor **18**, without the battery $\mathbf{B^1}$ being required. The action of the whole system is somewhat as follows:-

On the connecting conductor of the aerial collector network being short-circuited to earth, the capacitor pole **11** is charged, and slightly dampened oscillations are formed in the short-circuited oscillation circuit formed by capacitor **11** and self inductance **9**. Because of the coupling through coil **10**, voltage fluctuations of the same frequency take place in the grid circuit **15** and in turn, these fluctuations influence the strength of the electrode current passing through the high vacuum amplifying valve and thus produce current fluctuations of the same frequency in the anode circuit. A permanent supply of energy. Consequently, a permanent supply of energy is supplied to the oscillation circuits **9** and **10** takes place, until a balance is achieved where the oscillation energy consumed exactly matches the energy absorbed. This produces constant undamped oscillations in the oscillation circuits **9 - 11**.

For regular working of such oscillation producers, high vacuum strengthening tubes are necessary and it is also necessary that the grid and anode voltages shall have a phase difference of 180^0 so that if the grid is negatively charged, then the anode is positively charged and vice versa. This necessary difference of phase may be obtained by most varied connections, for example, by placing the oscillating circuit in the grid circuit or by separating the oscillation circuit and inductive coupling from the anodes and the grid circuit, and so forth.

A second important factor is that care must be taken that the grid and anode voltages have a certain relation to one another; the latter may be obtained by altering the coupling and a suitable selection of the self induction in the grid circuit, or as shown by the dotted lines **18, 17, 16** by means of a larger or smaller number of capacitors of suitable size connected in series; in this case, the battery $\mathbf{B^1}$ may be omitted. With a suitable selection of the grid potential, a glow discharge takes place between the grid **g** and the anode **A**, and accordingly at the grid there is a cathode drop and a dark space is formed. The size of this cathode drop is influenced by the ions which are emitted in the lower space in consequence of shock ionisation of the incandescent cathodes **K** and pass through the grid in the upper space. On the other hand, the number of the ions passing through the grid is dependent on the voltage between the grid and the cathode. Thus, if the grid voltage undergoes periodic fluctuations (as in the present case), the amount of the cathode drop at the grid fluctuates, and consequently, the internal resistance of the valve fluctuates correspondingly, so that when a back-coupling of the feed circuit with the grid circuit takes

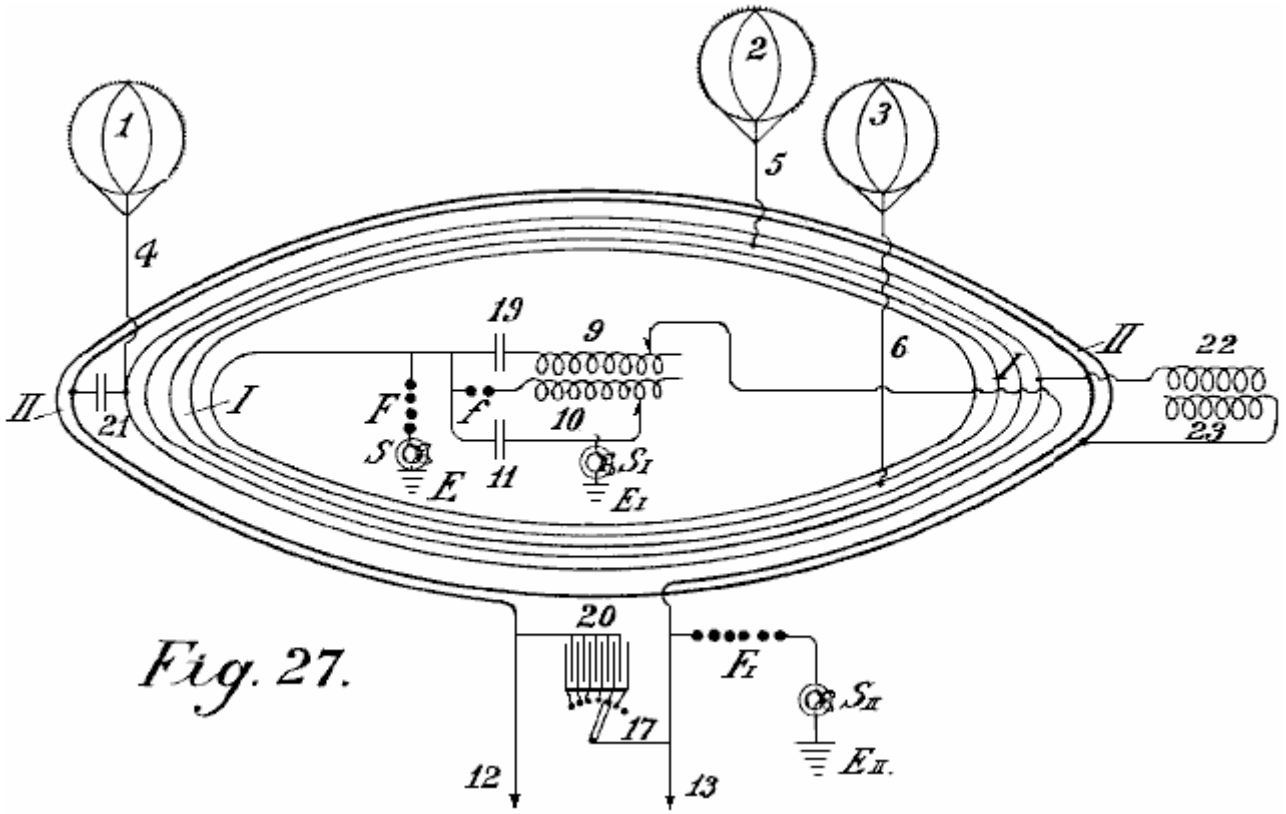
place, the necessary means are in place for producing undamped oscillations and of taking current as required, from the collecting conductor.

With a suitably loose coupling, the frequency of the undamped oscillations produced is equal to the self-frequency of the oscillation circuits **9** and **10**. By selecting a suitable self-induction for coil **9** and capacitor **11**, it is possible to extend operation from frequencies which produce electromagnetic oscillations with a wavelength of only a few metres, down to the lowest practical alternating current frequency. For large installations, a suitable number of frequency producing tubes in the form of the well known high vacuum transmission tubes of 0.5 kW to 2 kW in size may be connected in parallel so that in this respect, no difficulty exists.

The use of such tubes for producing undamped oscillations, and the construction and method of inserting such transmission tubes in an accumulator or dynamo circuit is known, also, such oscillation producing tubes only work well at voltages of 1,000 volts up to 4,000 volts, so that on the contrary, their use at lower voltages is considerably more difficult. By the use of high voltage static electricity, this method of producing undamped oscillations as compared with that through spark gaps, must be regarded as an ideal solution, particularly for small installations with outputs from 1 kW to 100 kW.

By the application of safety spark gaps, with interpolation of electromagnets, not only is short-circuiting avoided but also the taking up of current is regulated. Oscillation producers inserted in the above way, form a constantly acting alternating electromagnetic field in the collector coil, whereby, as already stated, a considerable accumulating effect takes place. The withdrawal or 'working' wire is connected at **12** and **13**, but current may be taken by means of a secondary coil which is firmly or moveably mounted in any suitable way inside the large collector coil, i.e. in its alternating electromagnetic field, so long as the direction of its axis is parallel to that of the main current collecting coil.

In producing undamped oscillations of a high frequency (50 KHz and more) in the oscillation circuits **9** and **11**, electromagnets **S** and **S[1]** must be inserted if the high frequency oscillations are not to penetrate the collector coil, between the oscillation producers and the collector coil. In all other cases they are connected shortly before the earthing (as in **Fig.27** and **Fig.28**).



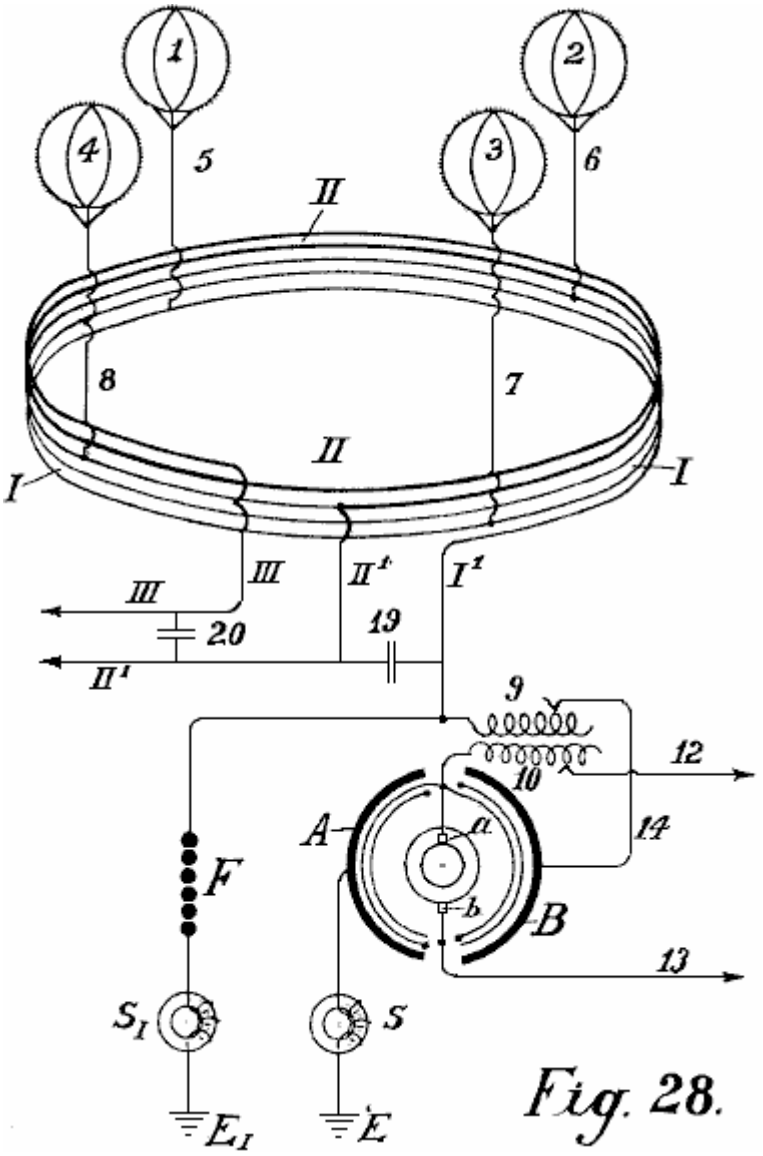


Fig. 27.

In **Fig.27** a second method of construction of the connecting conductor of the balloon aerials is illustrated in the form of a coil. The main difference is that in addition to the connecting conductor **I** another annular conductor **II** is inserted parallel to the former on the high voltage masts in the air (or embedded as a cable in the earth) but both in the form of a coil. The connecting wire of the balloon aerials is both a primary conductor and a current producing network while the coil is the consumption network and is not in unipolar connection with the current producing network.

In **Fig.27** the current producing network **I** is shown with three balloon collectors **1, 2, 3** and aerial conductors **4, 5, 6**; it is short-circuited through capacitor **19** and inductor **9**. The oscillation forming circuit consists of spark gap **f**, inductor **10** and capacitor **11**. The earth wire **E** is connected to earth through electromagnet S^1. F_I is the safety spark gap which is also connected to earth through a second electromagnet S_{II} at E_{II}. On connecting up the capacitor circuit **11** it is charged over the spark gap **f** and an oscillatory discharge is formed. This discharging current acts through inductor **10** on the inductively coupled secondary **9**, which causes a change in the producing network, by modifying the voltage on capacitor **19**. This causes oscillations in the coil-shaped producer network. These oscillations induce a current in the secondary circuit **II**, which has a smaller number of windings and lower resistance, consequently, this produces a lower voltage and higher current in it.

In order to convert the current thus obtained, into current of an undamped character, and to tune its wavelengths, a sufficiently large regulatable capacitor **20** is inserted between the ends **12** and **13** of the secondary conductor **II**. Here also, current may be taken without an earth conductor, but it is advisable to insert a safety spark gap E^1 and to connect this with the earth via electromagnet S^2. The producer network may be connected with the working network **II** over an inductionless capacitor **21** or over an induction capacitor **22, 23**. In this case, the secondary conductor is unipolarly connected with the energy conductor.

In **Fig.28**, the connecting conductor between the separate collecting balloons is carried out according to the autotransformer principle. The collecting coil connects four aerial balloons **1, 2, 3, 4**, the windings of which are not made side-by-side but one above the other. In **Fig.28**, the collector coil **I** is shown with a thin line and the metallically connected prolongation coils **II** with a thick line. Between the ends I^1 and II^1 of the energy network **I**, a regulating capacitor **19** is inserted. The wire I^1 is connected with the output wire and with the spark gap **F**.

As transformer of the atmospheric electricity, an arrangement is employed which consists of using rotary pairs of capacitors in which the stator surface **B** is connected with the main current, while the other **A** is connected to the earth pole. These pairs of short-circuited capacitors are caused to rotate and the converted current can be taken from them via two collector rings and brushes. This current is alternating current with a frequency dependent on the number of balloons and the rate of revolutions of the rotor. As the alternating current formed in the rotor can act through coils **10** on the inductor **9**, an increase or decrease of the feed current in **I** can be obtained according to the direction of the current by back-induction. Current oscillations of uniform rhythm are produced in the coil-shaped windings of the producer network.

As the ends of this conductor are short-circuited through the regulatable capacitor **19**, these rhythms produce short-circuited undamped oscillations in the energy conductor. The frequency of these oscillations can be altered at will by adjusting the capacitance of capacitor **19**. These currents may also be used as working current via the conductors **II**^{1} and **III**. By inserting capacitor **20**, a connection between these conductors may also be made, whereby harmonic oscillations of desired wavelength are formed. By this means, quite new effects as regards current distribution are obtained. The withdrawal of current can even take place without direct wire connection if, at a suitable point in the interior of the producing network (quite immaterially whether this has a diameter of 1 or 100 km) a coil tuned to these wavelength and of the desired capacity, is firmly or moveably mounted in the aerial conductor in such a way that its axis is parallel with the axis of the collector coil. In this case, a current is induced in the producing network, the size of which is dependent on the total capacity and resistance and on the frequency selected. A future possibility is taking energy from the producer network by radio signals as in addition to atmospheric electricity, magnetic earth currents and energy from the upper atmosphere may be tapped.

Of course, vacuum tubes may be used to produce undamped oscillations anywhere spark gaps are shown in the circuits. The separate large-diameter coils of the producer network may be connected to one another through separate conductors all in parallel or all in series or in groups in series. By regulating the number of oscillations and the magnitude of the voltage, more or fewer large collector coils of this kind may be used. The coils may also be divided spirally over the entire section. The coils may be carried out in annular form or in triangular, quadrangular, hexagonal or octagonal form.

Of course, wires which form guides for the current waves, may be carried from a suitable place to the centre or also laterally. This is necessary when the currents have to be conducted over mountains and valleys and so forth. In all these cases, the current must be converted into a current of suitable frequency.

As already mentioned, separate collecting balloons may be directly metallically interconnected a equidistant stations distributed over the entire country, or may be connected by interpolation of suitable capacitor sets by means of high voltage conductors. The static electricity is converted through a spark gap into dynamic energy of high frequency and could then in that form be used as an energy source after special regulation.

According to this invention, in order to increase the collecting effect of the balloon in the aerial collector conductor or in the earth wire, radiating collectors are used. These consist of either incandescent metal or oxide electrodes in the form of vacuum grid valves, or electric arcs (mercury or similar electrodes), Nernst lamps, or flames of various kinds maybe simply connected with the respective conductor.

It is well known that energy can be drawn off from a cathode consisting of an incandescent body opposite an anode charged with positive electricity (vacuum grid tube). Hitherto however, a cathode was always first directly placed opposite an anode, and secondly, the system always consisted of a closed circuit.

Now if we dispense with the ordinary ideas in forming light or flame arcs in which a cathode must always stand directly opposite an anode charged to a high voltage or another body freely floating in the air, or consider the incandescent cathode to be only a source of unipolar discharge, (which represents group and point discharges in electro-static machines similar to unipolar discharges), it may be ascertained that incandescent cathodes and less perfectly, all incandescent radiators, flames and the like, have relatively large current densities and allow large quantities of electric energy to radiate into open space in the form of electron streams as transmitters.

The object of this invention is as described below, if such incandescent oxide electrodes or other incandescent radiators or flames are not freely suspended in space but instead are connected metallically with the earth so that they can be charged with negative terrestrial electricity, these radiators possess the property of absorbing the free positive electrical charges contained in the air space surrounding them (that is to say, of collecting them and conducting them to earth). They can therefore serve as collectors and have in comparison to the action of the spikes, a very large radius of action R; the effective capacity of these collectors is much greater than the geometrical capacity (R_0) calculated in an electro-static sense.

As is well known, our earth is surrounded with an electro-static field and the difference of potential dV/dh of the earth field according to the latest investigations, is in summer about 60 to 100 volts, and in winter, 300 to 500 volts

per metre difference in height, a simple calculation gives the result that when such a radiation collector or flame collector is arranged, for example, on the ground, and a second one is mounted vertically over it at a distance of 2,000 metres and both are connected by a conducting cable, there is a voltage difference in summer of about 2,000,000 volts and in winter 6,000,000 volts or more.

According to Stefan Boltzmann's law of radiation, the quantity of energy which an incandescent surface (temperature T) of 1 sq. cm. radiates in a unit of time into the open air (temperature T_0) is expressed by the following formula:

$$S = R\,(T^4 - T_0^4) \text{ watts per square centimetre}$$

and the universal radiation constant R, according to the latest researches of Ferry, is equal to 6.30×10^{-12} watts per square centimetre.

Now, if an incandescent surface of 1 sq. cm., as compared to the surrounding space, shows a periodic fall of potential dV, it radiates (independent of the direction of the current) in accordance with the above formula, for example at a temperature of 3715^0 C. an energy of 1.6 kW per square centimetre. As for the radiation, the same value can be calculated for the collection of energy, but reversed. Now, as carbon electrodes at the temperature of the electric arc, support a current density up to 60 to 65 amps per sq. cm., no difficulties will result in this direction in employing radiating collectors as accumulators.

If the earth be regarded as a cosmically insulated capacitor in the sense of geometrical electro-statics *x*, according to Chwolson, there results from the geometric capacity of the earth:

For negative charging 1.3×10^6 Coulomb For negative potential $V = 10 \times 10^8$ volts.

It follows from this that EJT is approximately equal to 24.7×10^{24} watts/sec. Now if it is desired to make a theoretical short circuit through an earthed flame collector, this would represent an electrical total work of about $79{,}500 \times 10^{10}$ kilowatt years. As the earth must be regarded as a rotating mechanism which is thermo-dynamically, electromagnetically and kinematically coupled with the sun and star system by cosmic radiation and gravitation, a reduction in the electric energy of the earth field is not to be feared. The energies which the incandescent collectors could withdraw from the earth field can only cause a lowering of the earth temperature. This is however, not the case as the earth does not represent a cosmically entirely insulated system. On the contrary, there is conveyed from the sun to the earth an energy of $18{,}500 \times 10^{10}$ kilowatts. Accordingly, any lowering of the earth temperature without a simultaneous lowering of the sun's temperature would contradict Stefan Boltzmann's law of radiation.

From this it must be concluded that if the earth temperature sinks, the total radiation absorbed by the earth increases, and further, the rate of cooling of the earth is directly dependent on that of the sun and the other radiators cosmically coupled with the sun.

The incandescent radiation collectors may, according to this invention, be used for collecting atmospheric electricity if they (1) are charged with the negative earth electricity (that is to say, when they are directly connected to the earth by means of a metallic conductor) and (2) if large capacities (metal surfaces) charged with electricity are mounted opposite them as positive poles in the air. This is regarded as the main feature of the present invention as without these inventive ideas it would not be possible to collect with an incandescent collector, sufficiently large quantities of the electrical charges contained in the atmosphere as technology requires; the radius of action of the flame collectors would also be too small, especially if it be considered that the very small surface density does not allow of large quantities of charge being absorbed from the atmosphere.

It has already been proposed to employ flame collectors for collecting atmospheric electricity and it is known that their collecting effect is substantially greater opposite the points. It is however, not known that the quantities of current which hitherto be obtained are too small for technical purposes. According to my experiments, the reason for this is to be found in the inadequate capacities of the collector conductor poles. If such flame or radiating collectors have no or only small positive surfaces, their radius of action for large technical purposes is too small. If the incandescent collectors be constantly kept in movement in the air, they may collect more according to the speed of the movement, but this is again not capable of being carried out in practice.

By this invention, the collector effect is considerably increased by a body charged with a positive potential and of the best possible capacity, being also held floating (without direct earth connection) opposite such an incandescent collector which is held floating in the air at a desired height. If, for example, a collecting balloon of sheet metal or metallised fabric, be caused to mount to 300 to 3,000 metres in the air, and as a positive pole it is brought opposite such a radiating collector connected by a conductor to earth, quite different results are obtained.

The metallic balloon shell which has a large surface area is charged to a high potential by atmospheric electricity. This potential is greater the higher the collecting balloon is above the incandescent collector. The positive electricity acts concentratedly on the anode floating in the air as it is attracted through the radiation shock ionisation, proceeding from the incandescent cathode. The consequence of this is that the radius of action of the incandescent cathode collector is considerably increased and so is the collecting effect of the balloon surface. Further, the large capacity of the anode floating in the air, plays therefore an important part because it allows the collection of large charges resulting in a more uniform current even when there is substantial current withdrawal - this cannot be the case with small surfaces.

In the present case, the metallic collecting balloon is a positive anode floating in the air and the end of the earth conductor of this balloon serves as positive pole surface opposite the surface of the radiating incandescent cathode, which in turn is charged with negative earth electricity as it is connected to the earth by a conductor. The process may be carried out by two such contacts (negative incandescent cathode and anode end of a capacity floating in the air) a capacitor and an inductive resistance being switched on in parallel, whereby simultaneously undamped oscillations may be formed.

In very large installations it is advisable to connect two such radiating collectors in series. Thus an arc light incandescent cathode may be placed below on the open ground and an incandescent cathode which is heated by special electro-magnetic currents, be located high in the air. Of course for this, the special vacuum Liebig tubes with or without grids may also be used. An ordinary arc lamp with oxide electrodes may be introduced on the ground and the positive pole is not directly connected with the collecting balloon, but through the upper incandescent cathode or over a capacitor. The method of connecting the incandescent cathode floating in the air may be seen in **Figs.29-33**.

B is the air balloon, **K** a Cardan ring (connection with the hawser) **C** the balloon, **L** a good conducting cable, **P** a positive pole, **N** negative incandescent cathode and **E** the earth conductor.

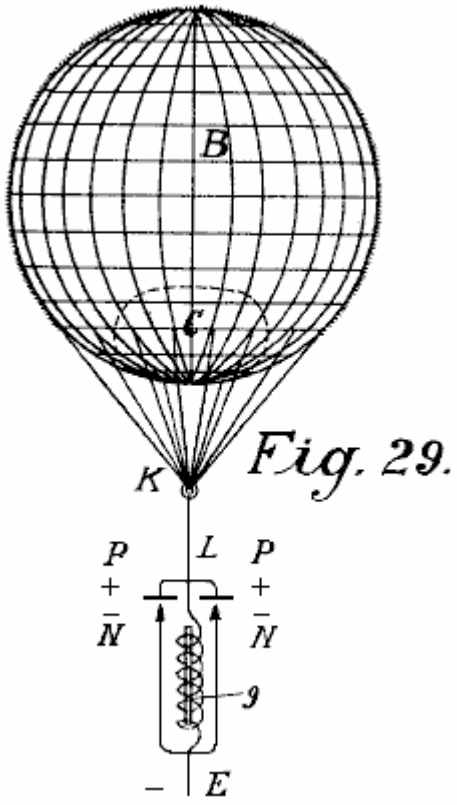

Fig. 29.

Fig.29 represents the simplest form of construction. If electric oscillations are produced below on the ground by means of a carbon arc lamp or in any other suitable way, a considerably greater electric resistance is opposed to that in the direct way by inserting an electrical inductive resistance **9**. Consequently, between **P** and **N**, a voltage is formed, and as, over **N** and **P** only an inductionless ohmic resistance is present, a spark will spring over so long as the separate induction coefficients and the like are correctly calculated. The consequence of this is that the oxide electrode (carbon or the like) is rendered incandescent and then shows as incandescent cathode, an increased collecting effect. The positive poles must be substantially larger than the negative in order that they may not also become incandescent. As they are further connected with the large balloon area which has a large capacity and is charged at high voltage, an incandescent body which is held floating in the air and a positive pole which can collect large capacities is thereby obtained in the simplest way. The incandescent cathode is first

caused to become incandescent by means of separate energy produced on the earth, and then maintained by the energy collected from the atmosphere.

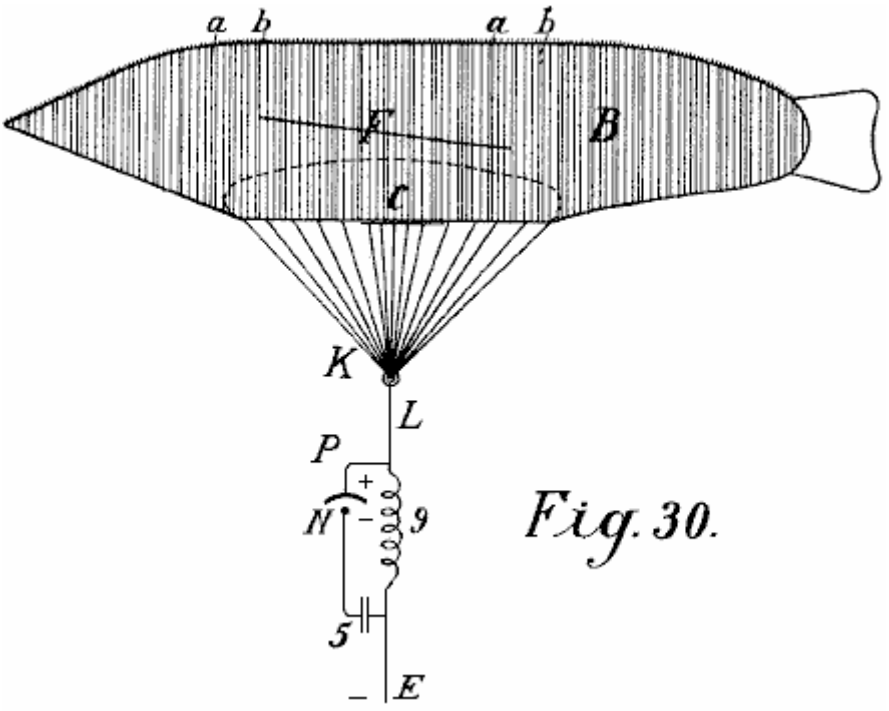

Fig. 30.

Fig.30 only shows the difference that instead of a round balloon, a cigar-shaped one may be used, also, a capacitor **5** is inserted between the incandescent cathode and the earth conductor so that a short-circuited oscillation circuit over **P N 5** and **9** is obtained. This has the advantage that quite small quantities of electricity cause the cathode to become incandescent and much larger cathode bodies may be made incandescent.

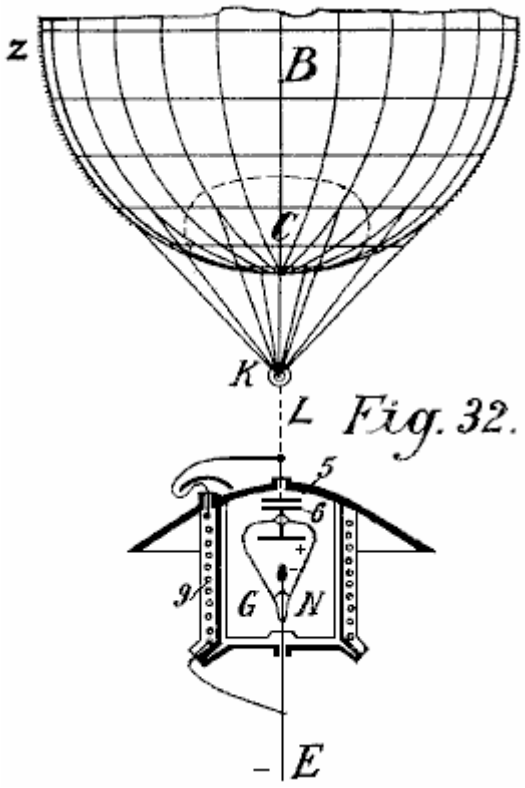

Fig. 32.

In this form of construction, both the incandescent cathode and the positive electrode may be enclosed in a vacuum chamber as shown in **Fig.32**. A cable **L** is carried well insulated through the cover of a vessel and ends in a capacitor disc **5**. The cover is arched in order to keep the rain off. The vessel is entirely or partially made of magnetic metal and well insulated inside and outside. Opposite disc **5** another disc **6** and on this again a metallic positive pole of the vacuum tube **g** with the incandescent cathode (oxide electrode) **N** is arranged. The negative electrode is on the one hand connected to the earth conductor **E**, and on the other hand with the inductive resistance **9** which is also connected with the cable **L** with the positive pole and wound around the vessel in coils.

The action is exactly the same as that in **Fig.29** only instead of an open incandescent cathode, one enclosed in vacuo is used. As in such collectors, only small bodies be brought to incandescence, in large installations a plurality of such vacuum tubes must be inserted in proximity to one another. According to the previous constructions **Fig.31** and **Fig.33** are quite self evident without further explanations.

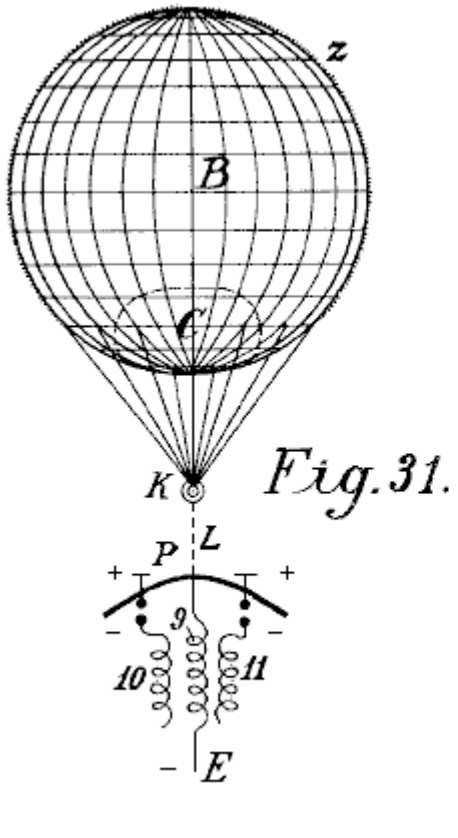

Fig. 31.

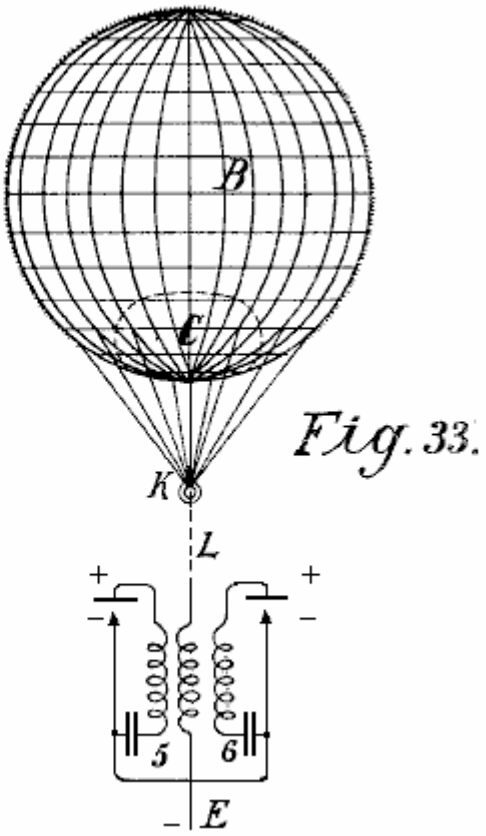

Fig. 33.

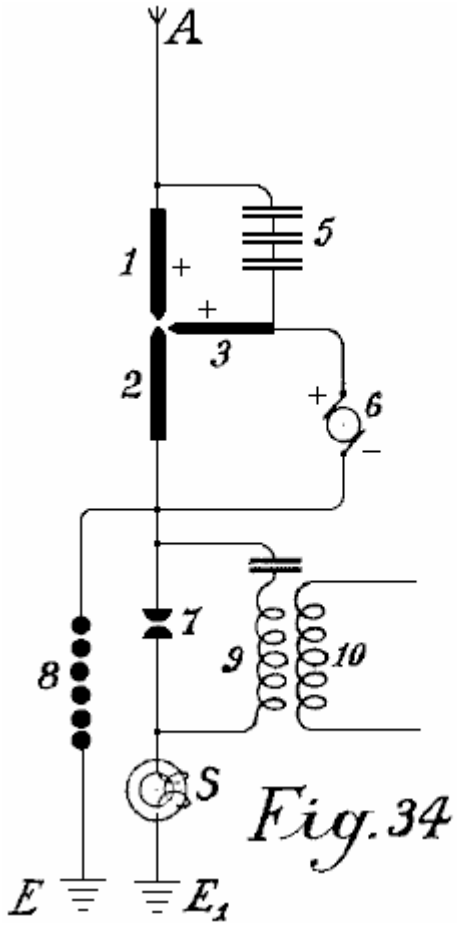

Fig. 34

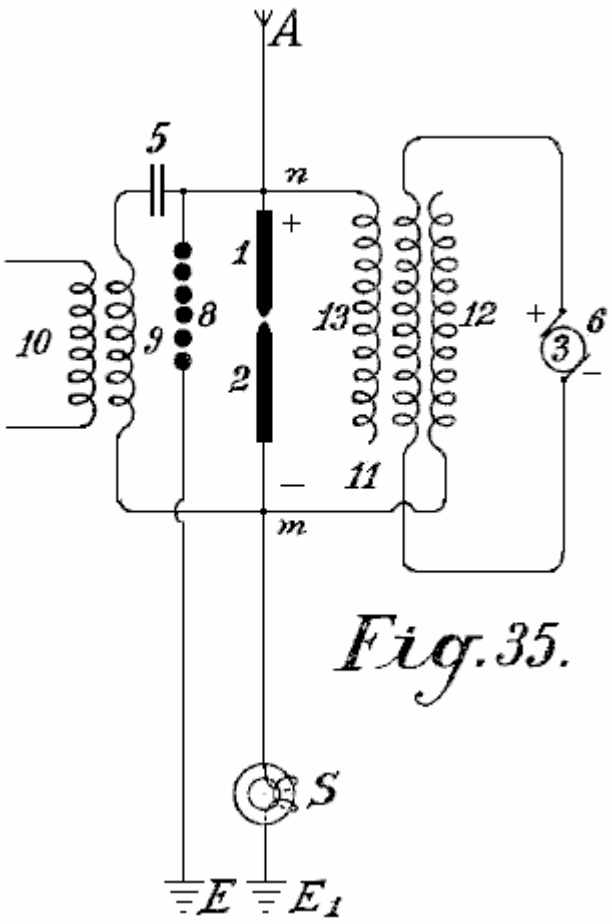

Fig. 35.

Figs.34-37 represent further diagrams of connections over radiating and flame collectors, and in fact, how they are to be arranged on the ground. **Fig.34** shows an arc light collector with oxide electrodes for direct current and its connection. **Fig.35** shows a similar one for alternating current. **Fig.36** an incandescent collector with a Nernst lamp and **Fig.37** a similar one with a gas flame.

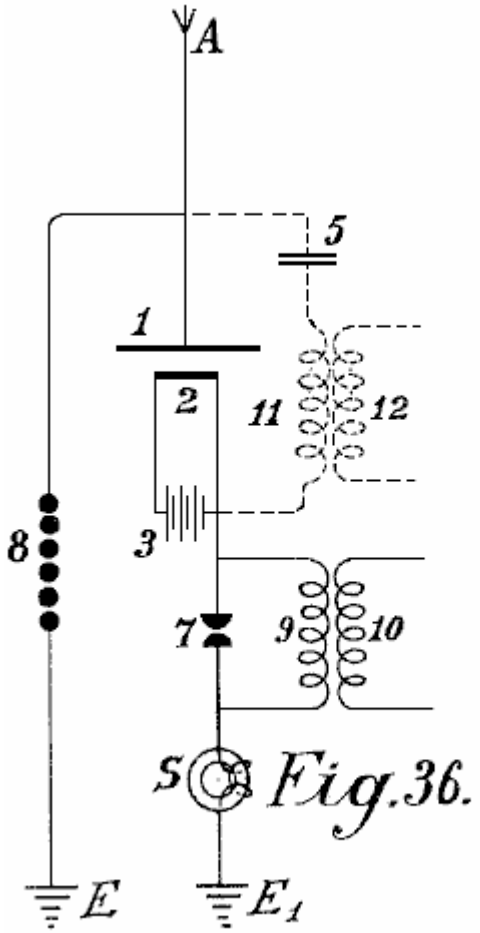

Fig.36.

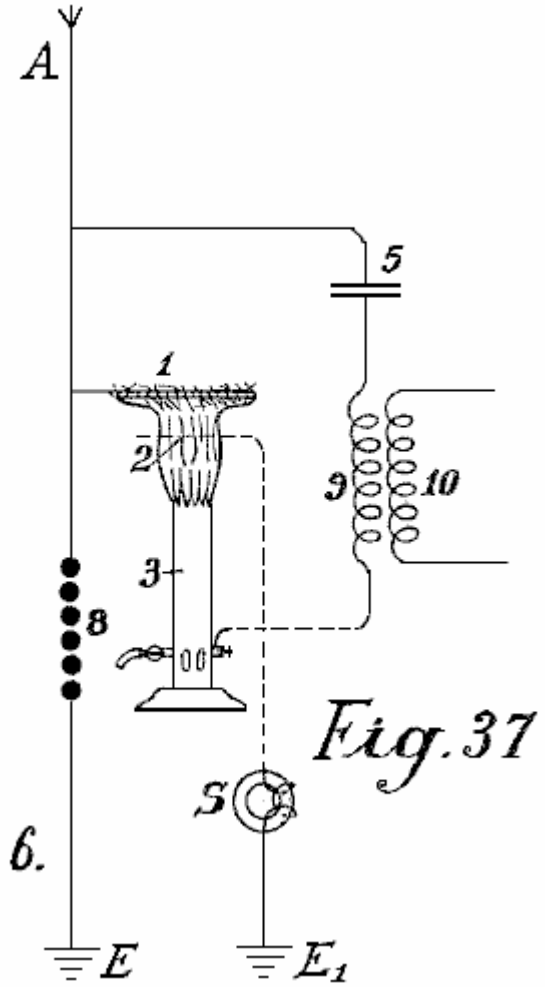

Fig.37

The positive pole **1** of the radiating collectors is always directly connected to the aerial collecting conductor **A**. In **Fig.34**, this is further connected over the capacitor set **5** with a second positive electrode **3**. The direct current dynamo **b** produces current which flows over between the electrodes **3** and **2** as an arc light. On the formation of an arc, the negative incandescent electrode **2** absorbs electricity from the positive poles standing opposite it and highly charged with atmospheric electricity which it conveys to the working circuit. The spark gap 7, inductive resistance **9** and induction coil **10** are like the ones previously described. The protective electromagnet **S** protects the installation from earth circuiting and the safety spark gap **8** from excess voltage or overcharging.

In **Fig.35**, the connection is so far altered that the alternating current dynamo feeds the excitation coil **11** of the induction capacitor. **12** is its negative and **13** its positive pole. If the coil **3** on the magnet core of the dynamo is correctly calculated and the frequency of the alternating current sufficiently high, then an arc light can be formed between poles **1** and **2**. As the cathode **2** is connected to the negatively charged earth, and therefore always acts as a negative pole, a form of rectification of the alternating current produced by the dynamo **3** is obtained, since the second half of the period is always suppressed. The working circuit may be carried out in the same way as in **Fig.34**; the working spark gap **7** may however be dispensed with, and instead of it, between the points **n** and **m**, a capacitor **5** and an induction resistance **9** may be inserted, from which, a current is taken inductively.

Fig.36 represents a form of construction similar to that shown in **Fig.34** except that here instead of an arc lamp, a Nernst incandescent body is used. The Nernst lamp is fed through the battery **3**. The working section is connected with the negative pole, the safety spark gap with the positive poles. The working spark gap **7** may also be dispensed with and the current for it taken at **12** over the oscillation circuit **5, 11** (shown in dotted lines).

Flame collectors (**Fig.37**) may also be employed according to this invention. The wire network **1** is connected with the aerial collector conductor **A** and the burner with the earth. At the upper end of the burner, long points are provided which project into the flame. The positive electrode is connected with the negative over a capacitor **5** and the induction coil **9** with the earth.

The novelty in this invention is:

(1) The use of incandescent cathodes opposite positive poles which are connected to large metallic capacities as automatic collecting surfaces.
(2) The connection of the incandescent cathodes to the earth whereby, in addition to the electricity conveyed to them from the battery of machine which causes the incandescing, also the negative charge of the earth potential is conveyed, and
(3) The connection of the positive and negative poles of the radiating collectors over a capacitor circuit alone or with the introduction of a suitable inductive resistance, whereby simultaneously an oscillatory oscillation circuit may be obtained. The collecting effect is by these methods quite considerably increased.

ROY MEYERS

Patent GB1913,01098 14th January 1914 Inventor: Roy J. Meyers

APPARATUS FOR PRODUCING ELECTRICITY

ABSTRACT

A rectifier for use with apparatus for producing electricity from the earth consists of mercury- vapour lamps constructed and arranged as shown in **Fig.4**. Each lamp comprises two wires **6<1>, 7<1>** wound around a steel tube **15** surrounding a mercury tube **11** preferably of copper. The coil **6<1>** is connected between the electrode **14** and the terminal **18**, and the coil **7<1>** between the terminals **19, 5**. The coils **6<1>, 7<1>** are preferably composed of soft iron.

DESCRIPTION

This invention relates to improvements in apparatus for the production of electrical currents, and the primary object in view is the production of a commercially serviceable electrical current without the employment of mechanical or chemical action. To this end the invention comprises means for producing what I believe to be dynamic electricity from the earth and its ambient elements.

I am, of course aware that it has been proposed to obtain static charges from upper strata of the atmosphere, but such charges are recognised as of widely variant potential and have thus far proved of no practical commercial value, and the present invention is distinguished from all such apparatus as has heretofore been employed for attracting static charges by the fact that this improved apparatus is not designed or employed to produce or generate irregular, fluctuating or other electrical charges which lack constancy, but on the other hand I have by actual test been able to produce from a very small apparatus at comparatively low elevation, say about 50 or 60 feet above the earth's surface, a substantially constant current at a commercially usable voltage and amperage.

This current I ascertained by repeated tests is capable of being readily increased by additions of the unit elements in the apparatus described below, and I am convinced from the constancy of the current obtained and its comparatively low potential that the current is dynamic and not static, although, of course, it is not impossible that certain static discharges occur and, in fact, I have found occasion to provide against the damage which might result from such discharge by the provision of lightning arresters and cut-out apparatus which assist in rendering the obtained current stable by eliminating sudden fluctuations which sometimes occur during conditions of high humidity from what I consider static discharges.

The nature of my invention is obviously such that I have been unable to establish authoritatively all of the principles involved, and some of the theories herein expressed may possibly prove erroneous, but I do know and am able to demonstrate that the apparatus which I have discovered does produce, generate, or otherwise acquire a difference of potential representing a current amperage as stated above.

The invention comprises the means for producing electrical currents of serviceable potential substantially without the employment of mechanical or chemical action, and in this connection I have been able to observe no chemical action whatever on the parts utilised although deterioration may possibly occur in some of the parts, but so far as I am able to determine such deterioration does not add to the current supply but is merely incidental to the effect of climatic action.

The invention more specifically comprises the employment of a magnet or magnets and a co-operating element, such as zinc positioned adjacent to the magnet or magnets and connected in such manner and arranged relative to the earth so as to produce current, my observation being that current is produced only when such magnets have their poles facing substantially to the north and south and the zincs are disposed substantially along the magnets.

The invention also comprehends other details of construction, combinations and arrangements of parts as will be fully set forth.

DESCRIPTION OF THE DRAWINGS

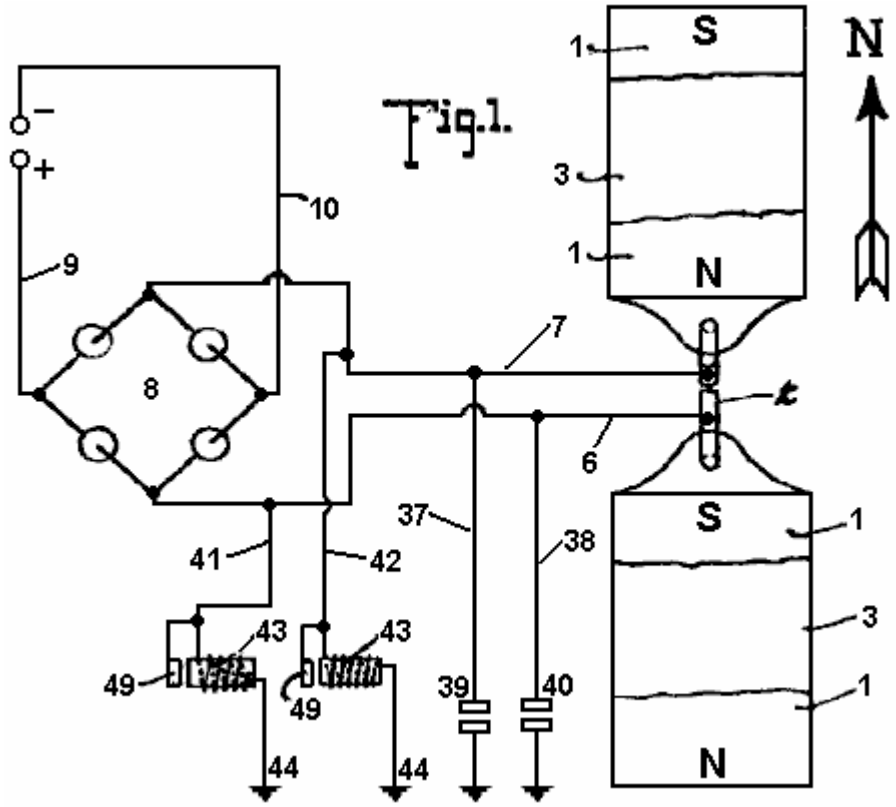

Fig.1 is a plan view of an apparatus embodying the features of the present invention, the arrow accompanying the figure indicating substantially the geographical north, parts of this figure are diagrammatic.

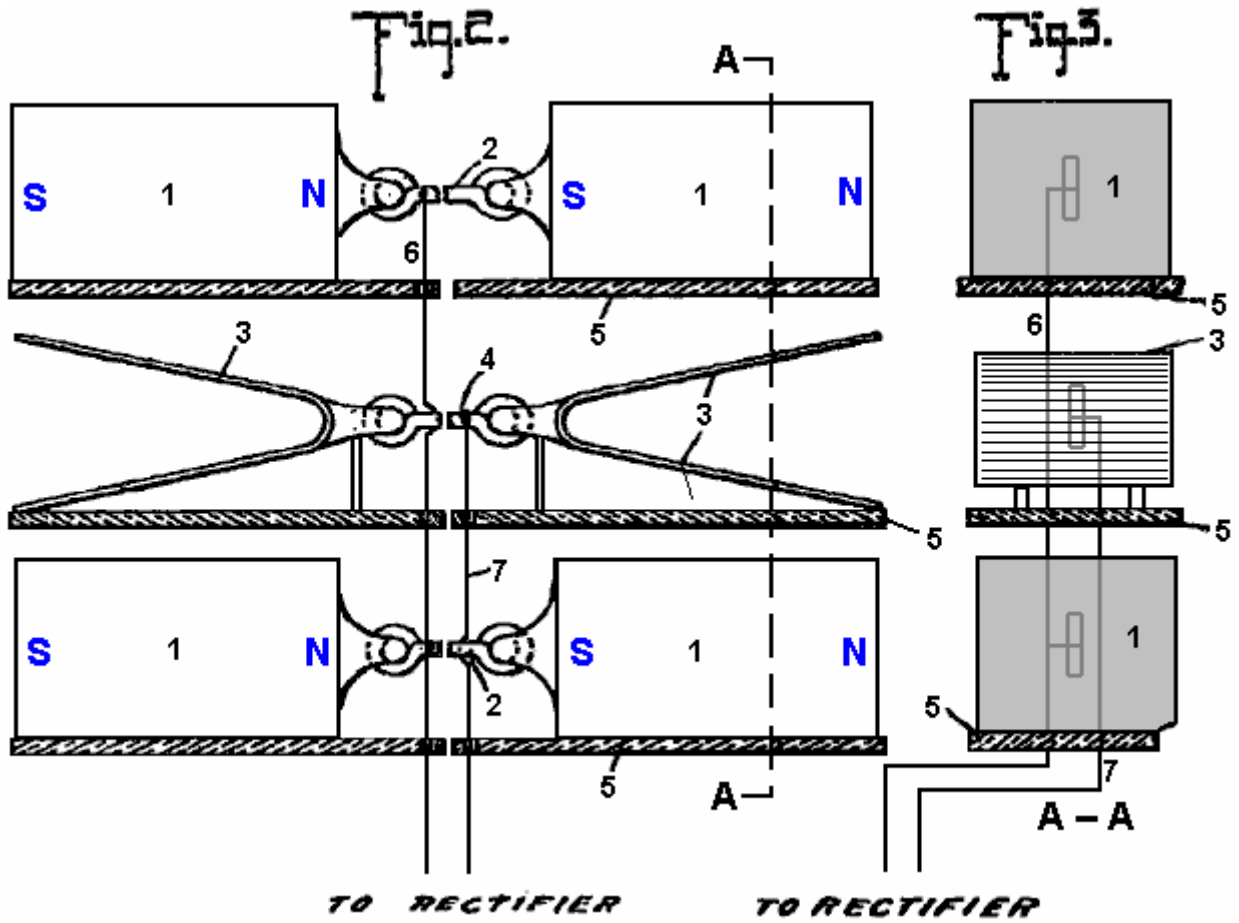

Fig.2 is a view is side elevation of the parts seen in plan in **Fig.1**
Fig.3 is a vertical section taken on the plane indicated by the line **A--A** of **Fig.2**.

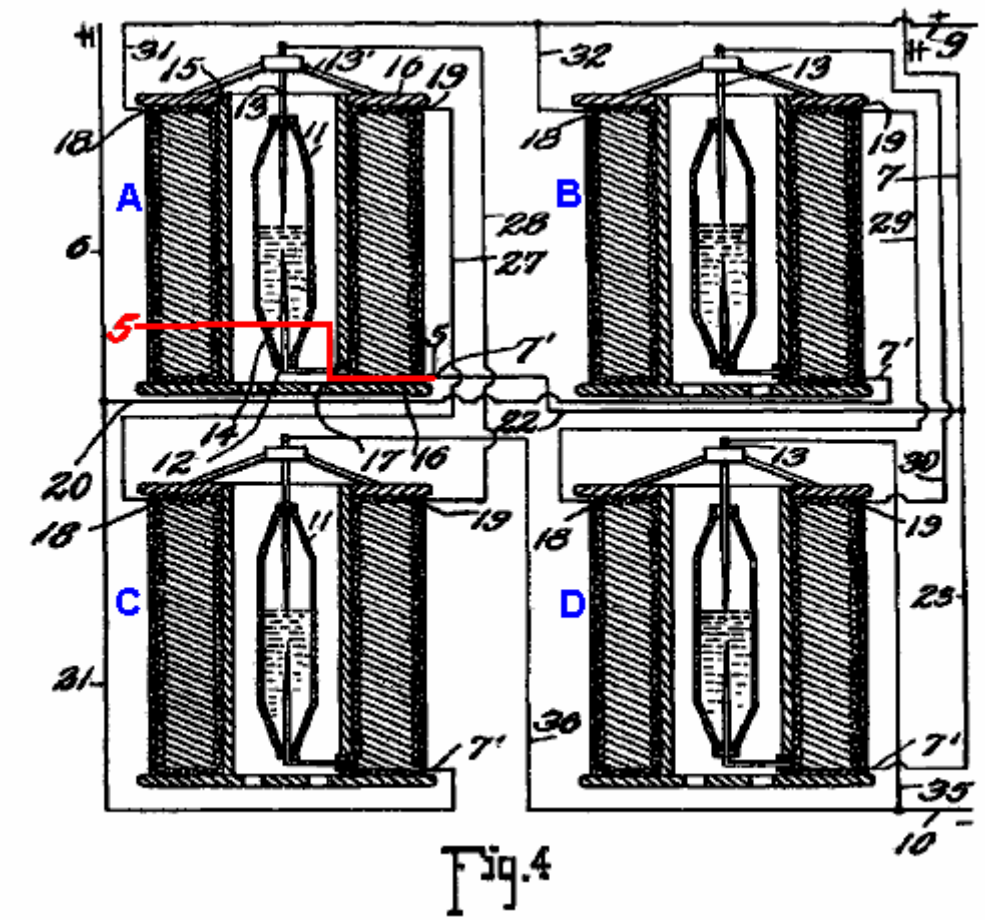

Fig.4 is a detail view, partly in elevation and partly in section, showing the connections of the converter and intensifier.

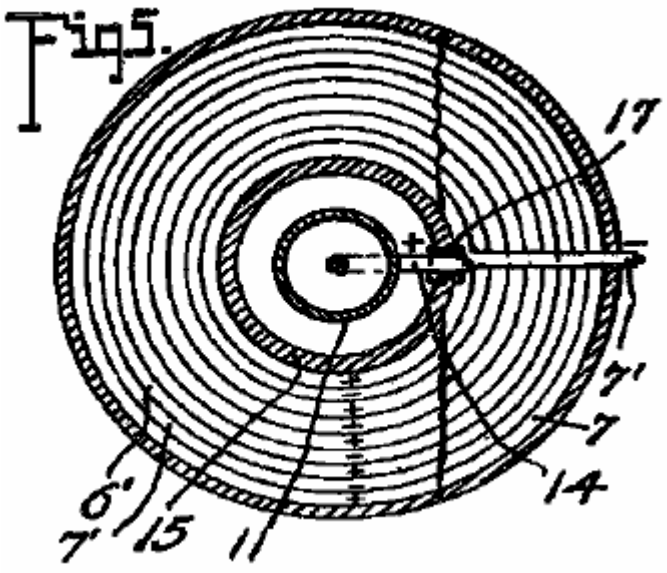

Fig.5 is a transverse section taken on the planes indicated by line **5-5** of **Fig.4**, looking downwards.

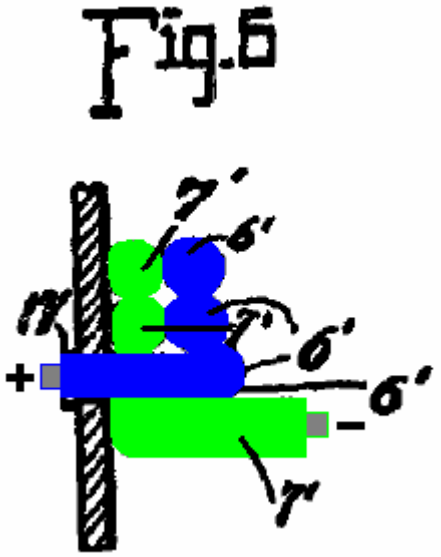

Fig.6 is an enlarged detail fragmentary section illustrating the parts at the junction of the conductors and one of the intensifiers.

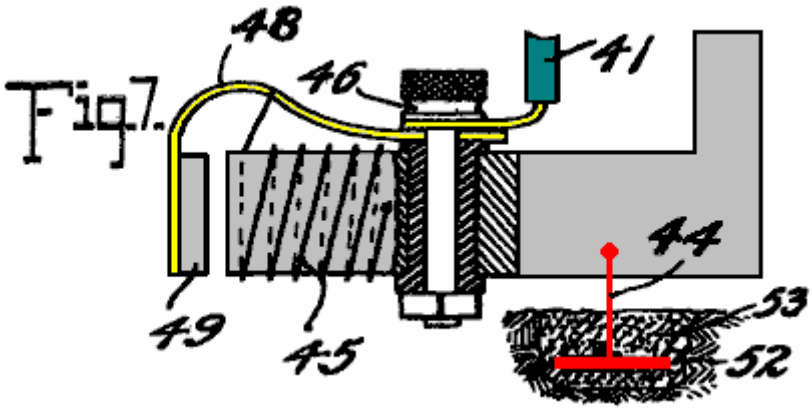

Fig.7 is an enlarged detail view partly in elevation and partly in section of one of the automatic cut-outs

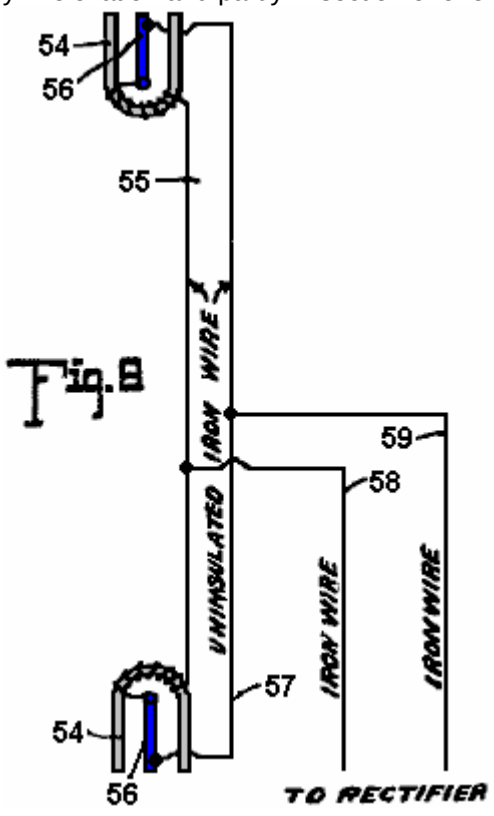

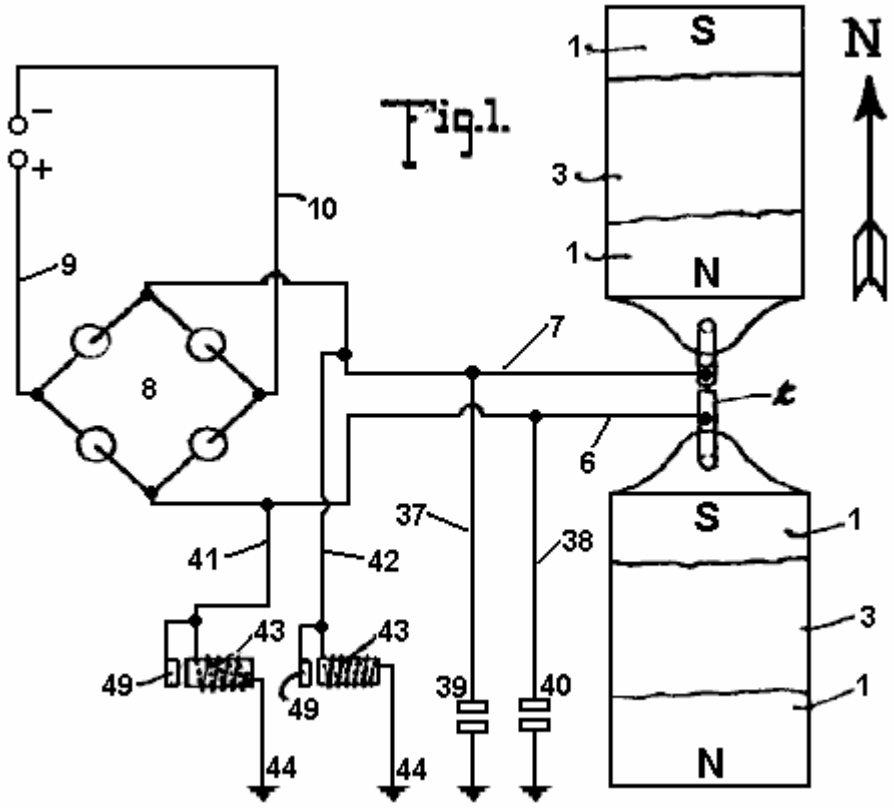

Fig.8 is a diagrammatic view of one of the simplest forms of embodiment of the invention.

Referring to the drawing by numerals, **1,1** indicates magnets connected by a magnetic substance **2**, preferably an iron wire. The magnets **1** are arranged in pairs, one pair being spaced beneath the other, and interposed between the magnets are zinc plates **3,3** connected by an iron wire conductor **4**. Suitable insulating supports **5** are arranged for sustaining the respective magnets **1** and plates **3,3**. Each plate **3** is preferably bent substantially into V form, as clearly seen in **Fig.1**, and the V of one of the plates opens or faces toward the North and the V of the other plate to the South. I have determined by experimentation that it is essential that the plates **3** be disposed substantially North and South with their flat faces approximately parallel to the adjacent faces of the co-operating magnets, although by experience I have not discovered any material difference in the current obtained when the plates are disposed slightly to one side of North and South, as for instance when the plates are disposed slightly to one side of North and South, as for instance when disposed in the line of the magnetic polarity of the earth. The same is true with respect to the magnets **1**, the said magnets being disposed substantially North and South for operative purposes, although I find that it is immaterial whether the North pole of one of the magnets is disposed to the North and the South pole to the South, or vice versa, and it is my conviction from experience that it is essential to have the magnets of each pair connected by magnetic material so that the magnets substantially become one with a pole exposed to the North and a pole exposed to the South.

In **Fig.1**, I have indicated in full lines by the letters **8** and **N** the respective polarities of the magnets **1**, and have indicated in dotted lines the other pole of those magnets when the connection **2** is severed. I have found that the magnets and zinc plates operate to produce, (whether by collection or generation I am not certain), electrical currents when disposed substantially North and South, but when disposed substantially East and West, no such currents are produced. I also find that the question of elevation is by no means vital, but it is true that more efficient results are obtained by placing the zincs and magnets on elevated supports. I furthermore find from tests, that it is possible to obtain currents from the apparatus with the zincs and magnets disposed in a building or otherwise enclosed, although more efficient results are obtained by having them located in the open.

While in **Figures 1, 2,** and **3**, I have shown the magnets and the zinc plates as superimposed, it will be apparent, as described in detail below, that these elements may be repositioned in horizontal planes, and substantially the same results will be secured. Furthermore, the magnets **1** with the interposed zincs **3**, as shown in **Figures 1, 2** and **3** merely represent a unit which may be repeated either horizontally or vertically for increasing the current supply, and when the unit is repeated the zinc plates are arranged alternating with the magnets throughout the entire series as indicated below.

A conductor **6** is connected in multiple with the conductors **2** and a conductor **7** is connected with conductor **4**, the conductor **6** extending to one terminal of a rectifier which I have indicated by the general reference character **8**, and the conductor **7** extending to the other terminal of the rectifier. The rectifier as seen in the diagram **Fig.1** may

assume any of several well known embodiments of the electrical valve type and may consist of four asymmetric cells or Cooper-Hewitt mercury vapour lamps connected as indicated in **Fig.1** for permitting communication of the positive impulses from the conductor **6** only to the line conductor **9** and the negative impulses from conductor **6** on only to the line conductor **10**. The current from this rectifier may be delivered through the conductors **9** and **10** to any suitable source for consumption.

While the said rectifier **8** may consist of any of the known types, as above outlined, it preferably consists of a specially constructed rectifier which also has the capacity of intensifying the current and comprises specifically the elements shown in detail in **Figures 4, 5,** and **6** wherein I have disclosed the detail wiring of the rectifier when composed of four of the rectifying and intensify in elements instead of asymmetric cells or simple mercury vapour valves. As each of these structures is an exact embodiment of all the others, one only will be described, and the description will apply to all. The rectifying element of each construction consists of a mercury tube **11** which is preferably formed of glass or other suitable material, and comprises a cylinder having its end portions tapered and each terminating in an insulating plug or stopper **12**. Through the upper stopper **12** is extended the electrode **13** which extends well into the tube and preferably about one-half its length, to a point adjacent the inner end of an opposing electrode **14** which latter electrode extends from there down through the insulation **12** at the lower end of the tube. The tube **11** is supplied with mercury and is adapted to operate on the principle of the mercury vapour lamp, serving to rectify current by checking back impulses of one sign and permitting passage of impulses of the other.

To avoid the necessity for utilising a starter, as is common with the lamp type of electrical valve, the supply of mercury within the tube may be sufficient to contact with the lower end of the electrode **13** when current is not being supplied, so that as soon as current is passed from one electrode to the other sufficiently for volatilising that portion of the mercury immediately adjacent the lower end of electrode **13**, the structure begins its operation as a rectifier. The tube **11** is surrounded by a tube **15** which is preferably spaced from tube **11** sufficiently for allowing atmospheric or other cooling circulation to pass the tube **11**. In some instances, it may be desirable to cool the tube **11** by a surrounding body of liquid, as mentioned below. The tube **15** may be of insulating material but I find efficient results attained by the employment of a steel tube, and fixed to the ends of the of the tube are insulating disks **16**, **16** forming a spool on which are wound twin wires **6'** and **7'**, the wire **6'** being connected at the inner helix of the coil with the outer end of the electrode **14**, the lower portion of said electrode being extended to one side of the tube **11** and passed through an insulating sleeve **17** extending through the tube **15**, and at its outer end merging into the adjacent end of the wire **6'**. The wire **7'** extends directly from the outer portion of the spool through the several helices to a point adjacent to the junction of the electrode **14** with wire **6'** and thence continues parallel to the wire throughout the coil, the wire **6'** ending in a terminal **18** and the wire **7'** ending in a terminal **19**.

For the sake of convenience of description and of tracing the circuits, each of the apparatus just above described and herein known as an intensifier and rectifier will be mentioned as **A**, **B**, **C** and **D**, respectively. Conductor **6** is formed with branches **20** and **21** and conductor **7** is formed with similar branches **22** and **23**. Branch **20** from conductor **6** connects with conductor **7'** of intensifier **B** and branch **21** of conductor **6** connects with the conductor **7'** of intensifier **C**, while branch **22** of conductor **7** of intensifier **C**, while branch **22** of conductor **7** connects with conductor **7'** of intensifier **D**. A conductor **27** is connected to terminal **19** of intensifier **A** and extends to and is connected with the terminal **18** of intensifier **C**, and a conductor **7** connects with conductor **7'** of intensifier **D**. A conductor **27** is connected to terminal **19** of intensifier **A**, and extends to and is connected to terminal **18** of intensifier **C**, and a conductor **28** is connected to the terminal **19** of intensifier **C** and extends from the terminal **19** of intensifier **B** to the terminal **18** of intensifier **D** to electrode **13** of intensifier **B**. Each electrode **13** is supported on a spider **13'** resting on the upper disk **16** of the respective intensifier. Conductors **31** and **32** are connected to the terminals **18** of intensifiers **A** and **B** and are united to form the positive line wire **9** which co-operates with the negative line wire **10** and extends to any suitable point of consumption. The line wire **10** is provided with branches **35** and **36** extending to the electrodes **13** of intensifiers **C** and **D** to complete the negative side of the circuit.

Thus it will be seen that alternating currents produced in the wires **6** and **7** will be rectified and delivered in the form of a direct current through the line wires **9** and **10**, and I find by experiment that the wires **6** and **7** should be of iron, preferably soft, and may of course be insulated, the other wiring not specified as iron being of copper or other suitable material.

In carrying out the operation as stated, the circuits may be traced as follows: A positive impulse starting at the zincs **3** is directed along conductor **7** to branch **23** to conductor **7'** and the winding of the rectifier of intensifier **B** through the rectifier to the conductor **6'**, through its winding to the contact **18**, conductor **32** and to the line wire **9**. The next, or negative, impulse directed along conductor **7** cannot find its way along branch **23** and the circuit just above traced because it cannot pass across the rectifier of intensifier **B** but instead the negative impulse passes along conductor **22** to conductor **7** of intensifier **A** and its winding to the contact **19** and to conductor **27** to contact **18** of intensifier **C**, to the winding of the wire **6'** thereof to the electrode **14** through the rectifier to the of the

electrode **13** and conductor of intensifier **A**, electrode **14** thereof and conductor **6'** to contact **18** and wire **31** to line wire **9**.

Obviously the positive impulse cannot pass along the wire **20** because of its inverse approach to the rectifier of intensifier **B**. The next impulse or negative impulse delivered to conductor **6** cannot pass along conductor **21** because of its connection with electrode **13** of the rectifier of intensifier **A**, but instead passes along conductor **20** to the wire **7'** and its winding forming part of intensifier **B** to the contact **19** and conductor **29** to contact **18** and the winding of wire **6'** of intensifier **D** to the electrode **14** and through the rectifier to the electrode **13** and conductor **35** to line wire **10**. Thus the current is rectified and all positive impulses directed along one line and all negative impulses along the other lie s that the potential difference between the two lines will be maximum for the given current of the alternating circuit. It is, of course, apparent that a less number of intensifiers with their accompanying rectifier elements may be employed with a sacrifice of the impulses which are checked back from a lack of ability to pass the respective rectifier elements, and in fact I have secured efficient results by the use of a single intensifier with its rectifier elements, as shown below.

Grounding conductors **37** and **38** are connected respectively with the conductors **6** and **7** and are provided with the ordinary lightning arresters **39** and **40** respectively for protecting the circuit against high tension static charges.

Conductors **41** and **42** are connected respectively with the conductors **6** and **7** and each connects with an automatic cut-out **43** which is grounded as at **4**. Each of the automatic cut-outs is exactly like the other and one of the these is shown in detail in **Fig.7** and comprises the inductive resistance **45** provided with an insulated binding post **46** with which the respective conductor **6** or **7** is connected, the post also supporting a spring **48** which sustains an armature **49** adjacent to the core of the resistance **45**. The helix of resistance **45** is connected preferably through the spring to the binding post at one end and at the other end is grounded on the core of the resistance, the core being grounded by ground conductor **44** which extends to the metallic plate **52** embedded in moist carbon or other inductive material buried in the earth. Each of the conductors **41**, **42** and **44** is of iron, and in this connection I wish it understood that where I state the specific substance I am able to verify the accuracy of the statement by the results of tests which I have made, but of course I wish to include along with such substances all equivalents, as for instance, where iron is mentioned its by-products, such as steel, and its equivalents such as nickel and other magnetic substances are intended to be understood.

The cut-out apparatus seen in detail in **Fig.7** is employed particularly for insuring against high voltage currents, it being obvious from the structure shown that when potential rises beyond the limit established by the tension of the spring sustaining the armature **40**, the armature will be moved to a position contacting with the core of the cut-out device and thereby directly close the ground connection for line wire **41** with conductor **44**, eliminating the resistance of winding **45** and allowing the high voltage current to be discharged to the ground. Immediately upon such discharge the winding **45** losing its current will allow the core to become demagnetised and release the armature **49** whereby the ground connection is substantially broken leaving only the connection through the winding **45** the resistance of which is sufficient for insuring against loss of low voltage current.

In **Fig.8** I have illustrated an apparatus which though apparently primitive in construction and arrangement shows the first successful embodiment which I produced in the course of discovery of the present invention, and it will be observed that the essential features of the invention are shown there. The structure shown in the figure consists of horseshoe magnets **54**, **55**, one facing North and the other South, that is, each opening in the respective directions indicated and the two being connected by an iron wire **55** which is uninsulated and wrapped about the respective magnets each end portion of the wire **55** being extended from the respective magnets to and connected with, as by being soldered to, a zinc plate **56**, there being a plate **56** for each magnet and each plate being arranged longitudinally substantially parallel with the legs of the magnet and with the faces of the plate exposed toward the respective legs of the magnet, the plate being thus arranged endwise toward the North and South. An iron wire **57** connects the plates **56**, the ends of the wire being preferably connected adjacent the outer ends of the plates but from experiment I find that the wire may be connected at practically any point to the plate. Wires **58** and **59** are connected respectively with the wires **55** and **57** and supply an alternating current at a comparatively low voltage, and to control such current the wires **58** and **59** may be extended to a rectifier or combined rectifier and intensifier, as discussed above.

The tests which I have found successful with the apparatus seen in **Fig.8** were carried out by the employment first of horseshoe magnets approximately 4 inches in length, the bar comprising the horseshoe being about one inch square, the zincs being dimensioned proportionately and from this apparatus with the employment of a single intensifier and rectifier, as above stated, I was able to obtain a constant output of 8 volts.

It should be obvious that the magnets forming one of the electrodes of this apparatus may be permanent or may be electromagnets, or a combination of the two.

While the magnets mentioned throughout the above may be formed of any magnetic substance, I find the best results obtained by the employment of the nickel chrome steel.

While the successful operation of the various devices which I have constructed embodying the present invention have not enabled me to arrive definitely and positively at fixed conclusion relative to the principles and theories of operation and the source from which current is supplied, I wish it to be understood that I consider myself as the first inventor of the general type described above, capable of producing commercially serviceable electricity, for which reason my claims hereinafter appended contemplate that I may utilise a wide range of equivalents so far as concerns details of construction suggested as preferably employed.

The current which I am able to obtain is dynamic in the sense that it is not static and its production is accomplished without chemical or mechanical action either incident to the actual chemical or mechanical motion or incident to changing caloric conditions so that the elimination of necessity for the use of chemical or mechanical action is to be considered as including the elimination of the necessity for the use of heat or varying degrees thereof.

Pat. Application US 2006/0082,334 20th April 2006 Inventors: Paulo & Alexandra Correa

ENERGY CONVERSION SYSTEMS

This patent application shows the details of devices which can produce ordinary electricity from Tesla longitudinal waves. If these claims are correct (and there does not appear to be the slightest reason for believing that they are not), then implementations of this patent application are capable of producing free electrical power and the importance of this information is enormous.

ABSTRACT

This invention relates to apparatus for the conversion of mass-free energy into electrical or kinetic energy, which uses in its preferred form a transmitter and a receiver both incorporating Tesla coils, the distal ends of whose secondary windings are co-resonant and connected to plates of a chamber, preferably evacuated or filled with water, such that energy radiated by the transmitter may be picked up by the receiver, the receiver preferably further including a pulsed plasma reactor driven by the receiver coil and a split phase motor driven by the reactor. Preferably the reactor operates in pulsed abnormal gas discharge mode, and the motor is an inertially dampened drag motor. The invention also extends to apparatus in which an otherwise driven plasma reactor operating in pulsed abnormal gas discharge mode in turn used to drive an inertially dampened drag motor.

DESCRIPTION

This is a continuation of application Ser. No. 09/907,823, filed Jul. 19, 2001.

FIELD OF THE INVENTION

This invention relates to systems for the conversion of energy, inter alia in the form of what we will refer to for convenience as Tesla waves (see below), to conventional electrical energy.

BACKGROUND OF THE INVENTION

Energy converters that are fed by local or environmental energy are usually explained by taking recourse to the notion that they convert zero point electromagnetic radiation (ZPE) to electric energy. The ZPE theories have gained a life of their own, as T. Kuhn has pointed out (in his "Black Body Theory and the Quantum"), after emerging from Planck's second theory, specifically from the term ½ hυ in the new formula for oscillator energy. In 1913, Einstein and Stern suggested that motional frequencies contributing to specific heat fell into two categories--those that were independent of temperature and those that were not (e.g. rotational energy), leading them to conclude that zero-point energy on the order of ½ hυ was most likely. In the second part of their paper, however, they provided a derivation of Planck's Law without taking recourse to discontinuity, by assuming that the value of the ZPE was simply ha. It is worth noting that Einstein had already in 1905 ("Erzeugung und Verwandlung des Lichtes betreffenden heuristichen Gesichtspunkt",Ann. d. Phys, 17, 132) framed the problem of discontinuity, even if only heuristically, as one of placing limits upon the infinite energy of the vacuum state raised by the Rayleigh-Jeans dispersion law. According to Einstein, the Rayleigh-Jeans law would result in an impossibility, the existence of infinite energy in the radiation field, and this was precisely incompatible with Planck's discovery - which suggested instead, that at high frequencies the entropy of waves was replaced by the entropy of particles. Einstein, therefore, could only hope for a stochastic validation of Maxwell's equations at high frequencies "by supposing that electromagnetic theory yields correct time-average values of field quantities", and went on to assert that the vibration-energy of high frequency resonators is exclusively discontinuous (integral multiples of hυ).

Since then, ZPE theories have gone on a course independent from Planck's second theory. The more recent root of modern ZPE theories stems from the work of H. Casimir who, in 1948, apparently showed the existence of a force acting between two uncharged parallel plates. Fundamentally the Casimir effect is predicated upon the existence of a background field of energy permeating even the “vacuum”, which exerts a radiation pressure, homogeneously and from all directions in space, on every body bathed in it. Given two bodies or particles in proximity, they shield one another from this background radiation spectrum along the axis (i.e. the shortest distance) of their coupling, such that the radiation pressure on the facing surfaces of the two objects would be less than the radiation pressure experienced by all other surfaces and coming from all other directions in space. Under these conditions, the two objects are effectively pushed towards one another as if by an attractive force. As the distance separating the two objects diminishes, the force pushing them together increases until they collapse one on to the other. In this sense, the Casimir effect would be the macroscopic analogy of the microscopic van der Waals forces of attraction responsible for such dipole-dipole interactions as hydrogen bonding. However, it is worth noting that the van der Waals force is said to tend to establish its normal radius, or

the optimal distance between dipoles, as the distance where the greatest attractive force is exerted, beyond which the van der Waals forces of nuclear and electronic repulsion overtake the attraction force.

Subsequently, another Dutch physicist, M. Sparnaay, demonstrated that the Casimir force did not arise from thermal radiation and, in 1958, went on to attribute this force to the differential of radiation pressure between the ZPE radiation from the vacuum state surrounding the plates and the ZPE radiation present in the space between them. Sparnaay's proposal is that a classical, non-quantal, isotropic and ubiquitous electromagnetic zero-point energy exists in the vacuum, and even at a temperature of absolute zero. It is further assumed that since the ZPE radiation is invariant with respect to the Lorentz transformations, it obeys the rule that the intensity of its radiation is proportional to the cube of the frequency, resulting in an infinite energy density for its radiation spectrum.

What appeared to be the virtue of this reformulated theory was the notion that the vacuum no longer figured as pure space empty of energy, but rather as a space exposed to constantly fluctuating “fields of electromagnetic energy”.

Puthoff has utilised the isomorphism between van der Waals and Casimir forces to put forth the zero-point (ZP) energy theory of gravity, based on the interpretation that the virtual electromagnetic ZP field spectrum predicted by quantum electrodynamics (QED) is functionally equivalent to an actual vacuum state defined as a background of classical or Maxwellian electromagnetic radiation of random phases, and thus can be treated by stochastic electrodynamics (SED). Whereas in QED, the quanta are taken as virtual entities and the infinite energy of the vacuum has no physical reality, for SED, the ZPE spectrum results from the distortion of a real physical field and does not require particle creation. Gravity then, could be seen as only the macroscopic manifestation of the Casimir force.

We do not dispute the fact that even in space-absent matter, there is radiant energy present which is not of a thermal nature. But we claim that this energy is not electromagnetic, nor is its energy spectrum-infinite. That this is so, stems not just from our opinion that it is high time that Einstein's heuristic hypothesis should be taken as literally factual - in the dual sense that all electromagnetic energy is photon energy and all photons are local productions, but above all from the fact that it is apparent, from the experiments of Wang and his colleagues (Wang, Li, Kuzmich, A & Dogariu, A. "Gain-assisted superluminal light propagation", Nature 406; #6793; 277), that the photon stimulus can propagate at supraluminal speeds and lies therefore well outside of any scope of electromagnetic theory, be this Maxwell's classical approach taken up by ZPE theories, or Einstein's special relativistic phenomenology of Maxwell's theory. The fact is, that if the light stimulus can propagate at speeds greater than those of light, then what propagates is not light at all, and thus not energy configured electromagnetically. Light is solely a local production of photons in response to the propagation of a stimulus that itself is not electromagnetic.

It is critical to understand that the implication from this, that - aside from local electromagnetic radiation and from thermal radiation associated with the motions of molecules (thermo-mechanical energy), there is at least one other form of energy radiation which is everywhere present, even in space-absent matter. Undoubtedly, it is that energy which prevents any attainment of absolute zero, for any possible local outpumping of heat is matched by an immediate local conversion of some of this energy into a minimum thermal radiation required by the manifolds of Space and Time. Undoubtedly also, this radiation is ubiquitous and not subject to relativistic transformations (i.e. it is Lorentz invariant). What it is not, is electromagnetic radiation consisting of randomistic phases of transverse waves.

To understand this properly, one must summarise the differences from existing ZPE theories - and all these differences come down to the fact that this energy, which is neither electromagnetic nor thermal per se, (and is certainly not merely thermo-mechanical), has nevertheless identifiable characteristics both distributed across sub-types or variants and also common to all of them.

Essentially, the first sub-type or variant consists of longitudinal mass-free waves which deploy electric energy. They could well be called Tesla waves, since Tesla-type transformers can indeed be shown experimentally to radiate mass-free electric energy, in the form of longitudinal magnetic and electric waves having properties not reducible to photon energy nor to “electromagnetic waves”, and having speeds of displacement which can be much greater than the limit c for all strictly electromagnetic interactions.

One may well denote the second sub-type by the designation of mass-free thermal radiation, since it contributes to temperature changes - and, as obviously indicated by the impossibility of reaching an absolute zero of temperature, this contribution occurs independently of the presence of matter, or mass-energy, in Space. In other words, not all thermal radiation can be reduced to vibration, rotation and translation (drift motion) of molecules, i.e. to thermomechanical energy, because the properties of pressure and volume which determine temperature and affect matter, appear indeed to a great extent to be independent from matter, a fact which itself is responsible for the observed catastrophic and unexpected phase changes of matter and has required to this day the insufficient explanation offered semi-empirically by the Van der Waals Force Law.

Finally, the third sub-type may be designated latent mass-free energy radiation - since it deploys neither charge, nor thermal or baroscopic effects, and yet it is responsible for "true latent heat" or for the "intrinsic potential energy" of a molecule. It is also responsible for the kineto-regenerative phenomenon whereby an electroscope performs a variable charge-mediated work against the local gravitational field.

The common characteristic of all three sub-types of mass-free energy radiation is that they share the same non-classical fine structure, written as follows for any energy unit, where **c** is any speed of light wave function, and the wavelength λ and wave function W are interconnected as a function of the physical quality of the energy field under consideration: $E=\lambda cW$

In the instance of longitudinal electric radiation, this takes on the directly quantifiable form:

$$E=(\lambda_q c)W_v=p_e W_v=(h/\lambda_x)W_v=\int=qV$$

where:

W_V is the voltage-equivalent wave function corresponding to V,

P_e constitutes the linear momentum corresponding to the conventional q or e,

h is the Planck constant,

λ_x is the Duane-Hunt constant expressed as a wavelength,

λ_q is a wavelength constant; and the sign

$=\int=$ signifies exact equality between an expression in the conventional dimensions of length, mass and time, and an expression in length and time dimensions alone.

In the instance of mass-free thermal radiation (contributing to temperature changes), the transformation obeys Boltzmann's rule (**k** is now Boltzmann's constant and T is Kelvin-scale temperature):

$$E=\lambda_{n1}cW_{n1}=\lambda_{n1}(\pi_V\zeta_p)(\lambda_{n1})\sim=kT$$

and in the third instance - of latent mass-free radiation, the transformation obeys the rule:

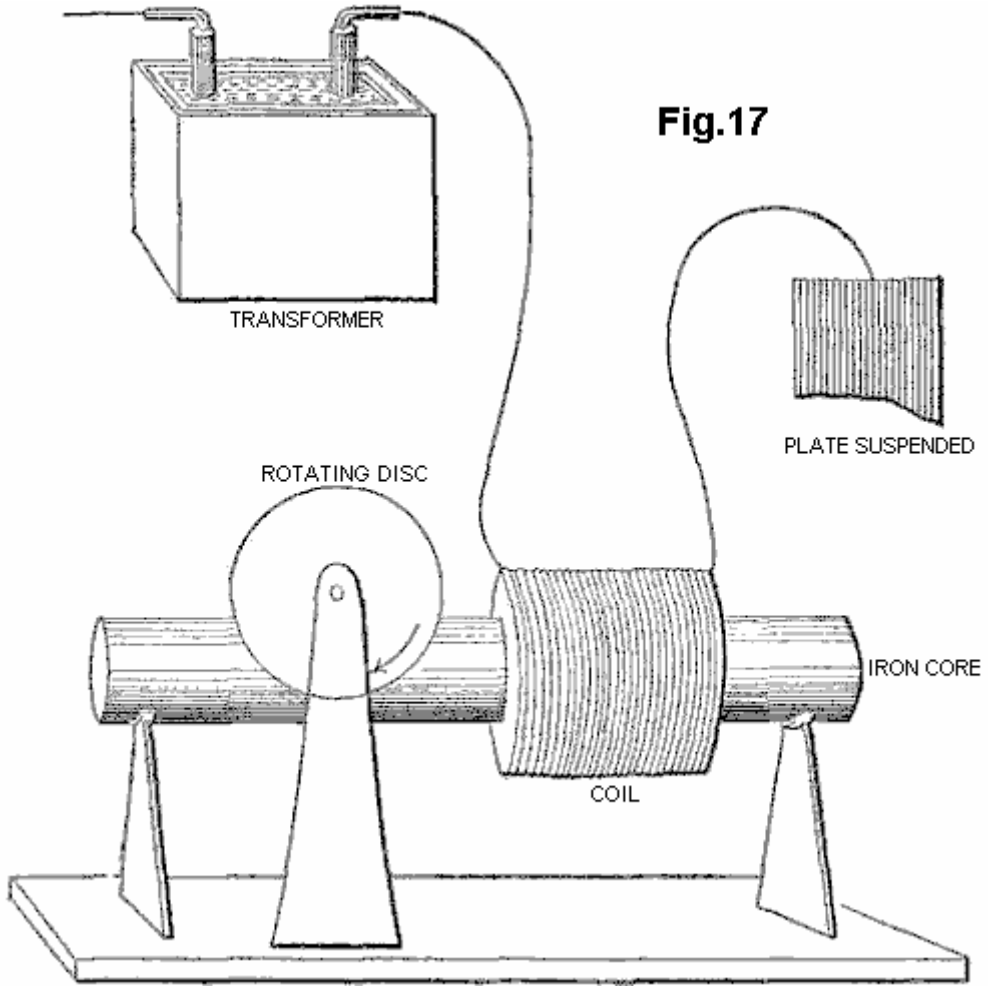
$$E=\lambda_{n1}cW_{n1} = \lambda_{n1}(\lambda_{n1}\zeta_{n1})(\lambda_{n1}f_{n1}) = \lambda_{n1}{}^3\zeta_{n1}f_{n1}$$

where ζ and f are frequency functions, f being a specific gravitational frequency term, and f_{n1} being defined as equal to $(\lambda_{n1})^{-0.5}\text{meter}^{0.5}\text{sec}^{-1}$ and ζ_{n1} has the value of c/λ_{n1}

If the electric variant of mass-free radiation has a direct quantum equivalence, via the Duane-Hunt Law, none of the three primary aether energy variants possess either the classic form of electromagnetic energy which requires square superimposition of speed of light wave functions **c**, as $\mathbf{c^2}$, or the quantum form of energy, requiring $E = h\nu$. The critical first step in the right direction may well be attributed to Dr. W. Reich, as it regards the fact that mass-free energy couples two unequal wave functions, only one of which is electromagnetic and abides by the limit **c**. We then unravelled the threefold structure described above, and further showed that, in the case of longitudinal electric waves, the postulated equivalence $(q=\lambda_q c)$ is merely phenomenological, as these waves are not restricted by the function **c** in their conveying of electric charge across space. It can further be demonstrated that all black-body photons are bound by an upper frequency limit (64×10^{14} Hz), above which only ionising photons are produced, and that all black-body photons arise precisely from the interaction of mass-free electric radiation with molecules of matter (including light leptons), whereby the energy of that radiation is locally converted into photon or electromagnetic radiation. In other words, all non-ionising electromagnetic energy appears to be secondary energy which results locally from the interaction of matter with mass-free electric energy. It cannot therefore consist of the primary energy that is present in the vacuum, an energy that is neither virtual nor electromagnetic, but actual and concrete in its electric, thermal and antigravitic manifestations. Lastly, gravitational energy, being either the potential or the kinetic energy responsible for the force of attraction between units of matter, is a manifestation that also requires, much as electromagnetic radiation does, coupling of mass-free energy to matter or to mass-energy.

The Tesla coil is a generator of a mass-free electric energy flux which it transmits both by conduction through the atmosphere and by conduction through the ground. Tesla thought it did just that, but it has been since regarded instead (because of Maxwell, Hertz and Marconi) as a transmitter of electromagnetic energy. The transmitter operates by a consumption of mass-bound electric power in the primary, and by induction it generates in the

coupled secondary two electric fluxes, one mass-bound in the coil conductor, and the other mass-free in the body of the solenoid. Tesla also proposed and demonstrated a receiver for the mass-free energy flux in the form of a second Tesla coil resonant with the first. The receiver coil must be identical and tuned to the transmitter coil; the capacitance of the antenna plate must match that of the transmitter plate; both transmitter and receiver coils must be grounded; and the receiver coil input and output must be unipolar, as if the coil were wired in series.



The generators of mass-free energy with which we are concerned, provide current pulses associated with a dampened wave (DW) oscillation of much higher frequency than the pulse repetition frequency. A particular problem in recovering the mass-free energy content of such pulses is provided by the dampened wave oscillations. Although in our U.S. Pat. No. 5,416,391 we describe arrangements incorporating split phase motors to recover such energy, their efficiency is a great deal less than what should theoretically be attainable. Other workers such as Tesla and Reich, have encountered the same problem to an even greater degree.

In nineteenth century motor engineering terminology, dynamos capable of producing direct current by continuous homopolar induction were known as “unipolar” generators. The term “unipolar induction” appears to have originated with W. Weber, to designate homopolar machines where the conductor moves continuously to cut the magnetic lines of one kind of magnetic pole only, and thus require sliding contacts to collect the generated current. Faraday's rotating copper disc apparatus was, in this sense, a homopolar generator when the disc was driven manually, or a homopolar motor when the current was provided to it. Where the rotating conductor continuously cuts the magnetic field of alternatingly opposite magnetic poles, the operation of a machine, whether a generator or a motor, is said to be “heteropolar”. Unipolar machines went on to have a life of their own in the form of low voltage and high current DC generators - from Faraday, through Plucker, Varley, Siemens, Ferraris, Hummel, to Lord Kelvin, Pancinoti, Tesla and others - almost exclusively in the form of disc dynamos, but some having wound rotors.

In Mordey's alternator, and in so-called “inductor alternators”, however, homopolar generators were employed to obtain alternating currents, with the use of rotors wound back and forth across the field. Use of smooth, unwound rotors in AC induction motors (as opposed to AC synchronous motors, such as hysteresis motors) was a later development than homopolar dynamos. By 1888, Tesla and Ferraris amongst still others, had independently produced rotating magnetic fields in a motor, by employing two separate alternate currents with the same frequency but different phase. Single phase alternate current motors were developed later, and split-phase motors were developed last. Ferraris (Ferraris, G (1888) "Rotazioni elettrodynamiche", Turin Acad, March issue.) proposed the elementary theory of the 2-phase motor, where the current induced in the rotor is proportional to the slip (the difference between-the angular velocity of the magnetic field and that of the rotating cylinder), and the power of the motor is proportional to both the slip and the velocity of the rotor.

If an iron rotor is placed within the rotating magnetic field of a 2-phase stator, it will be set in rotation, but not synchronously, given that it is always attracted to the moving magnetic poles with a lag. But if an aluminium or copper rotor is used instead, it gets “dragged” around by the rotating stator field because of the eddy currents induced in it. If the aluminium or copper rotor were to rotate synchronously with the stator magnetic field, there would be no induced eddy currents and thus no motor action would result. The motor action depends, in this instance, upon the presence of asynchronous slip, since the function of the latter is to sustain the induction of those currents in the rotor that are responsible for the motor action of the dragged rotor. This then is the origin of the term “AC drag motors”. Once the drag rotor evolved from a cylinder to a hollow cup, they earned the epithet of “drag-cup motors”. Later, already in the 20th century, the cups were fitted over a central stator member, and the sleeve rotor 2-phase servo motor was born.

Tesla knew that impulse currents as well as CW (constant wave) sinusoidal currents could be used to drive AC motors. Regarding his invention of a hysteresis motor (which he called a “magnetic lag motor”), he stated: " . . . pulsatory as well as an alternating current might be used to drive these motors . . . " (Martin, T C (1894) "The inventions, researches and writings of Nikola Tesla", Chapter XII, p. 68). In his search for efficient utilisation of the high frequency DW (dampened wave) impulse currents of his induction coils, Tesla began by employing an AC disc induction motor as shown in Fig.17 of his famous 1892 address (Tesla, N (1892) "Experiments with alternate currents of high potential and high frequency", in "Nikola Tesla Lectures", 1956, Beograd, pp. L-70-71). This consisted of a copper or aluminium disc mounted vertically along the longitudinal axis of an iron core on which was wound a single motor coil which was series wired to the distal terminal of an induction coil at one end, and to a large suspended and insulated metal plate at the other. What was new about this was the implementation of an AC disc induction motor drive, where the exciting current travelled directly through the winding with just a unipolar connection to the coil secondary (under certain conditions, even the series connection to the plate could be removed, or replaced with a direct connection to the experimenter's body): "What I wish to show you is that this motor rotates with one single connection between it and the generator" (Tesla, N. (1892), op. cit., L-70, Tesla's emphasis). Indeed, he had just made a critical discovery that, unlike in the case of mass-bound charge where current flow requires depolarisation of a bipolar tension, mass-free charge engages current flow unipolarly as a mere matter of proper phase synchronisation:

Tesla thought that his motor was particularly adequate to respond to windings which had “high-self-induction”, such as a single coil wound on an iron core. The basis of this self-induction is the magnetic reaction of a circuit, or an element of a circuit - an inductor - whereby it chokes, dims or dampens the amplitude of electric waves and retards their phase.

For the motor to respond to still higher frequencies, one needed to wind over the primary motor winding, a partial overlap secondary, closed through a capacitor, since "it is not at all easy to obtain rotation with excessive frequencies, as the secondary cuts off almost completely the lines of the primary" (Idem, L-71.).

Tesla stated that "an additional feature of interest about this motor" was that one could run it with a single connection to the earth ground, although in fact one end of the motor primary coil had to remain connected to the large, suspended metal plate, placed so as to receive or be bathed by "an alternating electrostatic field", while the other end was taken to ground. Thus Tesla had an ordinary induction coil that transmitted this "alternating electrostatic field", an untuned Tesla antenna receiving this "field", and a receiver circuit comprising his iron-core wound motor primary, a closely coupled, capacitatively closed secondary, and the coupled non-ferromagnetic disc rotor. Eventually, in his power transmission system, he would replace this transmitter with a Tesla coil, and place an identical receiving coil at the receiving end, to tune both systems and bring them into resonance. But his motor remained undeveloped, and so did the entire receiver system.

Tesla returned to this subject a year later, saying "on a former occasion I have described a simple form of motor comprising a single exciting coil, an iron core and disc" (Tesla, N (1893) "On light and other high frequency phenomena", in "Nikola Tesla Lectures", 1956, Beograd, pp. L-130, and L-131 with respect to Fig.16-II). He describes how he developed a variety of ways to operate such AC motors unipolarly from an induction transformer, and as well other arrangements for "operating a certain class of alternating motors founded on the action of currents of differing phase". Here, the connection to the induction transformer is altered so that the motor primary is driven from the coarse secondary of a transformer, whose finer primary is coupled, at one end, directly and with a single wire to the Tesla secondary, and at the other left unconnected. On this occasion, Tesla mentions that such a motor has been called a “magnetic lag motor”, but that this expression (which, incidentally, he had himself applied to his own invention of magnetic hysteresis motors) is objected to by "those who attribute the rotation of the disc to eddy currents when the core is finally subdivided" (Tesla, N (1893), op. cit., p. L-130).

In none of the other motor solutions, 2-phase or split-phase, that he suggests as unipolar couplings to the secondary of an induction coil, does the non-ferromagnetic disc rotor motor again figure. But he returns to it a page later, and indirectly so, by first addressing the disadvantages of ferromagnetic rotors: "Very high frequencies are of course not practicable with motors on account of the necessity of employing iron cores. But one may use sudden discharges of low frequency and thus obtain certain advantages of high-frequency currents-without rendering the iron core entirely incapable of following the changes and without entailing a very great expenditure of energy in the core. I have found it quite practicable to operate, with such low frequency disruptive discharges of condensers, alternating-current motors."

In other words--whereas his experiments with constant wave (CW) alternating currents, and as well with high-voltage dampened wave (DW) impulses from induction coils, indicated the existence of an upper frequency limit to iron core motor performance, one might employ instead high-current, DW impulses - of high DW frequencies but low impulse rates - to move these motors quite efficiently. Then he adds "A certain class of [AC] motors which I advanced a few years ago, that contain closed secondary circuits, will rotate quite vigorously when the discharges are directed through the exciting coils. One reason that such a motor operates so well with these discharges is that the difference of phase between the primary and secondary currents is 90 degrees, which is generally not the case with harmonically rising and falling currents of low frequency. It might not be without interest to show an experiment with a simple motor of this kind, inasmuch as it is commonly thought that disruptive discharges are unsuitable for such purposes."

What he proposes next, forms the basis of modern residential and industrial AC electric power meters, the AC copper disc motor whose rotor turns on the window of these meters, propelled forward by the supply frequency. But instead of employing any such Constant Wave input, Tesla uses the disruptive discharges of capacitors, incipiently operating as current rectifiers. With the proper conditions, e.g. correct voltage from the generator, adequate current from the capacitor, optimum capacitance for the firing rate, and tuned spark-gap, to mention a few, Tesla found that the non-ferromagnetic disc rotor turned but with considerable effort. But this hardly compared to the results obtained with a high-frequency CW alternator, which could drive the disc "with a much smaller effort". In summary then, Tesla went as far as being the first to devise a motor driven by Tesla waves, that employed a non-ferromagnetic rotor, and whose arrangement encompassed both transmitter and receiver circuits. For this purpose, he employed a single-phase method in which the signal is fed unipolarly to the winding, placed in series with a plate capacitance.

Tesla also later proposed driving a similar single-phase non-ferromagnetic disc motor from bipolar capacitative discharges through an atmospheric spark-gap now placed in parallel with the main motor winding, and again simulating a split-phase by a closely-wound secondary which was closed by a capacitance.

As Tesla admits, the results of all his AC eddy current motor solutions were meagre and limited by current and frequency problems. Likewise, the two-phase arrangements proposed by Reich for his OR motor, involving a superimposition of the Dampened Waves of a first phase on a fixed Continuous Wave second phase, require an external power source and a pulse amplifier circuit, and failed to meet Reich's own requirements.

We have previously proposed the use of squirrel cage motors with capacitative splitting of phase to convert the Dampened Wave output of plasma pulsers, but once a Squirrel Cage is introduced, the dampening effect which the non-ferromagnetic copper cage exerts in being dragged by the revolving stator field, is counteracted by the ferromagnetic cylinder of laminated iron, in which the copper cage is embedded, working to diminish the slip and bring the rotor to near synchronism. This is, in all likelihood, what limits Squirrel Cage motors responding to the DC component of the Dampened Wave impulse, and thus be limited to respond to fluxes of mass-bound charges. Historically, as we shall see, the obvious advantage of the Squirrel Cage servo motors lay in the fact that, in particular for 2-phase applications, they were far more efficient at performing work without evolution of heat. Indeed, if the eddy currents in the non-ferromagnetic rotor are permitted to circulate in non-ordered form, the rotor material and stator will heat up rapidly and consume much power in that heating. This is in fact considered to be a weakness of AC non-ferromagnetic-rotor induction motors.

SUMMARY OF THE INVENTION

The present invention is concerned with conversion to conventional electrical energy of the variants of mass-free energy radiation considered above, referred to for convenience as Tesla waves, mass-free thermal radiation and latent mass-free radiation. The first variant of such radiation was recognised, generated and at least partially disclosed by Tesla about a hundred years ago, although his work has been widely misinterpreted and also confused with his work on the transmission of radio or electromagnetic waves. The Tesla coil is a convenient generator of such radiation, and is used as such in many of the embodiments of our invention described below, but it should be clearly understood that our invention in its broadest sense is not restricted to the use of such a coil as a source of mass-free radiation and any natural or artificial source may be utilised. For example, the sun is

a natural source of such radiation, although interaction with the atmosphere means that it is largely unavailable at the earth's surface, limiting applications to locations outside of the earth's atmosphere.

According to the invention, a device for the conversion of mass-free radiation into electrical or mechanical energy comprises a transmitter of mass-free electrical radiation having a dampened wave component, a receiver of such radiation tuned to resonance with the dampened wave frequency of the transmitter, a co-resonant output circuit coupled into and extracting electrical or kinetic energy from the receiver, and at least one structure defining a transmission cavity between the transmitter and the receiver, a full-wave rectifier in the co-resonant output circuit, and an oscillatory pulsed plasma discharge device incorporated in the co-resonant output circuit. The output circuit preferably comprises a full-wave rectifier presenting a capacitance to the receiver, or an electric motor, preferably a split-phase motor, presenting inductance to the receiver. The transmitter and receiver each preferably comprise a Tesla coil and/or an autogenous pulsed abnormal glow discharge device. The transmission cavity is preferably at least partially evacuated, and comprises spaced plates connected respectively to the farthest out poles of the secondaries of Tesla coils incorporated in the transmitter and receiver respectively, the plates being parallel or concentric. The structure defining the cavity may be immersed in ion-containing water. The split-phase motor is preferably an inertially-dampened AC drag motor.

The invention, and experiments demonstrating its basis, are described further below with reference to the accompanying drawings.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Based upon observations of weight loss in metallic matter as induced by exposure to high frequency alternating electric fields, we developed an experimental method to optimise this-weight loss, and from this a device that treats the forces causing weight loss as manifestations of intrinsic potential energy ΔU (or true "latent heat") of the molecules of matter, and converts both "true latent heat" energy present in the neighbourhood of a receiver, and "sensible" heat induced within that receiver, into electric energy which can be used to drive a motor, flywheel or charge batteries.

It is commonly believed that the output of the Tesla coil is ionising electromagnetic radiation. We have demonstrated that it is not, i.e. that it is neither electromagnetic radiation, nor ionising electromagnetic radiation. The output of an air-cored, sequentially-wound secondary, consists exclusively of electric energy: upon contact with the coil, a mass-bound AC current can be extracted at the resonant frequency, whilst across a non-sparking gap, mass-free AC-like electric wave radiation having the characteristics of longitudinal waves, can be intercepted anywhere in adjacent space. Accordingly, the radiation output from such coils is different to electromagnetic radiation.

The basic demonstration that the output of a Tesla coil does not consist of ionising radiation, is that it does not accelerate the spontaneous discharge rate of electroscopes, whether positively or negatively charged. In fact, in its immediate periphery, the coil only accelerates the spontaneous discharge rate of the negatively charged electroscope (i.e. the charge leakage rate), whereas it arrests the discharge of the positively charged electroscope (i.e. the charge seepage rate falls to zero). But this dual effect is not due to any emission of positive ions from the secondary, even if it can positively charge a discharged electroscope brought to its proximity. This charging effect is in fact an artifact, in that metals but not dielectrics are ready to lose their conduction and outer valence band electrons when exposed to the mass-free electric radiation of the coil.

This is simply demonstrated by the apparatus of **Fig.1**, in which the outer terminal of the secondary winding **6** of a Tesla coil having a primary winding **4** driven by a vibrator **2** is connected to the input of a full-wave voltage wave divider formed by diodes **8** and **10** and reservoir capacitors **12** and **14** (the same reference numerals are used for similar parts in subsequent diagrams). If the rectifiers employed are non-doped, then the coil appears to only charge the divider at the positive capacitance **10**, but if doped rectifiers are employed, the coil will be observed to charge both capacitances equally. Whereas positive ionises can charge either doped or un-doped dividers

positively, no positive ionise can charge a doped divider negatively, clearly demonstrating that the Tesla coil does not emit positive ions.

The basic demonstration that the output of a Tesla coil is not non-ionising electromagnetic radiation of high frequency, such as optical radiation, or of lower frequency, such as thermal photons, is also a simple one. Placement of a sensitive wide spectrum photoelectric cell (capable of detecting radiation to the limits of vacuum UV), wired in the traditional closed circuit manner from a battery supply, at any distance short of sparking from the outer terminal of the coil will show in the dark that the light output from the coil is negligible. This rules out optical radiation at high frequency. The demonstration that the sensible heat output from the Tesla coil is also negligible will be addressed below.

Our theory proposed the existence of physical processes whereby mass-free electric radiation can be converted into electromagnetic radiation. Such a process is at work whenever mass-free electric wave radiation interacts with electrons, such as those that remain in the valence bands of atoms. This mass-free electric energy interacts with charge carriers, such as electrons, to confer on them an electrokinetic energy which they shed in the form of light whenever that electrokinetic energy is dissociated from those carriers (e.g. by deceleration, collision or friction processes). Such a process is at work to a negligible extent in the coil itself and its usual terminal capacitance, hence the faint glow that can be seen to issue from it, but it can also be greatly amplified in the form of a corona discharge by connecting a large area plate to the output of the secondary, as Tesla himself did in his own experiments, and thus by increasing the capacitance of the coil system.

Now, what is interesting in this process is that, in the absence of virtually any I^2R losses at the plate, and if the plate thus introduced is bent at the edges so that it has no pointed edges, or if it is in the form of a bowl, or in any other manner that precludes sparking at edges and specially corners, and thus enhances the corona discharge, any electroscope, whether negatively or positively charged, now brought close to the plate will show a tendency to arrest its spontaneous discharge rate. One might say that this is simply the result obtained in a Faraday cage which disperses charge on its outside and electrically insulates its interior, and indeed if an electroscope is placed inside a Faraday cage no amount of Tesla radiation on the outside of that cage, save direct sparking, adversely affects the leakage or seepage rate of the electroscope. In fact, since the effect of such a cage can be shown to be that of, by itself, inducing arrest of either spontaneous electroscopic discharge, this effect simply remains or is magnified when the cage is bathed by Tesla radiation. However, a cage constitutes an electrically isolated environment, whereas a plate with or without curved or bent edges does not. Furthermore, the change observed in the properties of the output radiation from a Tesla coil when certain metal plates or surfaces are directly connected to the outer terminal of the secondary, takes place whilst the capacitance of the coil is increased by the connected plate, and thus the plate is an electrically active element of the circuit - and hence the opposite of an electrically isolated element.

For a long time, we believed that the anomalous cathode reaction forces observed in autoelectronic discharges (atmospheric sparks, autogenous PAGD (pulsed abnormal glow discharge) and vacuum arc discharges) were exclusive to an autoelectronic emission mechanism prompted by a direct potential between discharging electrodes. Sparking driven by AC potentials could sustain the same forces, but their mutual cancellation over time would not deploy a net force. In this sense, when a large gold leaf connected directly to the ground (via a water pipe or any other suitable connection) or to another large area plate suspended at some height above the ground, is vertically placed at a sparking distance above the surface of another plate connected to the secondary of a Tesla coil, one would not expect the AC spark to sustain any net force across the gap between the gold leaf and the plate. In terms of cathode reaction forces, one would expect their cancellation to be simply brought about by the high frequency of the current alternation in the coil, as both leaf and plate would alternate between being the emitting cathode or the receiving anode. However, this is not what is observed - instead, the gold leaf **16** lifts away from the plate **18** (**Fig.2**). If instead, the suspended gold leaf is connected to the coil terminal, and the bottom plate is connected to the ground in the same manner as described above, this also yields the same result.

Even more curious is the finding that this anomalous reaction force deployed by an alternate current of mass-bound charges in the arc, remains present when the sparking is prevented and instead the corona effect is enhanced (by employing a large plate connected to the outer pole of the secondary, and by employing a distance at which sparking ceases), as if the lift itself were the property of the corona underlying the spark channels and not the property per se of the autoelectronic emission mechanism.

By mounting the suspended leaf **16** (41 mg of hammered 99.9996% pure gold) directly at the end of a long dielectric rod **20** balanced at the centre and placed on a light stand over an electronic balance **22**, we sought to determine the observed lift of the leaf as weight lost. Surprisingly, and despite the most apparent lifting motion of the leaf, the balance registered a substantial weight gain, indicating the addition of 1 to 5 mg weight (with the same 14W input to the vibrator stage), independently of whether the leaf was connected to the terminal of the coil or instead to the earth ground via a water pipe. This suggested to us that, whether formed as a DC or AC spark channel, or whether in the form of a corona discharge, the electric gap develops an expansion force (exactly

opposite to a Casimir force) on both electrodes, independently of their polarity, which force is responsible for the observed repulsion. Yet, this expansion goes hand in hand with an increase in their weight such that some other process is at work in that electric gap.

To examine this problem further, we assembled a different experiment where the gold leaf **16** was suspended between two large metal plates **18** and **24** placed 20 cm apart, and the leaf was not electrically connected to them or to any other circuit, while attached to the dielectric rod employed to suspend it over the electronic balance. Given that the leaf is suitably and equally spaced from both plates, there is no arcing between it and either plate. The obvious expectation is that, since the electric field bathing the leaf alternates at high frequency (measured in hundreds of kilohertz), and the corona from both electrodes should equalise and balance any electric wind, no lift should be observed. In fact, no lift is apparent, but a most curious observation is made: depending upon which orientation is employed for the plates, the gold leaf either gains or loses 4-6% of its weight. This gain or loss is registered for as long as the coil is on. If the top plate is grounded and the bottom one connected to the different terminal of the secondary, a gain in weight is observed (**Fig.3**). If the connections are reversed, an equal weight loss is registered (**Fig.4**).

Furthermore, in this last instance, if the grounded plate **24** is entirely removed (**Fig.5**), and only the top plate remains connected to the outer terminal of the secondary, the observed loss of weight continues to occur such that in effect, this reaction can be obtained with unipolar electric fields of high frequency, and it provides a unidirectional force which, once exerted upon metallic objects bathed by its field, can be made to oppose or augment gravity.

Now, these effects can be greatly magnified, in the order of 10-fold, if the same gold leaf is made part of a simple series floating electric circuit where the leaf functions as a large area plate, and is wired in series with a coil **26** which, for best results, should be wound so as to be of a length resonant with the secondary of the Tesla-type coil employed; and this coil is connected in turn to a point antenna **28** upwardly oriented (**Fig.6**). The entire floating circuit is mounted on the rod **20** and this in turn, is mounted over the sensitive balance. If both plates are kept as in **Fig.3** and **Fig.4**, the observed weight loss and weight gain both vary between 30% and 95% of the total weight of the leaf. Again, the gain or loss of weight is registered for as long as the coil is on.

These anomalous findings suggested that, whatever is the nature of the energy responsible for the force observed in that high frequency alternating current gap, any metallic object placed in that gap will experience a force repelling it from the electric ground. This force will be maximised if the gap frequency is tuned to the elementary or molecular structure of the metallic object. If the electric ground is placed opposite the actual plane of the earth ground, that force will act in the direction of gravity. If, instead, the electric ground and the earth ground are made to coincide on the same plane, that force will act opposite the direction of gravity, i.e. will repel the metallic object from the ground.

No such weight alteration was observed with solid dielectrics, for instance with polyethylene and other thermoplastic sheets.

These facts rule out the possibility of a hidden electrostatic attraction force, acting between the plate connected to the different terminal of the secondary and the gold leaf. Firstly, such an attraction would be able to lift the gold leaf entirely, as is easily observed with the unipole of any electrostatic generator operating with a few milliwatts output with either negative or positive polarity; secondly, the same attraction, if it existed and were the product of an electric force, would surely be manifested independently from whether the experimental leaf was metallic or a dielectric (as again is observed with electrostatic generators).

The results suggest therefore, that whenever a large plate is connected to a Tesla-type coil, it induces in surrounding matter that is not part of its own circuit, a directional thrust which is oriented in a direction which is opposite to the electric ground and, if the electrical ground is on the same side as the surface of the Earth, then a thrust is produced which opposes gravity.

When this thrust is made to oppose gravity, we believe that its effect upon the gold leaf can be compared to the lifting power imparted to the water molecule when it transits from the liquid to the vapour state and which is associated with the increase in internal (or intrinsic) potential “thermal” energy ΔU (See Halliday D & ResnickR (1978) "Physics", Vol. 1, section 22-8, p. 489). The "specific latent heat" of water (m*L) contains indeed both an expression for the sensible radiant thermal work involving volume and pressure relations:
$W = P(V_V-V_L)$ where P = a pressure of 1 atmosphere, and V_V and V_L are the molar volumes in the vapour and liquid phases respectively, and an expression for a quantity of "latent" energy (ΔU) which is associated with the molecule in the more rarefied state. Hence, the relation for the latter with respect to water vapour is: $\Delta U = mL - P(V_V-V_L)$

We propose that likewise, if a very small portion of the energy of the mass-free electric waves is indirectly transformed by mass-bound charge carriers on that plate into blackbody photons (once those charge carriers shed their electrokinetic energy), the greater portion of those waves are directly transformed in the space adjacent to that plate into the latent energy equivalent to ΔU for the atoms of the surrounding air, and so on, until this process itself is also occurring for the atoms of that gold leaf, thus inducing their non-electrical weight loss and suggesting the existence of a non-thermal "antigravitokinetic" energy term previously unknown to mankind other than as "latent heat" or "internal potential energy".

From this viewpoint, the energy released by any Tesla-type coil to its surroundings, would be tantamount to a radiative injection of "internal potential energy" which would confer on local gas molecules a weight cancellation (a cancellation of gravitational mass occurring in the absence of any cancellation of inertial mass - a process which the inventors theorise is explained by the neutralisation of elementary gravitons), and the same process would be equally at work for metallic solids but not dielectric solids.

Gold vapour also deploys a substantial intrinsic potential energy. With an enthalpy of vaporisation on the order of H_V = 324 kJ mol^{-1}, the molar volumetric work performed by gold vapour at atmospheric pressure at the temperature of vaporisation T_V (2,856^{0}C., i.e. 3,129 degrees Kelvin) is:

$W = P\Delta V_{V\text{-}L}$ = 23.58 kJ $mol.^{-1}$ where $\Delta V_{V\text{-}L}$ = 0.2327m^3. The intrinsic potential energy of gold vapour is then given by:

$\Delta U = H_V - W$ = 300.4 kJ $mol.^{-1}$ i.e. 12.74 times greater than the volumetric work performed during the phase transition.

It is our contention that this intrinsic potential energy, associated with molecules as their "latent heat", has fine structure that in turn is altered if this energy is released from these molecules and fails to gain a "sensible" thermal form. What is suggested is that the fine structure of "latent heat" is not electromagnetic and obeys instead the molecular function:

$\Delta U / N_A = \lambda_{n2}^2 c f_{n2}$ where N_A is Avogadro's number, the wavelength denoted as λ_{n2} is the wavelength-equivalent of the mass of the molecule to which the "latent heat" is associated, obtained by a conversion method proposed in these inventors' theory, and the frequency term f is a non-electromagnetic frequency term, specifically in this case a gravitational frequency function.

Employing the conversion of Joules into m^3 sec^{-2} proposed by these inventors as being exactly:

1J = 10 N_A m^3 sec^{-2}, and putting the wavelength λ_{n2} down as the wavelength-equivalent of the mass of the gold atom, λ_{Au}, at 1.9698 m, that frequency term f_{n2} can be obtained as being equal to 2.6 x 10^{-3} sec^{-1}.

According to the present inventors' theory, the wave function c constitutive of the fine structure of "latent heat" associated with molecules of matter, carries the same wavelength λ_{Au} and its frequency is given in the usual manner by c/λ_{Au} = 1.52 x 103 sec^{-1}. The resultant frequency for the non-Planckian unit quantum of "latent energy" associated with each gold atom at the vaporisation temperature is then obtained by the geometric mean of the two synchronous frequency terms: $[(c/\lambda_{Au}) f_{n2}]^{0.5}$ = 624 Hz. However, this is the signature of that intrinsic potential energy when associated with that gold atom at its vaporisation temperature. It is not the signature of the energy quantum itself if it is released from that molecule, nor prior to being absorbed (i.e. in transit), at that same temperature.

The fine structure of the same non-Planckian "latent" energy quantum varies to encompass different determinations of the constituent wavelength and frequency functions. The basic relation for the determination of the wavelength of a "latent thermal" energy quantum not associated with matter, but corresponding to one that is, is:

$\lambda_{n1} = [(\Delta U / N_A) / c]^{0.666}$ $meters^{-0.333}$ $seconds^{0.666}$

which gives 0.046478 m for the unbound equivalent of the "latent heat" unit quantum of vaporisation associated with the gold atom at a pressure of one atmosphere. The fine structure of the free quantum is still parallel, as given by:

$\Delta U / N_A = \lambda_{n1}^2 c f_{n1}$

but now notice how the frequency terms have changed value, with the f_{n1} function having the value 4.65 sec^{-1} and c / λ_{n1} yielding 6.48 x 10^9 sec^{-1}. The geometric mean of the superimposition of the two frequencies is then:

$[(c / \lambda_{n1}^2).f_{n1}]^{0.5}$ = 173.7 KHz

We contend that it is at this frequency that the atoms of gold vapour absorb "latent heat".

However, this is just the overall scenario of what happens at the temperature of vaporisation of gold. But at room temperature (e.g. 293 degrees Kelvin), and with respect to processes where there is no sublimation of the atoms of that gold leaf under way (and indeed, once the coil is turned off, the leaf returns to its normal weight), one must infer to a different phase of matter what portion of "latent heat" energy, if any, do the atoms of gold hold in the solid phase lattice. Assuming the same proportionality between the "sensible" and "latent" thermal energy terms for atoms of gold at room temperature, where the unit thermal energy is $N_A kT$ = 2.436 kJ mol^{-1}, we speculate that the gold atom could absorb up to 12.74 times the value of this "sensible" thermal energy, and thus hold $N_A kT$ = 31.053 kJ more energy in its own micro-atmosphere.

If this speculation is correct, and employing the above novel methodology, then the mean geometric frequency of the maximal "latent heat" energy quantum of a gold atom at room temperature would be 538 KHz (versus 174 KHz at the vaporisation temperature), and once absorbed its mean frequency mode would reduce to 201.5 Hz (versus 630 Hz once the atom has vaporised).

To test this hypothesis, we employed two different Tesla-type coils having output frequencies of 200 KHz and 394 KHz. The circuit tested was that shown in **Fig.6**, and both coils were operated at 50 KV outputs. Whereas the former coil, closer to the 174 KHz marker, could only systematically produce 10mg to 11 mg of weight cancellation in the gold leaf of the floating circuit, the second coil, closer to the speculated 538 KHz marker, could produce 15mg to 35 mg of weight cancellation in the same gold leaf. The empirical results appear therefore to suggest that our speculation may well be a valid one.

The above-mentioned full wave divider (see **Fig.1**) can be easily coupled to our autogenous Pulsed Abnormal Glow Discharge technology as described in our U.S. Pat. No. 5,416,391 to form an alternative source of direct current, ultimately powered by Tesla waves, and such a drive can equally be applied to any other vacuum device that can sustain endogenous oscillatory discharges, whether in the PAGD regime or any other pulsatory regime. For the purposes of experimental and visual determination of power outputs from the divider in question, we have utilised either 2 Torr vacuum tubes operating in the high-current PAGD regime, or 20-100 Torr spark tubes requiring high voltages (2 to 10 KV) for their spark breakdown. As taught in the above US Patent, the output from the full wave voltage divider can be assessed by the energy spent in driving the tube and the motor, whose rotary speed is proportional, within the limits chosen, to the power input.

Two separate sets of experiments presented in Table 1 below, showed that direct connection of the wave divider to the outer terminal of the coil (set constantly at 6 clicks on the vibrator stage in **Fig.1**) or to the same terminal but across a large (2 or 3 square feet) plate **30** that increased the capacitance of the secondary (**Fig.7**), presented the same power output in either case (the effect of the plate is to lower the voltage of the output proportional to the increase in current). A substantial increase in power output through the divider is observed only when an identically wound Tesla coil is connected in reverse (**Fig.8**) with the non-common end of its winding **4** not connected, in order to obtain a condition of resonance, and this observed increase is further augmented by now interposing either of the metal plates **18**, **24** between the two chirally connected and identical coils (**Fig.9**). The increase in plate area appears to have the effect of increasing the output for as long as the plate is isolated between the two chiral image coils. Throughout these experiments, the input power to the vibrator was fixed at 14W (60 Hz AC). [Note: 'Chirality', or 'handedness', is a property of objects which are not symmetrical. Chiral objects have a unique three-dimensional shape and as a result a chiral object and its mirror image are not completely identical - PJK].

TABLE 1

Status	Pulse rate (PPS)	Motor rotation (RPM), M ± SEM
Expt A		
Tesla coil (TC) to divider	2.6	582.5 ± 3.9 (n = 4)
TC to inverted TC, to divider	4.4	621 7.6 (n = 4)
TC to 2 ft^2 plate, to inverted TC, to divider	5	775.25 ± 23.6 (n = 4)
Expt B		
Tesla coil (TC) to divider	2.2	613 ± 5.6 (n = 12)
TC to 3 ft^2 plate, to divider	2.3	605 ± 2.6 (n = 12)
TC to inverted TC, to divider	2.3	722 ± 5.7 (n = 12)
TC to 3 ft^2 plate, to inverted TC, to divider	4.2	877.6 ± 6.5 (n = 12)

In our loss of weight experiments described above, we noted that the phenomenon of weight loss by a metallic body placed in proximity of the coil output continued to be observed when only the plate connected to the distal pole of the secondary was retained. The leaf, although not part of the circuit of the secondary, could however be seen as part of a circuit for the capture of ambient radiant energy, specifically that generated by the coil and, as well, that also possibly picked up, in the process, from other ambient sources. To determine whether the last consideration is a possibility at all, or whether the energy picked up by an analogue of our metallic body or gold leaf in the experiments described above, is entirely a by-product of the energy transmitted by the plate connected to the outer pole of the secondary, we next determined what would happen if the pick-up for the full-wave divider were placed, not at the output from the secondary coil, but from an, in all respects identical, plate (the Receiver plate **R**, as opposed to the Transmitter plate **T**) placed a distance away from, and above, the first one. In other words, the gold leaf is replaced by a receiver plate, and this carries an attached test circuit identical to the test circuit employed to directly assess the coil output.

TABLE 2

Status	T R distance	Pulse rate (PPS)	Motor rotation (RPM), M ± SEM

	6"	10	936 ± 46.1 (n = 9)
3 ft^2 plates			
TC to T plate, to divider	0	2.3	605 ± 2.6 (n = 12)
R plate to divider	6"	3.3	890.1 ± 3.8 (n = 12)
R plate to inverted TC, to divider	6"	5.1	1009.2 ± 4 (n = 12)
R plate to divider	8"	4.0	783.1 ± 11.3 (n = 12)
R plate to inverted TC, to divider	8"	5.1	1005.7 ± 6 (n = 12)

As shown in Table 2 above, the results of the experiment show that there is no loss of energy picked up at the **R** plate (**Fig.10**) when compared to the most favourable situation involving the plate **30** (**Fig.9**) interposed between the chirally connected coils. This observation is however not always the case. For best results one should employ iron, gold or silver plates placed parallel to the horizon, with the **T** plate underneath the **R** plate. In fact, if one employs instead aluminium plates and suspends these vertically, one can consistently register a loss of output at the divider when changing the divider input from the **T** to the **R** plates.

If however the plate **R** is connected in turn to a second identical coil, also wired in reverse, and this second coil in turn serves as input to the full-wave divider (**Fig.11**), then a most curious occurrence takes place - the power output increases considerably (see Table 2), as if the divider circuit had undergone an energy injection not present at the source. Note that the circuits are in fact resonant, but the energy injection contributing nearly 60-66% (for both plate areas in the previous experiment) of the input that we refer to, is not caused by inductive resonance, since the effect of resonance can be ascribed to the set-up described in **Fig.9**. The distance between the plates, as well as their orientation with respect to the local horizon system of the observer also appear to matter, best results being achieved at optimal distances (e.g. for 2 square feet plates the best gap, at 43% RH and room temperature, was at least 6 inches).

We tested the possibility that environmental heat produced by operation of the coil might be the source of the injected energy, the plate of the second system acting possibly as collector for the heat present in the gap. As it turned out, experiments showed repeatedly that in the gap between the **T** and **R** plates there was no significant thermal radiation propagating between one and the other. The more illustrative experiments are those in which we identified where the sensible thermal energy appears, and which involved coupling two cavities: the Transmitter-Receiver gap between plates **T** and **R**, and a Faraday cage enclosure **34** (see **Fig.12**). The first cavity appears to be much like that of a capacitor: the two identical parallel plates are surrounded by a thick dielectric insulator **32**, and a thermometer **T2** is inserted half-way through it. A thermometer **T1** is also fixed to the **T** plate, to measure it's temperature. The second cavity is a simple insulated metal cage with a thermometer **T3** inserted 2 cm into its top. Some 2-4 cm above the top of the cage there is placed a fourth thermometer **T4**, inside an insulated cylinder.

If the Tesla Coil is a source of thermal energy (e.g. IR radiation, microwaves, etc.) we would expect the **T** plate to be the hottest element from which, by radiation, thermal energy would reach the middle of the first cavity making the next thermometer **T2** second hottest, and that the third thermometer **T3** inside the second cavity, even if it might initially be slightly warmer than the other two, would, over time, become comparatively cooler than either one of the other two thermometers, despite the fact that the rising heat would still be seen to warm it up over time. One would expect a similar outcome for the fourth thermometer **T4**, above the cage. As shown by **Fig.13**, where only the temperature differences (ΔT^0 - $T_C{}^0$) between the experimental thermometers and the control thermometer reading the air temperature $T_C{}^0$ of the laboratory are shown, the surface of the **T** plate warms up by 0.1^0C. at 3 minutes after initiation of the run (closed squares), whereas in the space of the T/R gap a diminutive warming, by 0.05^0C., is registered after 10 minutes (open circles). Conversely, the temperature inside the cage, at the top (shaded circles) rises by 0.1^0C. also by the third minute, and the temperature above the cage itself (shaded squares) rises by a much greater difference of 0.35^0C., which remains stable after the eighth minute.

These results show that it is not sensible heat that radiates from the **T** plate. Instead, some other form of radiation traverses these cavities to generate sensible heat at their metallic boundaries, such that more heat is generated above the **R** plate (inside the cage) and again above the third plate, i.e. above the top of the cage, than is generated in the T/R gap, i.e. near the **T** plate. This clearly shows that the Tesla coil is not a significant source of thermal radiation, and that sensible heat can be detected inside and on top of the Faraday cage only as a further transformation of the radiant energy transmitted across the T/R cavity.

The same experiment also illustrates that, whatever is the nature of the additional environmental energy being injected at the surface of **R** plate (as shown by Table 2 results above), it is most likely not thermal radiation, at least not energy in the form of sensible heat. And whatever is the nature of this ambient radiant energy being mobilised by the electric radiant energy transmitted from the **T** plate, it can produce significant heat inside an enclosure adjacent to plate **R**.

Since we also know experimentally, that this observation of an ambient energy injection at the **R** plate or **R** cage depends upon relative humidity, being most easily observable when the latter is low (<50% Relative Humidity), and being virtually impossible to observe when air is saturated with water vapour, we can infer that water vapour is a good absorber of the electric mass-free radiant energy emitted from the **T** plate. This strongly suggests that this absorption process is tantamount to increasing the potential intrinsic energy ΔU of the water vapour molecules adjacent to the **T** plate. In the absence of significant quantities of water vapour, when the atmosphere is dry, one may speculate that this absorption process is replaced by what one presumes is a parallel process involving the various gaseous molecules of air. However, either because the air molecules involve molecular species that readily give off this potential energy, as one might speculate is the case with molecular oxygen, hydrogen and nitrogen, or because the air molecules absorb far less "latent" energy (as appears to be the case with inert gases), and therefore there is more of it in the molecularly unbound state (as we explicitly propose as a possibility) and thus available for absorption by the appropriately tuned receiver, the increased ΔU of air molecules conferred by the absorption of the mass-free electric radiation in the T/R gap is transferred to the **R** conductor together with the latent energy which those molecules already possessed before entering that gap. Hence the

energy injection and its dependency upon the partial pressure of water vapour, which absconds instead with this "latent" energy and succeeds in withholding it from transmission to the **R** plate.

If the T/R gap can mobilise ambient energy which is neither electromagnetic nor thermal in nature, but which "latent" energy becomes injected into the divider circuit in electric form, the heat (i.e. sensible thermal energy) produced inside and on top of the cage, can also be mobilised electrically as input into the divider circuit. The obvious place to look for the positioning of the cool junction which could convert sensible heat into electrokinetic energy of mass-bound charges is at the top of the cage, where it is warmest (See top curve of **Fig.13** in shaded squares). This is clearly observed from the results shown in Table 3 below, where the initial temperature difference between the top of the box and the **T** plate surface was 0.5^0C., and the top of the box temperature rose by 0.2^0C. after 2.5 minutes when the divider was connected at the junction, versus 0.35^0C. when it was not (and the transmitter coil was on).

TABLE 3

Status	TR distance inches	Pulse rate PPS	Motor rotation RPM, M ± SEM (n = 12)
3 ft^2 plates			
TC to T plate, to divider	NA	4.2	877.6 ± 6.5
R plate to inverted TC, to divider	6"	5.1	1009.2 ± 4
Top of naked R plate/ cage to divider	6"	5.4	1047.1 ± 5.7
Top of insulated R plate/cage exposed to sun, to divider	6"	6.1	1072.4 ± 8.7

For the run performed with the naked **R** cage, the temperature directly above the top of the cage was 24.3^0C., at the outset, versus the control room temperature of 23.9^0C. For the run performed with the insulated **R** cage exposed directly to the sun at midday, on a cool and clear August day, the temperature directly above the top of the cage was 33^0C., versus the control air temperature of 18.4^0C. The temperature of the cool junction at the top of the cage was 31.9^0C. while the run was performed.

It is apparent from the data of Table 3, how a second injection of energy has occurred in the apparatus. If, within the T/R gap, the energy injected appears to be on the order of absorption of "latent heat", at the top of the cage cavity, at the cool junction, the injection is one of radiant "sensible" heat. Moreover, this secondary energy addition could be further enhanced by placing strong insulation around the whole apparatus or the cage itself, and further so, by exposing the whole apparatus to solar radiation.

We next turned our attention to the T/R gap cavity with the intention of determining whether atmospheric conditions or vacua yield the same or different results. We could not, of course, test the same large area plates as have been employed for the studies undertaken at atmospheric pressures. For the present purpose we employed instead large area electrodes (ca 0.2 ft^2) made of high grade stainless steel or even aluminium. Preliminary results showed that these T/R gap tubes, when coupled to the divider circuit, yielded faster pulse rates in the secondary circuit when evacuated than at atmospheric pressure. The strength of the corona discharge also intensified, as it eventually became replaced by a normal glow discharge. For purposes of improved spatial capture of (1) the electric mass-free energy radiated from the **T** electrode and (2) the non-radiant latent thermal energy mobilised by it to be collected electrically at the **R** plate, an axial cylindrical T electrode was inserted inside a larger concentric cylinder or between two common plates of large surface area (e.g. >100 cm^2) functioning as the **R** electrode(s), in a dielectric container suitable for evacuation (glass, polycarbonate), at a typical distance of at least 3 cm between electrodes, and the entire device was tested at different pressures.

The secondary circuit connected downstream from the full-wave divider was as shown in **Fig.14** (employing an autogenous pulsed abnormal glow discharge, or PAGD, converter circuit), with the PAGD reactor **36** set at 10 Torr (in light of the high-voltage input, which varied between 1,500V and 3,200V) and gave the results presented in Table 4 below. We should remark also that these pulses charged the charge pack **CP** through the coupling

capacitors **38**, bridge rectifier **40** and reservoir capacitors **42**, and blocking diodes **44**, as expected from the prior art represented by our patents related to PAGD devices.

TABLE 4

T/R tube Pressure (Torr)	Pulse rate (PPS)
760	0.376
0.025	0.513

The effect of the vacuum in the T/R gap tube seems to be dual. By transforming the corona discharge into a normal glow discharge, it increases the local production of photons (probably associated to the formation and discharge of metastable states in the plasma), and at the same time, increases the pulse rate in the output circuit and thus, in all probability, the energy injected in the T/R gap cavity. But this did not yet permit us to confirm whether or not it is "latent heat" energy of the plasma molecules which is being tapped at the receiver plate, even if it be plausible in principle that plasmas may effect more efficient transfer of "latent heat" to tuned receivers than atmospheric gases.

The vacuum dependency of the pulse rate of the PAGD reactor employed as example in the secondary circuit downstream from the divider is also rather well marked, with the fastest pulse rates being registered at 1 Torr for the sample run shown in Table 5 below.

TABLE 5

T/R tube Pressure (Torr)	Pulse rate (PPS)	PAGD Reactor Pressure (Torr)	Voltage (across divider)
0.025	0.115	90	4.5 kV
0.025	0.1553	75	3.5 kV
0.025	0.183	60	3.3 kV
0.025	0.291	30	
0.025	0.513	15	1.6 kV
0.025	0.602	10	1.4 kV
0.025	2.9	2	0.53 kV
0.025	4.1	1	0.45 kV

It is worth noting here that the illustrated polarity of the wiring of the PAGD reactor tube, as shown in **Fig.14**, is best for purposes of sustaining regular auto-electronic emission at high voltage. The reverse configuration, with the centre electrode negative and the plates positive favours instead heating of the cathode and a lapse into a normal glow discharge.

We tested a similar arrangement to that shown in **Fig.14** above, but with a PAGD motor circuit (see our U.S. Pat. No. 5,416,391). A split-phase motor **44** replaces the rectifier and charge pack, and the PAGD reactor is operated at the same pressure of 15 Torr, as shown in **Fig.15**. The T/R gap tube tested had a longer plate distance (2''), with one plate now functioning as Transmitter and the other as Receiver. Note also the different wiring of the PAGD reactor. The results, as shown below in Table 6, present pulse per second (PPS) and motor revolutions per minute (RPM) curve trends that appear to be analogous and parallel to the well known Paschen curves for breakdown voltage in vacuum - such that the T/R gap performs better either in the atmospheric corona discharge mode, or in the high vacuum normal glow discharge (NGD) mode, than in the low breakdown voltage range of the curve where the discharge forms a narrow channel and takes on the appearance of an "aurora" transitional region discharge (TRD).

TABLE 6

T/R tube Pressure (Torr)	Pulse rate (PPS)	Motor rotation (RPM), M ± SEM (n = 17)	Discharge Type
760	2.8	751.2 ± 7.1	Corona
100	2.1	611.5 ± 5.1	TRD
20	2.4	701.9 ± 4.6	TRD
0.006	2.8	748.4 ± 9.3	NGD
0.003	3.0	819.4 ± 6.3	NGD

These results suggest that plasmas with high lateral dispersion, i.e. formed over large electrode areas (e.g. corona and NGD plasmas) and thus devoid of pinch, are more likely to mobilise electrically, the intrinsic potential energy of the molecular charges than pinch plasmas appear to be able to do (e.g. TRD plasmas). Apparently also, the greater the vacuum drawn from the T/R gap cavity, the more efficient does the transfer of this intrinsic potential energy become, i.e. the mass-bound latent heat, to the electrokinetic energy of the charges circulating in the receiver circuit. At about 0.06 Torr, this transfer in vacuo is comparable to that observed under atmospheric conditions and thus for a much greater density of molecules.

We investigated whether it Is possible to tap the latent heat energy of water molecules. It is possible that in the vapour phase they can effectively hold on to their latent energy - but could they give off some of it once closely packed in liquid phase? To test this hypothesis we immersed the T/R gap in a glass water tank. The motor employed for these tests was a high-speed 2-phase drag-cup motor (see **Fig.18** and associated description), wired in split-phase with two identical phase windings capacitatively balanced, and the galvanised iron plates each had an area of one square foot. The results are shown in Table 7 below, and clearly indicate that it is possible to tap - within the T/R cavity - the `latent heat` of water in the liquid phase. As observed, immersion of the T/R cavity in water increased the motor output speed 22% (12,117 / 9,888) x 100). This corresponds to a 50% increase in power output, from 18W at 9,888 rpm to 27W at 12,117 rpm:

TABLE 7

	Pulse rate PPS	Motor rotation RPM M ± SEM	T/R distance cm
Direct from TC	0.3	8076 ± 89.3	NA
TC to T plate	0.5	9888 ± 78.7	NA
R plate	2.75	12117 ± 29.8	30
R plate	2.9	12203 ± 55.9	60

Thus the use of ion-containing water or other ion-containing aqueous liquid in the cavity promotes long distance propagation and a greater injection of latent and thermal energies in the receiver circuit. Such a result is not achieved if the cavity is filled with deionised water.

The preceding results lead therefore to the design of a presently preferred apparatus, based on these findings, for the conversion of mass-free electric energy, "latent heat" energy and "sensible" heat energy into conventional electric energy, as shown in **Fig.16**, which integrates all of the separate findings and improvements. The winding **6** of the Tesla coil at the bottom is driven in the usual manner employing a vibrator stage **2** to pulse the primary coil **4**. The outer pole of the secondary **6** is then connected to a circular metal plate **T** which is one end of an evacuated cylindrical cavity, connected to a vacuum pump or sealed at a desired pressure, or which forms a still containing water or other aqueous solution or liquid. This cavity constitutes the transmitter/receiver gap, and is therefore bounded by a dielectric envelope and wall structure **32**, with the circular receiver plate **R** as its top surface. In turn this plate **R** serves as the base of a conical Faraday cage **34**, preferably air-tight and at atmospheric pressure, but which could also be subject to evacuation, which conical structure carries at its apex provisions for a cold junction **45** and any possible enhancement of the same junction by surface application of different metallic conductors that may optimise the Peltier-Seebeck effect. The output from the cold junction where sensible thermal energy is added to the electrokinetic energy of charge carriers, is also the input to the distal end of the winding **6** of the chiral coil arrangement that sustains resonant capture of all three energy flows ((1) mass-free electric waves of a longitudinal nature, (2) true "latent heat" or the intrinsic (thermal) potential energy, and (3) the thermokinetic energy of molecules, (i.e. "sensible" heat) and, placed in series with the input of

the full wave divider **8**, **10**, feeds the circuit output from the series capacitors **12**, **14** grounded at their common tap. In the T/R gap, the transmitted electric longitudinal wave energy is captured along with any intrinsic potential energy shed by molecules caught in the field. Within the **R** element, expanded into an enclosure that guides "sensible" radiant heat, the latter is generated and then recaptured at the cold junction.

The apparatus consisting of the cylindrical T/R gap cavity and the contiguous conical cage is then preferably finished in gloss white and cylindrically enveloped within a matt black container **46** by effective thermal insulation **48**, the latter terminating at the height of the bottom disc **T**. Apparatus (not shown) may be provided to move the plate **T** vertically to adjust the T/R gap.

Another alternative embodiment of the apparatus is shown in **Fig.17**. Here the circuit driving the apparatus is as we have set forth in our prior patents, which employs an autogenous pulsed abnormal glow discharge tube **50** in the configuration shown, supplied by a battery pack **DP** through blocking diodes **52** and an RC circuit formed by resistor **54** and capacitor **56** to drive the primary **2** of a first Tesla coil to obtain at the distal pole of the secondary **6** the energy to be injected to plate **T** in the form of a central electrode of a coaxial vacuum chamber (sealed or not), of which the cylindrical metallic envelope forms the receiver plate **R**, the latter being placed centrally inside the conical cage **34** and contiguous with its walls and base. The top and bottom of the coaxial chamber carries suitable insulating discs, preferably with O-ring type fittings. Again, the apparatus is enclosed in insulation within a cylindrical container **46**, and the input into the capture circuit driven from the full wave divider is taken from the cold junction **45** at the apex of the air-tight cage. The output circuit is similar to that of **Fig.15**.

We have found however that even when the component values in the motor driver and motor circuits are carefully selected so that these circuits are co-resonant with the dampened wave (DW) component of the motor driver pulses, the motor power output falls well short of that which should theoretically be attainable. In an endeavour to meet this problem, we replaced the squirrel-cage type induction motor **44** by a drag cup motor of type KS 8624 from Western Electric in the expectation that the low-inertia non-magnetic rotor would allow better response to the Dampened Wave component. This motor is similar to one of the types used by Reich in his experiments. Although results were much improved they still fell short of expectations. Replacement of this motor by an inertially dampened motor of type KS 9303, also from Western Electric, provided much better results as discussed below.

Fundamentally, the difficulties we encountered stemmed from the inability of motor couplings to respond efficiently and smoothly, and at the same time, to the pulse and wave components of Dampened Wave impulses: that is, simultaneously to the high-intensity peak current pulses (the front end event), the DC-like component, and to the dampened wave trains these cause, i.e. the pulse tails (or back end event)-or AC-like component. This difficulty is present even when we just seek to run induction motors from the DW impulses of a Tesla coil, the very difficulty that led Tesla to abandon his project of driving a non-ferromagnetic disc rotor mounted on an iron core bar stator with dampened waves.

We believe that the key to the capture of the mass-free energy flux output in electric form by Tesla transmitters, including any injected latent or thermal energy that have undergone conversion into electrical energy is to employ the tuned, unipolar, Y-fed, PAGD-plasma pulser driven split-phase motor drive we have invented (U.S. Pat. No. 5,416,391) in conjunction with an inertially dampened AC servomotor-generator (see **Fig.18**): this has a motor shaft **64** which couples a drag-cup motor rotor **60**, preferably of aluminium, silver, gold or molybdenum, directly to a drag-cup generator rotor **62** that drives a permanent magnet (PM) flywheel **66**, freely rotatable in bearings **67**, that provides inertial damping. The shaft **64**, journalled by bearings **61** in the casing of the motor **44**, provides a power output through optional gearing **68**. The phase windings of the motor **44** are wound on a stator core **70** having concentric elements between which the rotor or cup **60** rotates. This structure makes it ideal for the capture of the DW impulses, whether sourced in the transmitter, amplified in the T/R cavity or sourced in the plasma pulser, all in synchrony. Effectively the motor couples the damping action of the drag-cup sleeve motor rotor, which action, as we have already found for the KS-8624 motors, is quite effective at absorbing the front-end DC-like event, with the inertial damping of the PM flywheel upon the drag-cup sleeve generator rotor, that in turn is quite efficient at absorbing the back-end AC-like wavetrain event.

The KS-9154 motor used by Reich was not an inertial dampened AC drag-cup servomotor-generator. Had Reich succeeded in overcoming the limitations of his 2-phase OR Motor solution, as we have now shown it is possible to do (by applying the Function Y circuit to the PAGD split-phase motor drive which we invented), his motor would have suffered the same limitations which we encountered with the KS 8624 motor.

Any motor, by itself, has an internal or inherent damping whereby the acceleration only vanishes when the rotor is running at constant speed. For motors which operate on the basis of the drag principle, where the asynchronous slip is actually constitutive of the motor action, by inducing eddy currents in the rotor, the inherent damping is always more pronounced than for other induction motors. The damping or braking torque is produced when a

constant current flows through a rotating drag disc or cup.

Aside from this inherent braking, dampers can also be applied to servo motors to further stabilise their rotation. They absorb energy, and the power output and torque of the motor is thereby reduced. Optimal operation of servo motors requires both rapid response on the part of the rotor to changes in the variable or control phase, and a stable response that is free from oscillation, cogging and overshooting. The rapid response is assured by employing low inertia rotors, such as drag-cups or cast alloy squirrel-cages, and the overshooting and oscillation are reduced to a minimum by damping or a retarding torque that increases with increasing motor speed. Typically, in a viscous-dampened servomotor, the damper is a drag-cup generator mounted rigidly on the shaft of the motor rotor, and the generator drag-cup rotates against the stator field of a static permanent magnet field. The generator develops a retarding torque directly proportional to speed, and the energy absorbed by the damper is proportional to speed squared. The damping can be adjusted and, as it increases, the same amount of input power yields lower torque and motor speeds. Inertial-dampened servo motors differ from viscous dampened motors in that the permanent magnet stator of the drag-cup generator is now mounted in its own bearings, either in the motor shaft or on a separate aligned shaft, forming a high-inertia flywheel.

This means that, whereas the motor rotor always experiences a viscous damping in viscous-dampened servo motors, in inertial-dampened servo motors the drag cup motor rotor only experiences a viscous damping while accelerating the flywheel, with the damping torque always opposing any change in rotor speed. Once the flywheel rotates synchronously with the rotor, all damping ceases. Note that this viscous damping is carried out via the coupling of the drag-cup generator rotor, rigidly affixed to the motor rotor, to the PM flywheel, so that their relative motion generates the viscous torque proportional to the relative velocity. Use of drag-cup sleeve rotors in inertially dampened servo motors was largely supplanted by squirrel-cage rotors once the latter became produced as cast alloy rotors. Since inertially dampened motors can be used in open and closed-loop servo applications, and present better stability - even in the presence of non-linearities - and higher velocity characteristics than other induction motors do (Diamond, A (1965) "Inertially dampened servo motors, performance analysis", Electro-Technology, 7:28-32.), they have been employed in antenna tracking systems, stable inertial-guidance platforms, analogue to digital converters, tachometers and torque tables.

The typical operation of an inertially dampened servomotor is as follows: with the reference phase fully excited, the motor rotor -fixedly linked to the generator rotor, as well as the flywheel - remain immobile; once power is applied to the control phase, the motor rotor immediately responds but the flywheel remains at rest. However, as the drag-cup generator **62** is forced to move through the permanent magnetic field of the flywheel, it creates a drag torque that slows down the attached motor rotor proportionally to the acceleration that it imparts to the flywheel that it now sets into motion, thus creating the viscous damper. As the flywheel accelerates, the relative speed of the motor with respect to the flywheel, as well as the damping torque, decrease until both motor and flywheel rotate synchronously and no damping torque is exercised - at which point the drag on the motor cup exerted by the generator cup is negligible.

The KS-9303 motor is an inertial dampened servomotor but is differentiated with respect to other inertially dampened motors, in that (1) it employs a drag-cup sleeve motor rotor made of aluminium, very much like that of the KS-8624, but with slightly altered dimensions and with a shaft extension for the drag-cup copper generator rotor, and (2) the moving flywheel structure was journalled on a separate, fixed shaft, as already described with reference to **Fig.18**. Now, in principle, even application of minimal damping decreases motor efficiency, resulting in diminished torque and speed. Whether the inertial-dampened motor has a drag-cup rotor, a sleeve rotor or a squirrel-cage rotor, the damping increases the rotor slip. Laithwaite considers drag-cup motors as being "dynamically inferior to their cage counterparts" (Laithwaite, E R (1957) "Induction machines for special purposes", London, England, p. 323). If we now add a viscous damping and retarding torque, we should not be able to get much more than a 55% efficiency in the best of conditions. On the other hand, the inertial damping arrangement described will only abstract or supply energy when the motor rotor is accelerating or decelerating relative to the flywheel.

These drag-cup motors, whether inertially dampened or not, develop a constant torque at constant rpm for a given supply frequency and a suitable phase shift capacitance. For each frequency the motors respond to, there is an optimum resonant split-phase capacitance, but other values nearby are still suited for operation, and for each value of capacitance, there is an optimum frequency to which the motors respond. For example the KS-8624 motor responds best at 450 Hz when a 1 microfarad capacitance is employed, responds best at 250 Hz when a capacitance of 10 microfarads is employed, and responds best at 60 Hz, when a capacitance of 100 microfarads is employed. As the capacitance increases, the resonant CW frequency of the motor is displaced to lower values. If we fix the capacitance at a value (e.g. 10 microfarads) suitable for testing the frequency response at a fixed voltage of 12 VAC, the observed result for both the KS-8624 and KS-9303 motors show a response distribution of the motor rotary velocity that has an identical peak at 250 Hz for both motors, with the response decreasing to zero smoothly on both sides of the peak.

These results indicate that, when wired as a split-phase motor, the motor rotary velocity varies not as a function of voltage or current, but as a function of frequency when the phase-splitting capacitance is fixed within a suitable range, there being an optimum frequency mode for each value of suitable capacitance, with lower values of capacitance favouring higher frequency modes. For a given frequency and capacitance, the motor rotary velocity remains essentially constant and independent from voltage and current input, and thus at a plateau. Torque, in the same circuit arrangement, follows exactly the same pattern as rotary velocity, as a function of input frequency at a fixed potential. Torque is linearly proportional to rpm in these motors when they are split-phase wired, and rpm linearly proportional to CW frequency, which makes them ideal for experimentation and determination of power output computations. Moreover, since these are drag machines, the slip itself determines the rotor currents and these are susceptible to tuning such that their retardation and relative position in the field can find resonant modes for varying CW frequency and capacitance.

In the circuit of **Fig.17** when using the KS 9303 motor, the inertial damping of the flywheel coupling retards the motor rotor currents sufficiently to allow them to build up torque, with the entire motor assembly serving as the preferred sink for all of the energy, mass-free and mass-bound, captured by the receiving coil circuit with a drawing action established by the motor on the circuit, and providing satisfactory absorption by an inertial damper of the combined, synchronised, dampened wave impulses, those occurring at a low frequency as a result of the firing of the PAGD reactor, and those occurring at a higher superimposed frequency -sourced in the transmitter circuit and picked-up by the receiver plate and coil. The action of each DW impulse train itself generates two different events: the DC-like auto-electronic-like discontinuity which sets the motor in motion and initiates the rotor currents, and the AC-like dampened wavetrain which supports the consistency of those rotors. The concentration of current required to kick-start the motor is provided by the DW impulses of the PAGD reactor, whereas, once the motor is in motion, and particularly, once it is stabilised by the flywheel, the cumulative action of the higher frequency DW impulses makes itself felt by accelerating the rotor to an optimum rotary velocity.

For the next series of tests we employed the basic circuit diagram of the improved motor shown in **Fig.19**. The transmission station is the typical Tesla transmitter with a line-fed, 60 Hz vibrator stage. At the line input to the first stage, we place a calibrated AC wattmeter (Weston Model 432), and a Beckman 330B rms ammeter in series with the hot lead, we set the vibrator stage for 41 clicks, consuming between 28.5W and 35W, depending upon circumstances yet to be described. This consumption was confirmed by driving the coil from an inverter powered by a 12 volt battery. The inverter consumes 2.16 watts, and is 90% efficient. The total consumption from the battery was 42 watts (12V at 3.5A); once the 2.16 watts is deducted and the efficiency taken into account, we obtain the same 36W (vibrator stage at max., i.e. 47 clicks, in this experiment). The T/R gap is adjusted to 3", and 2 square foot plates are used. Transmitter and receiver coils are tuned, and so are the plate capacitances, to 250 kHz, also the capacitances of the Function Y circuit connected at the output of the receiving coil.

The rectified voltage and current generated by the transmitter secondary and by the transmitter plate was ascertained with a coil-tuned wave-divider (Function Y) circuit by loading it with different resistive values. The results constitute a measure of the mass-bound electrical power output directly from the transmitter apparatus. The same method was employed to ascertain the voltage, current and power of the mass-bound charges circulating in the receiving plate and coil circuit. The results are shown in Table 8 below:

TABLE 8

Massbound currents rectified by Function Y at the output of the Tesla transmitter, transmitter plate and receiver plate, as a function of the bleeding resistance employed in each of the function Y arms

	VDC (kilovolts)	ADC (amp)	WDC (watts)	R/arm (Mohm)
Direct from 2°	42–50	$3 * 10^{-5}$	1.26–1.5	500
From 2° (T) plate	26	$2 * 10^{-5}$	0.52	500
From 2° (R) plate	15.1	$1.25 * 10^{-5}$	0.189	500
Direct from 2°	20.4	$3.4 * 10^{-4}$	6.936	50
From 2° (T) plate	15.2	$2.4 * 10^{-4}$	3.648	50
From 2° (R) plate	9	$1.2 * 10^{-4}$	1.08	50
Direct from 2°	3.3	$1.75 * 10^{-3}$	5.775	1
From 2° (T) plate	3.5	$2 * 10^{-3}$	7.0	1
From 2° (R) plate	2.95	$1.6 * 10^{-3}$	4.72	1

The results indicate that the highest mass-bound power assembled by the secondary transmitter circuit does not exceed 7 watts - and this is directly output from the secondary **26** when the load is 50 Megohm, or from the transmitter plate when the load is 1 Megohm. The mass-bound electric power emulated by the receiving circuit (plate, coil and Function Y without the plasma pulser circuitry) never exceeds the mass-bound electric power outputted directly by the transmitter, and peaks when the resistive load value (1 Megohm) approaches the pre-breakdown resistance range of the vacuum tube, at 4.72W. These findings then indicate that when the transmitter circuit is consuming a maximum of 35W, a typical output from the secondary of the transmitter is 7W, and at 3" of distance within the proximal field of the latter, the pick-up by a tuned receiver will be of the order of 5W of mass-bound current duplicated within the receiving coil. The loss in the first stage is therefore on the order of sevenfold.

Continuing with the description of the circuit of **Fig.19**, a 128 cm^2 plate area, 6 cm gap PAGD reactor is used, connected as described in our prior art to a high-vacuum rotary pump (Correa, P & Correa, A (1995) "Energy conversion system", U.S. Pat. No. 5,449,989). Pressure readings were obtained with a thermocouple gauge during the operational runs. The KS-9303 motors to be tested are then connected to the PAGD reactor in the usual capacitatively-coupled, inverter fashion described in our prior art (Correa, P & Correa, A (1995) "Electromechanical transduction of plasma pulses", U.S. Pat. No 5,416.391). Their rpm is detected by a stroboscopic tachometer and fed to a Mac Performa 6400 running a motor algorithm program calculating the power output. Motor measurements were made at five minutes into each run for the unloaded motors, and at ten minutes for the inertially dampened motors.

All experiments were carried out in the same work session. The experimental determination of the continuous rotary power output as a function of the reactor pulse rate confirmed that the improved circuit develops maximum rotary capture of the mass-free energy in the receiver circuit at the lowest rates of pulsation, just as we have previously found for the conversion system of U.S. Pat. No. 5,449,989. Furthermore, the data showed that even motors of type KS-8624 are able to output power mechanically in excess of the mass-bound power output by the transmitter (7W) or captured by the receiver (5 to a max. of 7W), once the PAGD rate decreases to 1.5 PPS. Such an anomaly can only be explained by the system having become able to begin capturing the mass-free energy flux in the receiver circuit that we know already is output by the transmitter circuit. But this excess mechanical power is still less than the power input into the transmitter, and clearly so. It represents a power gain with respect to the secondary, but a loss with respect to the primary. The full breadth of the capture of the mass-free electric energy flux circulating in the receiver circuit is not seen until the motors are resonantly loaded because they are inertially dampened.

The KS-9303 motors, once inertially dampened, and thus loaded, are able to recover enough power from the mass-free energy field to develop a mechanical power, not just greatly in excess of the mass-bound power of the secondary, but also greatly in excess of the mass-bound power input to the vibrator stage and the primary, at 28 to 35W. Once the pulse rate approaches the same 1.5 PPS marker, mechanical power in excess of the mass-bound electric power input to the primary becomes evident, peaking at nearly three times that input. In fact, the highest output recorded was also obtained with the lowest input to the transmitter circuit, the highest exact coefficient observed in this experiment being 100.8W / 28W = 3.6. Furthermore, with respect to the secondary mass-bound output, the same mechanical rotary output represents a much greater overunity coefficient of performance, on the order of 14.4 times greater. This is at least partly the result of the receiver and motor capture of the mass-free electric energy output by the transmitter, and may be partly the result of mass-free energy engrafted by the PAGD regime in the PAGD reactor.

Reviewing the mechanical power output results as a function of increasing vacuum in the PAGD reactor and at different output power levels, any motor performance below the 5-7W limit of the traditional mass-bound output power of the secondary represents an output mechanical power loss with respect to both the mass-bound secondary output and the mass-bound primary input. All the results for pressures down to 0.03 Torr fall into this category, and thus represent a very inefficient coupling to the PAGD regime. Any motor performance between 7W and 28-35W represent a loss with respect to the electrical power input to the transmitter system, but a net gain of power with respect to the mass-bound secondary power output. None of the non-inertially dampened motors tested were able to perform outside of this area, under the test conditions. With more efficient primary to secondary couplings in the transmitter station, however, one could advantageously employ these motors alone to extract some of the mass-free power of the secondary or to operate them in enclosed vessels without conventional external electrical connections.

To reach satisfactory levels of recovery of mass-free energy, one must dampen the superimposed DW impulses. Hence, all results showing outputs in excess of 35W were obtained using the inertially dampened KS-9303 motors, and represent a net overunity power gain over both the power input to the primary and the mass-bound power output by the secondary, or the mass-bound power emulated by the receiver circuitry. This happens when the PAGD pulse rate falls to 2 PPS, with the rotary power output steeply increasing as the rate falls to 1 PPS.

One of the interesting features of the motor circuitry we have proposed is that it can operate with pulsed plasmas in both the TRD and the AGD regions, the least efficient response occurring in the NGD region near the Paschen minimum. One might think that the voltage depression would allow increased current intensity supplied to the motors, but in fact that is not observed, with the flashing of the NGD yielding erratic oscillations and low values of current. In keeping with the notion that the TRD plasma is mainly composed of lagging positive ions, whereas the PAGD plasma is mostly an electron plasma, the observed direction of rotation of the motors is opposite in the TRD region to that of the AGD region. The NGD region therefore marks the depression where the velocity vectors change direction. In the second or PAGD region, motor operation is very quiet, unlike what is observed in the TRD region.

Part and parcel of the tuning of the circuit components is the selection of the optimum capacitances employed to couple the PAGD reactor to the motor circuit and split the phase to feed the auxiliary winding of the motor. We have experimented with capacitances ranging from 0.5 to 100 microfarads, and found that best results (for the specific circuit in question - including the characteristics of the transmission), were such that the optimum value of the PAGD coupling capacitance lay near 4 microfarads, and the phase splitting capacitance, near 1 to 4 microfarads, depending upon weather conditions. In good weather days lower capacitance values can be used, while in bad weather days higher capacitances are needed. For ease of comparison in demonstrating the need to tune the circuit by employing optimum capacitances in those two couplings (reactor to motor, and motor phase coupling), we employed the same capacitances in both circuit locations.

A comparison of tests using 1 and 4 microfarad values shows the difference caused by changing those capacitances from their optimum value: across all discharge regions of the pressure range that was examined, the four motors tested, operated with greater motor speeds when the capacitances are set to 4 microfarads rather than to 1 microfarad. The less efficient performance obtained with 1 microfarad capacitance fits the inverse correlation of pulse power with increasing pulse frequency, such as we have found for the PAGD regime. This is made evident by a comparison of rpm versus pulse rate for the two capacitance values being considered. They demonstrate the higher pulse rates observed with the lower capacitance, that correlate with the lower motor speeds, and result in lower efficiency of the motor response. The results equally indicate that low capacitance values increase the pulse rate, but if this increase is out of tune with the rest of the circuit values, it results in power waste because it imposes a rate that is not optimum.

We have also determined experimentally that the efficiency of the system is affected by external weather conditions, higher efficiencies being noted on a fine bright day than under poor weather conditions even though the apparatus is not exposed to such conditions. This may reflect a diminution under poor weather conditions of latent mass-free energy that can be taken up by the system.

The observed high efficiency of circuits including inertially dampened motors indicates that the phenomenon does not reduce to a mere optimum capture of, DC-like pulses produced by the reactor in what is essentially an AC motor circuit. Effectively, the pulsed plasma discharge deploys a front-end, DC-like pulse, or discontinuity, but this is followed by an AC-like dampened wave of a characteristic frequency (having a half-cycle periodicity identical to that of the front-end pulse) to which the motor circuit also responds. Moreover, the mass-free electric radiation from the transmitter circuit itself induces, in the receiver antenna, coil and circuit, and in the reactor discharge itself, the train of finer dampened wave impulses responsible, after conversion through the wave-divider, for the mass-bound rectified current which is employed to charge the plasma reactor to begin with. Serving as trigger of the plasma discharges in the reactor are the DW impulses circulating in the receiver circuit, such that the two different lines of DW impulses, in the receiver circuit (for example 120 PPS for the pulses and 154 kHz for the waves) and from the reactor, are synchronised by interpolated coincidences, since their pulse and wave frequencies are different. Ideally, these two superimposed DW frequencies are harmonics or made identical. The receiver stage involves capture of the mass-free electric energy received from the transmitter, duplication of the mass-bound current in the receiver coil, and injection of latent and sensible thermal energy in the T/R gap cavity which augments the emulated mass-bound current.

The mass-bound current is employed to charge the wave-divider capacitance bridge and therefore the reactor. In turn, the plasma pulses from the reactor are superimposed with the DW impulses from the receiving coil, and together they are coupled to the split-phase motor drive. Hence the first receiver stage employs the totality of the energy captured in the T/R gap cavity - mass-free electric energy transmitted by the **T** plate, latent and sensible thermal energy injected at the surface of the **R** plate - and produces in the receiving coil a mass-bound current comparable to that assembled in the transmitter coil by the action of the primary. The mass-bound current is stored in the wave-divider bridge and used to drive the plasma reactor in the PAGD region. Subsequently, the autogenous disruptive discharge that employs a substantial electron plasma generates both a concentrated, intense flux of mass-bound charges in the output circuit, and a mass-free oscillation of its own. The dampened motor is therefore fed directly with (1) the intense mass-bound current output from the reactor; (2) the pulse and wave components of the mass-free electric energy captured by the receiver plate and coil (and matched by conduction through the earth), and which are gated through the wave-divider and the reactor for the duration of the PAGD channel; and (3) any mass-free latent energy taken up from the vacuum by the PAGD event. Once the

motor is set into motion, and is resonantly loaded with an inertial damper, we believe that it will also respond to the much weaker DW impulses captured by the receiver, since these impulses encompass both a DC-like front end - further enhanced by analytic separation through the wave-divider - and a dampened wave at 154 kHz.

Essentially, the DW impulses that are ultimately sourced in the transmitter - and received unipolarly through the T/R gap - have sufficient DC-like potential (plus all the other requisite physical characteristics, such as frequency) to contribute directly to the motor response, once the motor has gained substantial speed (for they lack the current to set it into motion, one of the contributions from the plasma pulser). This is the case, provided that the motor itself is suited for absorption of both DC-like pulses and AC-like dampened waves, which is precisely the case with motors of the type shown in **Fig.18** since the inertia of the flywheel is overcome through homopolar absorption of the dampened oscillations simultaneously in the motor drag-cup rotor and in the generator drag-cup rotor.

We also tested these inertially dampened motors in the traditional DC power supply-driven PAGD circuit we have taught in our previous patents, that is, circuits with an overt HV DC power source, and thus in the absence of any Function Y circuit or transmitter circuit. Here then, only the DW impulses generated by the PAGD reactor can account for the motor response. The tube employed (A31) had an area of 256 cm^2, and a gap distance of 4 cm. Coupling capacitances employed were 4 microfarads for the inverter coupling, and 1 microfarad for the split phase motor coupling. The DC power supply delivered up to 1 ampere of current between 150 and 1,000 VDC, and the ballast resistor was adjusted to 215 ohms. Having determined the basic physical characteristics of the reactor's behaviour in the circuit under consideration, we conducted our experiment in the PAGD region. We chose a pressure of 0.6 Torr, just off from the Paschen minimum, as we intended to benefit from the lower sustaining voltage which it affords.

The experiment basically consisted of increasing the sustaining voltage at this fixed pressure in the PAGD regime, and measuring the diverse physical parameters of the circuit and motor response in order to ultimately ascertain the difference between the input electric DC power and the output mechanical rotary power. We first looked at how the motor rpm response varied as a function of the sustaining voltage (V_S): the results illustrate the importance of starting close to the Paschen minimum in the pressure scale, since the KS-9303 motors reach plateau response (at 17,000 rpm) when the reactor output voltage nears 450V. Any further increase in potential is simply wasted. Likewise, the same happened when we measured motor speed as a function of increasing peak DC current, plateau response being reached at 0.1 ADC. Again, any further increase in current is wasted. Essentially then, the optimal power input to the reactor when the output of the latter is coupled to the motor, lies around 45 watts. This is a typical expenditure in driving a PAGD reactor. As for pulse rate we once again find a motor response that is frequency proportional in the low frequency range, between 10 and 40 PPS (all pulse rates now refer solely to PAGDs per sec), but once rates of >40 PPS are reached, the response of the motor also reaches a plateau.

The observed increment in speed from 40 to 60 PPS translates only into an increase of 1,000 RPM, from 16,000 to 17,000 RPM. So, we can place the optimal PAGD rate at ca 40 PPS. The DC electric power input to drive the PAGD reactor was next compared to the rotary mechanical power output by the inertially loaded motor, driven in turn by the reactor. This comparison was first carried out with respect to the PAGD rates. The motor response far exceeds the conventional input power, indicating that the whole system can be tuned to resonance such that optimal power capture inside the reactor takes place, the critical limit rate lying at around 60 PPS, when the motor response is firmly within the pulse response plateau. At this juncture, the break-even efficiency for the measured rates of energy flux over time reach 700% (overunity coefficient of 7), in keeping with the observations and the values we have made in the PAGD conversion system. In the proportional part of the curve, before the plateau is reached, even greater rates of break-even efficiency - up to >1,000% were registered.

These results constitute the first time we have been able to confirm the presence of output energy in excess of break-even over conventional mass-bound energy input in the PAGD inverter system, and the results are comparable to what we have observed and previously reported for the PAGD converter system. At pulse rates greater than 60 PPS a greater input power results in decreased efficiency, also translated into a noticeable heating of the reactor and motor. And this is all the more remarkable as experiments we have conducted with inductive tuning of PAGD reactors, or employing PAGD reactors as replacements for the primaries of Tesla coil assemblies, and still, more recently, with the PAGD inverter circuit driving motors, have all shown that it is possible to operate these reactors with minimal mirroring and heating, preserving essentially the cold-cathode conditions and yet focusing the plasma column so that deposition on the insulator is negligible. It appears that above a certain threshold of optimal efficiency, surplus input energy is just dissipated thermally by both the reactor and the motors.

It should be understood that the above described embodiments are merely exemplary of our invention, and are, with the exception of the embodiments of **Figs. 16 to 19** designed primarily to verify aspects of the basis of the invention. It should also be understood that in each of these embodiments, the transmitter portion may be omitted

if an external or natural source of Tesla waves is available, provided that the receiver is tuned to the mass-free radiation mode of the source. For example if solar radiation is available in which the mass-free component has not interacted with the earth's atmosphere (as in space applications), the receiver is tuned to the voltage wave of the mass-free radiation sourced in the sun, e.g. by using a Tesla coil in the receiver constructed to have an appropriate voltage wave close to the 51.1 kV characteristic of such radiation.

CLAIMS

1. A device for the conversion of mass-free radiation into electrical or electrokinetic energy comprising a transmitter of mass-free electrical radiation having a dampened wave component, a receiver of such radiation tuned to resonance with the dampened wave frequency of the transmitter, a co-resonant output circuit coupled into and extracting electrical or electrokinetic energy from the receiver, and at least one of a transmission cavity between the transmitter and the receiver, a full-wave rectifier in the co-resonant output circuit, and an oscillatory pulsed glow discharge device incorporated in the co-resonant output circuit.

2. A device according to claim 1, wherein the output circuit comprises a full wave rectifier presenting a capacitance to the receiver.

3. A device according to claim 2, wherein the output circuit comprises an electric motor presenting inductance to the receiver.

4. A device according to claim 3, wherein the motor is a split phase motor.

5. A device according to claim 4, wherein the motor is a drag motor having a non-magnetic conductive rotor.

6. A device according to claim 5, wherein the motor has inertial damping.

7. A device according to claim 6, wherein the motor has a shaft, a drag cup rotor on the shaft, and inertial damping is provided by a further drag cup on the shaft.

8. A device according to claim 6, wherein the transmitter and receiver each comprise at least one of a Tesla coil and an autogenous pulsed abnormal glow discharge device.

9. A device according to claim 8, wherein the transmitter and receiver both comprise Tesla coils, and further including a transmission cavity which comprises spaced plates connected respectively to the distal poles of the secondaries of Tesla coils incorporated in the transmitter and receiver respectively.

10. A device according to claim 9, wherein the plates are parallel.

11. A device according to claim 9, wherein the plates are concentric.

12. A device according to claim 9, wherein at least the receiver comprises a Tesla coil driving a plasma reactor operating In PAGD (pulsed abnormal glow discharge) mode.

13. A device according to claim 1, wherein the transmitter and receiver each comprise at least one of a Tesla coil and an autogenous pulsed abnormal glow discharge device.

14. A device according to claim 12, wherein the transmitter and receiver both comprise Tesla coils, and further Including a transmission cavity which comprises spaced plates connected respectively to the distal poles of the secondaries of Tesla coils incorporated in the transmitter and receiver respectively.

15-17. (cancelled)

18. A device according to claim 1 wherein a transmitter/receiver cavity is present and filled with an aqueous liquid.

19. A device for the conversion of mass-free radiation into electrical or electrokinetic energy comprising a receiver of such radiation from a source of mass-free electrical radiation having a dampened wave component, the receiver being tuned to resonance with the dampened wave frequency of the source, a co-resonant output circuit coupled into and extracting electrical or electrokinetic energy from the receiver, and at least one of a transmission cavity between the source and the receiver, a full-wave rectifier in the co-resonant output circuit, and an oscillatory pulsed glow discharge device incorporated in the co-resonant output circuit.

PAULO and ALEXANDRA CORREA

US Patent 5,449,989 **12th September 1995** **Inventors: Correa, Paulo and Alexandra**

ENERGY CONVERSION SYSTEM

This patent shows a method of extracting environmental energy for practical use. In the extensive test runs, an input of 58 watts produced an output of 400 watts (COP = 6.9). This document is a very slightly re-worded copy of the original.

ABSTRACT

An energy conversion device includes a discharge tube which is operated in a pulsed abnormal glow discharge regime in a double ported circuit. A direct current source connected to an input port provides electrical energy to initiate emission pulses, and a current sink in the form of an electrical energy storage or utilisation device connected to the output port captures at least a substantial proportion of energy released by collapse of the emission pulses.

REFERENCE TO RELATED APPLICATIONS

This application is a continuation-in-part of U.S. application Ser. No. 07/922,863, filed Jul. 31, 1992 (abandoned), and is also a continuation-in-part of U.S. patent application Ser. No. 07/961,531, filed Oct. 15, 1992, now U.S. Pat. No. 5,416,391.

BACKGROUND OF THE INVENTION

1. Field of the Invention:

This invention relates to energy conversion circuits utilising discharge tubes operating in the pulsed abnormal glow discharge (PAGD) regime.

2. Review of the Art:

Such discharge tubes and circuits incorporating them are described in our co-pending U.S. patent application Ser. Nos. 07/922,863 and 07/961,531. The first of these applications discloses discharge tube constructions particularly suited for PAGD operation, and the second discloses certain practical applications of such tubes, particularly in electric motor control circuits. The review of the art contained in those applications is incorporated here by reference, as is their disclosure and drawings.

It is known that there are anomalous cathode reaction forces associated with the cathodic emissions responsible for vacuum arc discharges, the origin and explanation of which have been the subject of extensive discussion in scientific literature, being related as it is to on-going discussion of the relative merits of the laws of electrodynamics as variedly formulated by Ampere, Biot-Savart and Lorentz. Examples of literature on the subject are referenced later in this application.

SUMMARY OF THE INVENTION

The particular conditions which prevail in a discharge tube operated in the PAGD regime, in which a plasma eruption from the cathode is self-limiting and collapses before completion of a plasma channel to the anode gives rise to transient conditions which favour the exploitation of anomalous cathode reaction forces.

We have found that apparatus utilising discharge tubes operated in a self-sustaining pulsed abnormal glow discharge regime, in a double ported circuit designed so that energy input to the tube utilised to initiate a glow discharge pulse is handled by an input circuit substantially separate from an output circuit receiving energy from the tube during collapse of a pulse, provides valuable energy conversion capabilities.

The invention extends to a method of energy conversion, comprising initiating plasma eruptions from the cathode of a discharge tube operating in a pulsed abnormal glow discharge regime utilising electrical energy from a source in a first circuit connected to said discharge tube, and capturing electrical energy generated by the collapse of such eruptions in a second circuit connected to the discharge tube.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention is described further with reference to the accompanying drawings, in which:

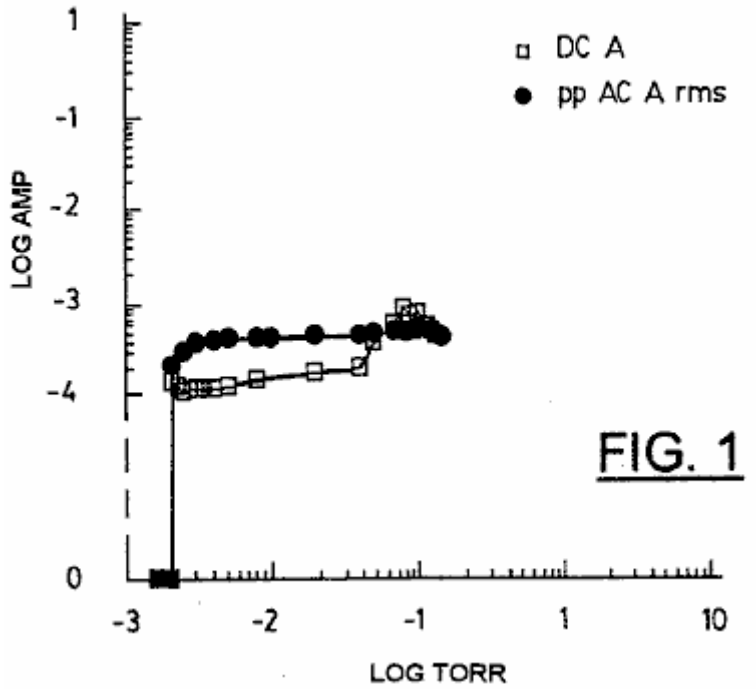

FIG. 1

Fig.1 shows variation of applied DC current and pulse AC rms currents characteristic of a low current PAGD regime, as a function of decreasing pressure, for a 128 cm^2 H34 aluminium plate pulse generator having a 5.5 cm gap length and being operated in the single or plate diode configuration of FIG. 11A, at about 600 V DC.

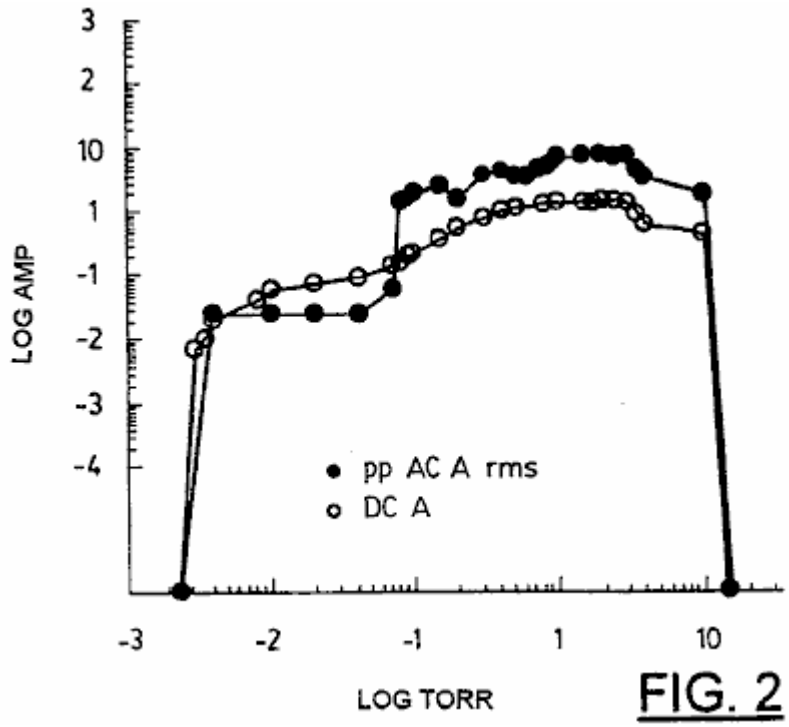

FIG. 2

Fig.2 shows variation of applied DC current and AC rms currents of a high current PAGD regime, as a function of the decreasing pressure, for a device identical to that of Fig.1, and operated at the same potential.

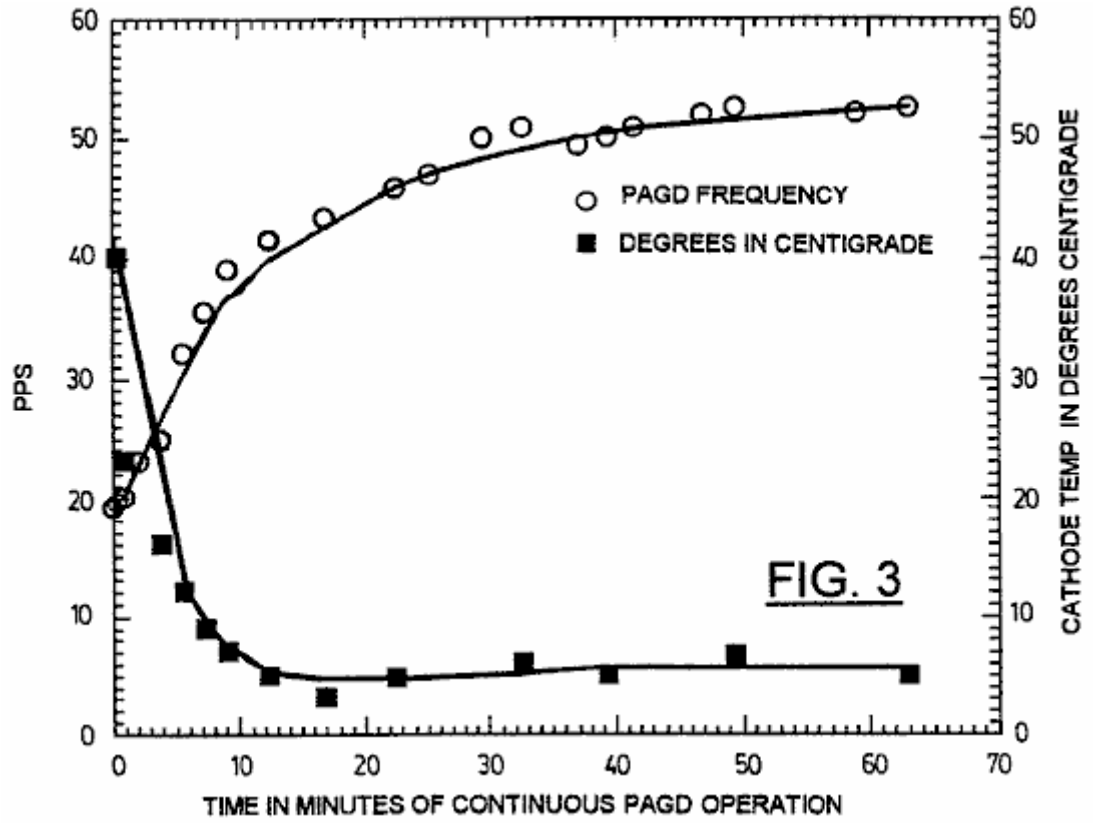

FIG. 3

Fig.3 shows PAGD rate vs pulse generator cathode temperature as a function of the time of continuous PAGD operation, for a pulse generator with 64 cm^2 plates having a 4 cm gap distance, operated at a DC voltage of 555 (av) and R1 = 600 ohms (see Fig.9).

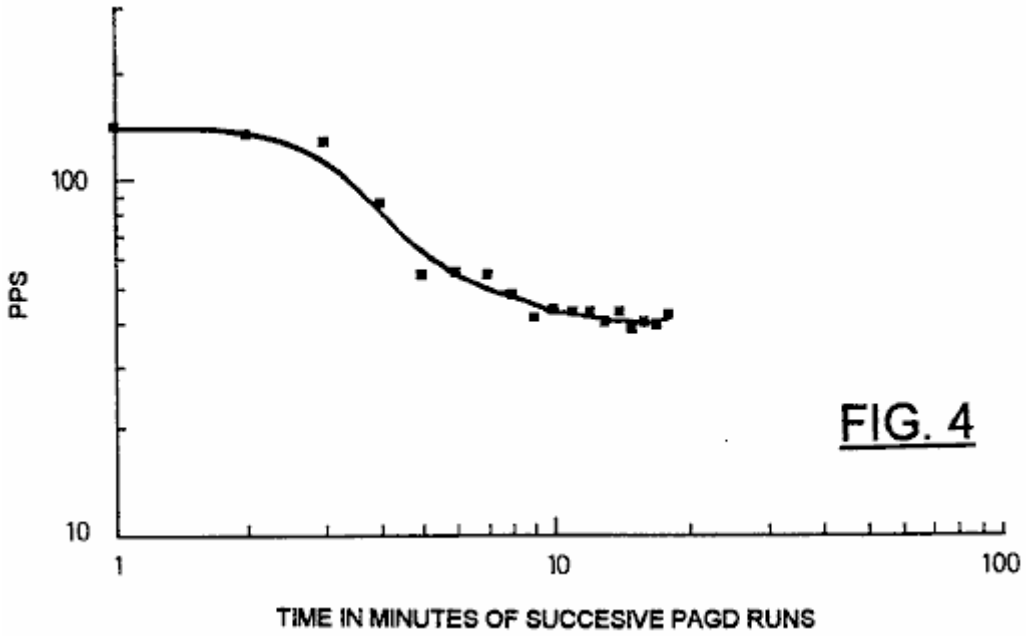

FIG. 4

Fig.4 shows PAGD frequency variation with time, for 18 successive spaced one-minute PAGD runs for a pulse generator with 128 cm^2 plates, and a 5.5 cm gap distance, operated at V DC = 560 (av) and R1 = 300 ohms.

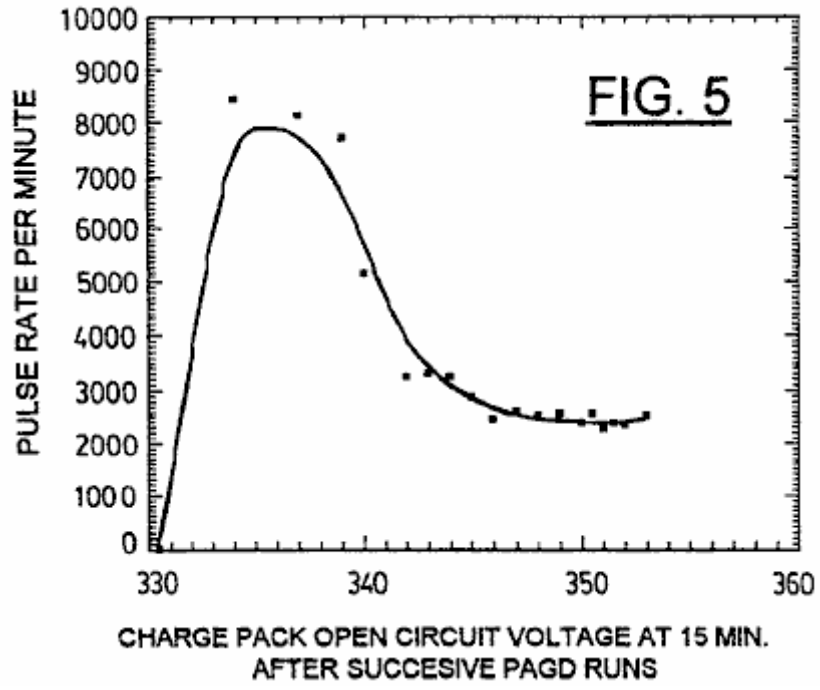

FIG. 5

Fig.5 shows variation of the PAGD frequency in pulses per minute (PPM) with increasing charge of a PAGD recovery charge pack (see Fig.9), as measured in terms of the open circuit voltage following 15 minutes of relaxation after each one minute long PAGD run, repeated 18 times in tandem, under similar conditions to Fig.4.

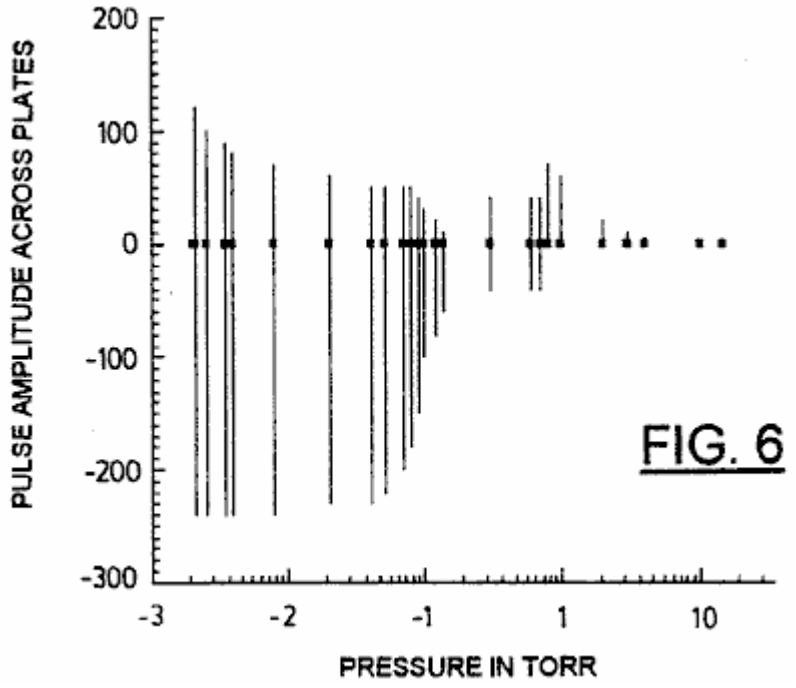

FIG. 6

Fig.6 shows volt amplitude variation of continuous PAGD at low applied current, as a function of decreasing air pressure, for a 128 cm^2 plate area device, gap length = 5 cm; (DC V at breakdown = 860).

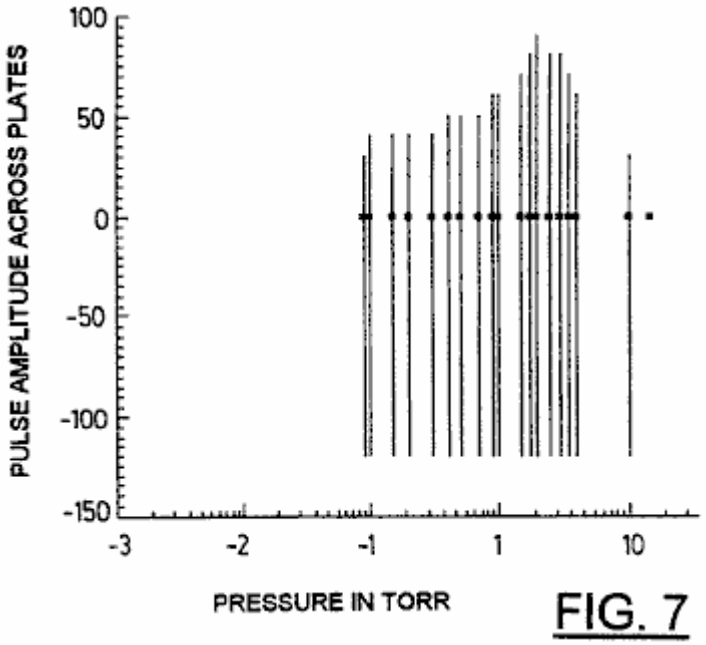

FIG. 7

Fig.7 shows volt amplitude variation of continuous PAGD at high applied current as a function of the decreasing air pressure, for a 128 cm^2 plate area device, gap length = 5 cm; (DC V at breakdown = 860).

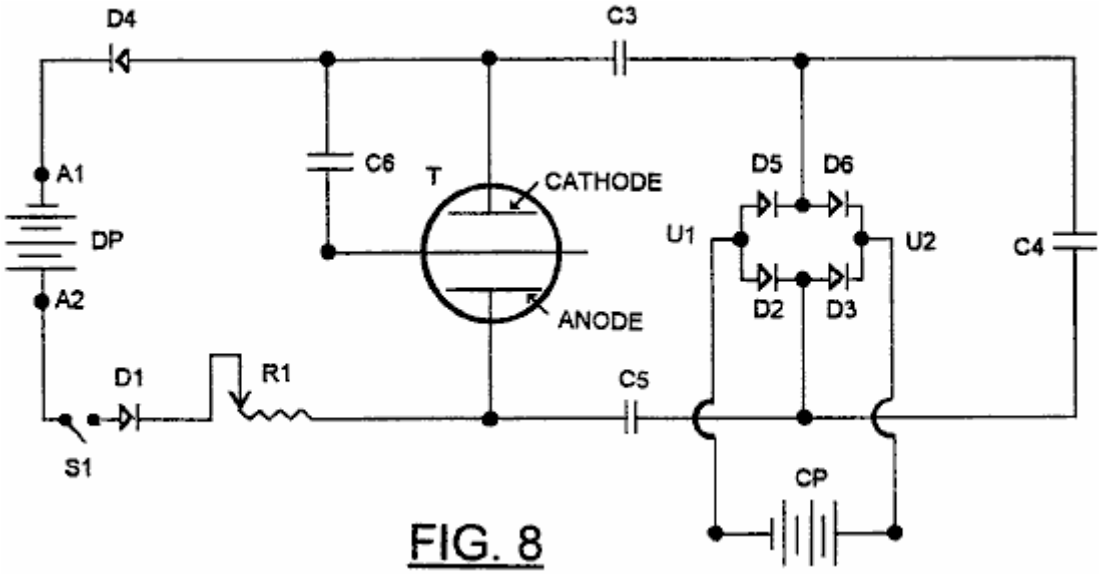

FIG. 8

Fig.8 is a schematic diagram of a first experimental diode (without C6) or triode PAGD circuit.

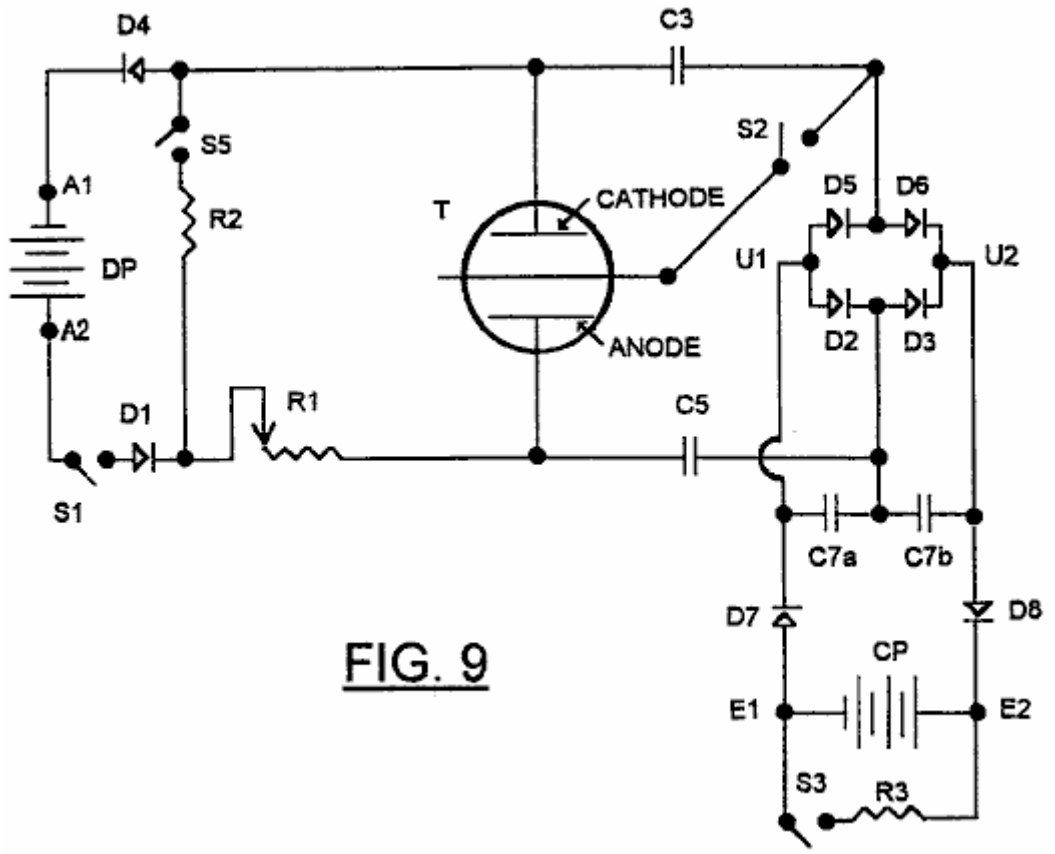

FIG. 9

Fig.9 is a schematic diagram of a preferred diode or triode PAGD circuit in accordance with the invention.

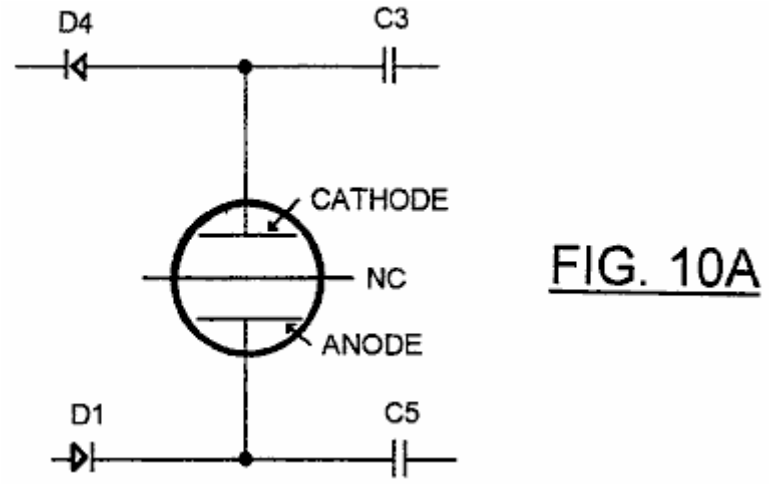

FIG. 10A

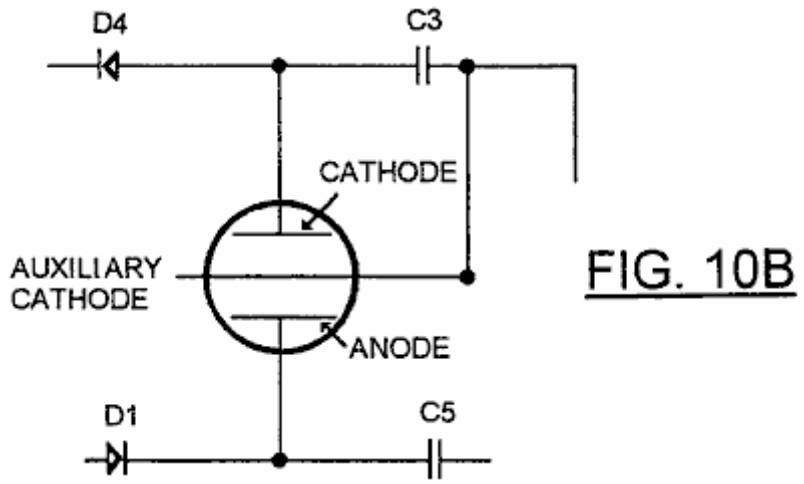

FIG. 10B

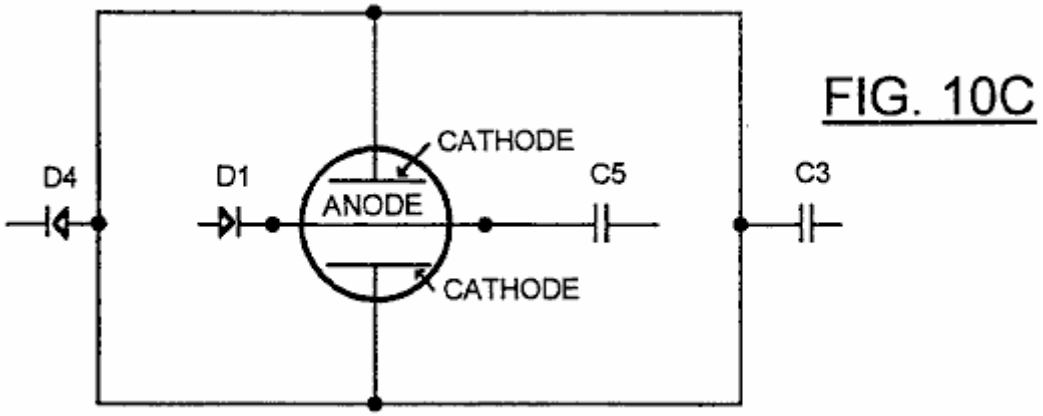

FIG. 10C

Fig.10A, **Fig.10B** and **Fig.10C** are fragmentary schematic diagrams showing variations in the configuration of the circuit of Fig.9.

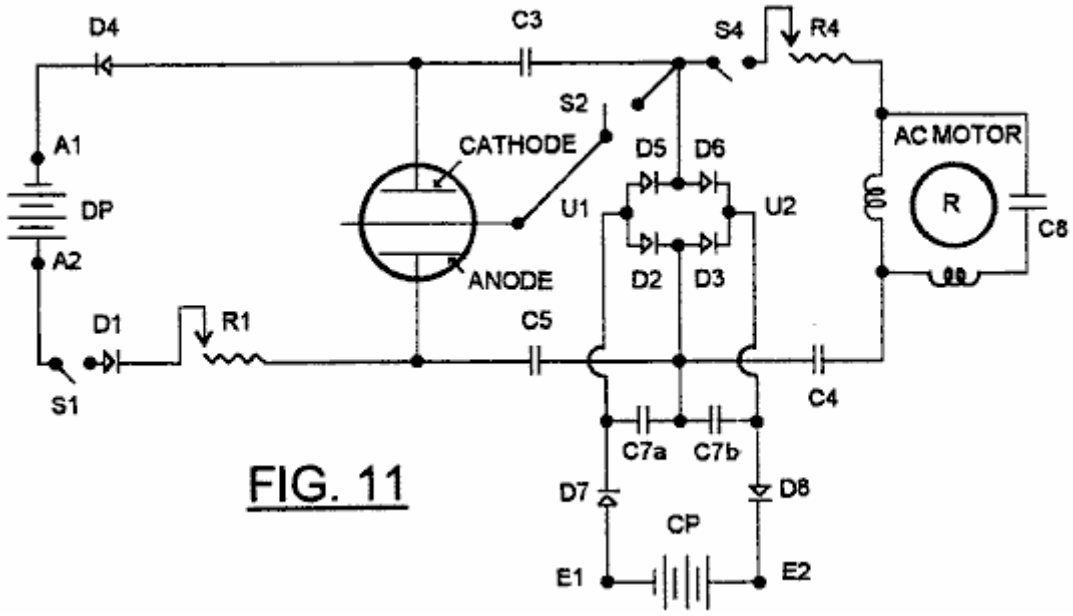

FIG. 11

Fig.11 is a modification of Fig.9, in which an electromagnetic machine, in the form of an electric motor, is connected into the circuit as an accessory electromechanical arm.

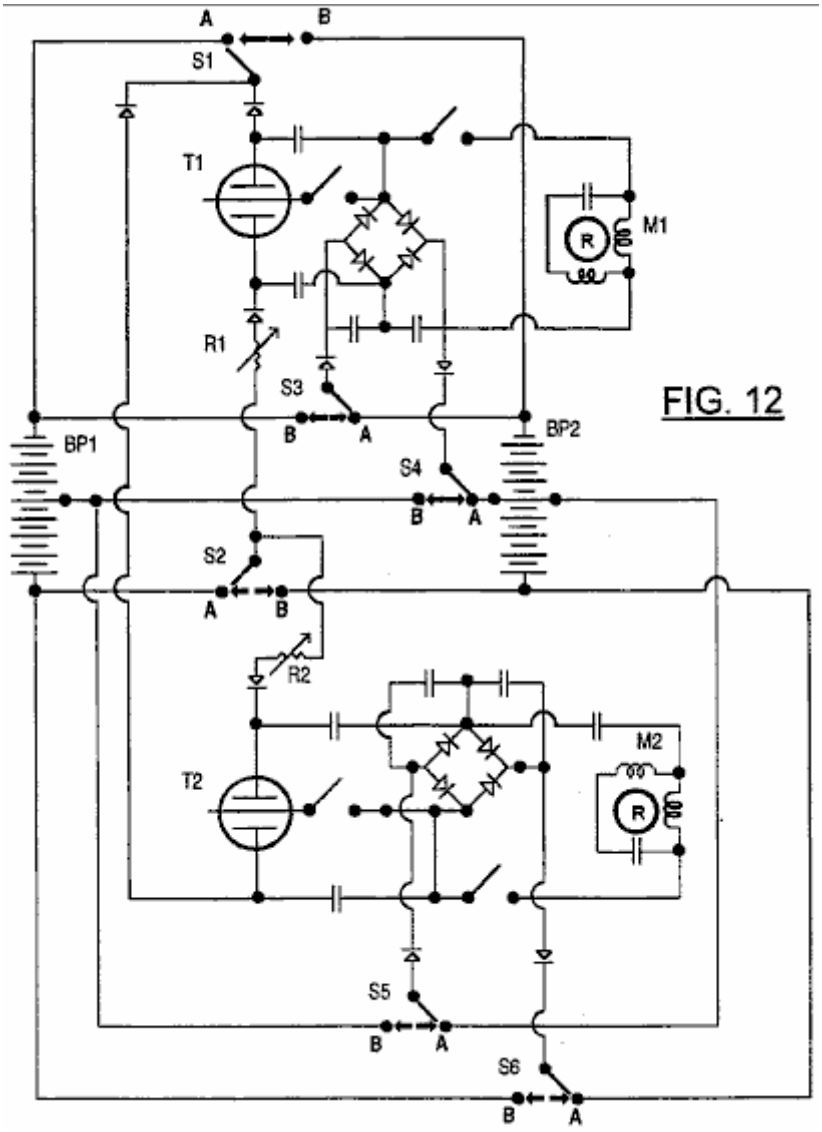

FIG. 12

Fig.12 shows a further development of the circuit of Fig.9, permitting interchange of driver pack and charge pack functions.

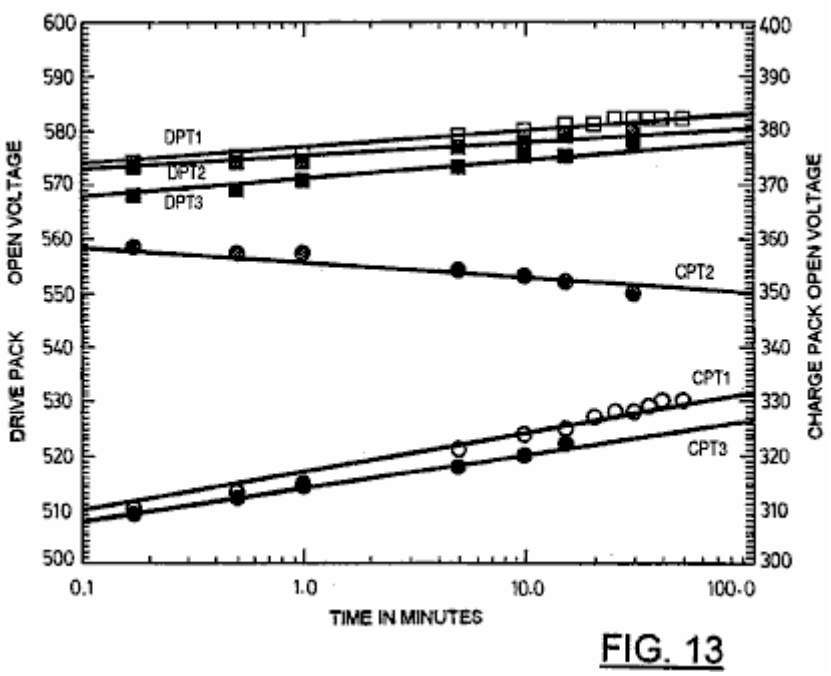

FIG. 13

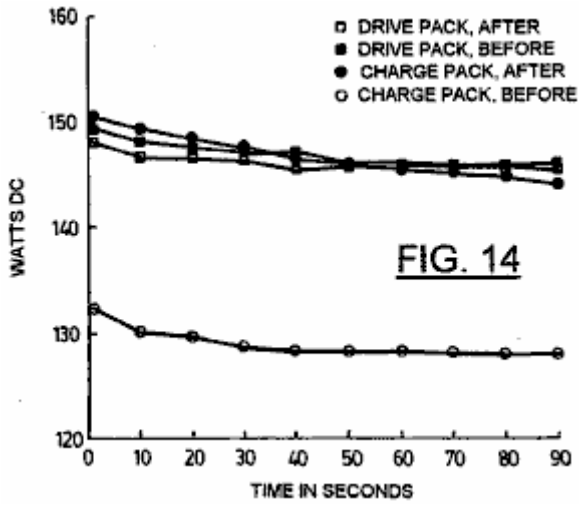
Fig.13 shows open circuit voltage relaxation curves for battery packs employed in tests of the invention, respectively after pre-PAGD resistive discharge (DPT1 and CPT1), after a PAGD run (DPT2 and CPT2) and after post-PAGD resistive discharge (DPT3 and CPT3).



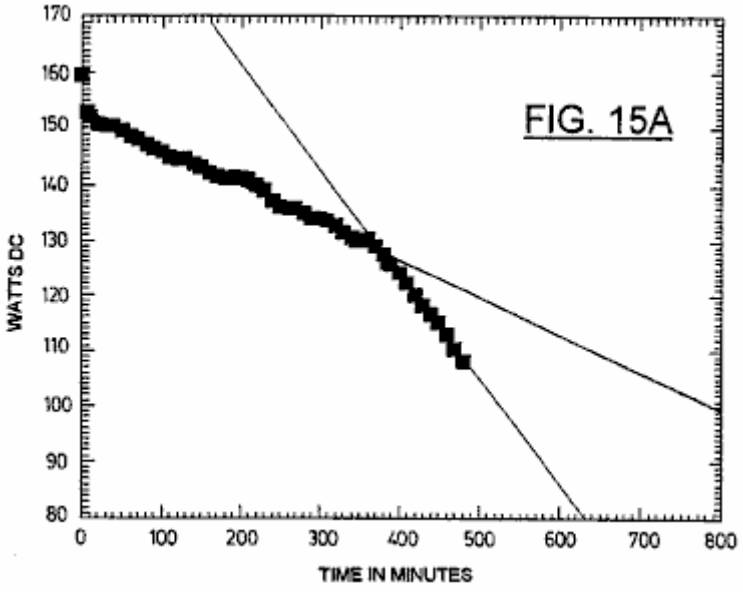


FIG. 14

Fig.14 shows an example of negligible actual power measurements taken immediately before or after a PAGD run, showing both the drive pack loss and the charge pack gain in DC Watts; DP resistance = 2083 ohms; CP resistance = 833 ohms.

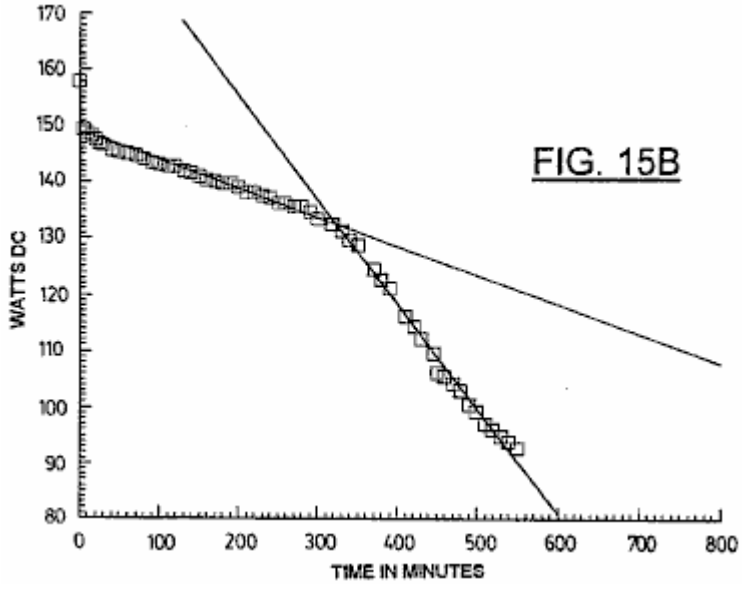

Fig.15A and **Fig.15B** show resistive voltage discharge curves for two separate lead-zero gel-cell packs utilised respectively as the drive and the charge packs; load resistances employed were 2083 ohms across the drive pack (Fig.15A) and 833 ohms across the charge pack (Fig.15B).

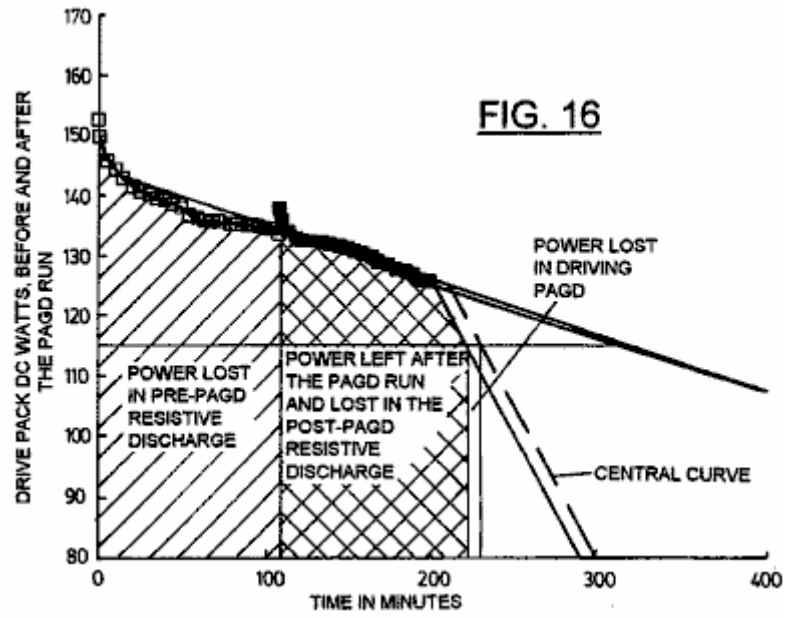

Fig.16 shows resistive discharge slopes for a drive pack before and after a very small expenditure of power in providing energy input to a PAGD run; R = 2083 ohms.

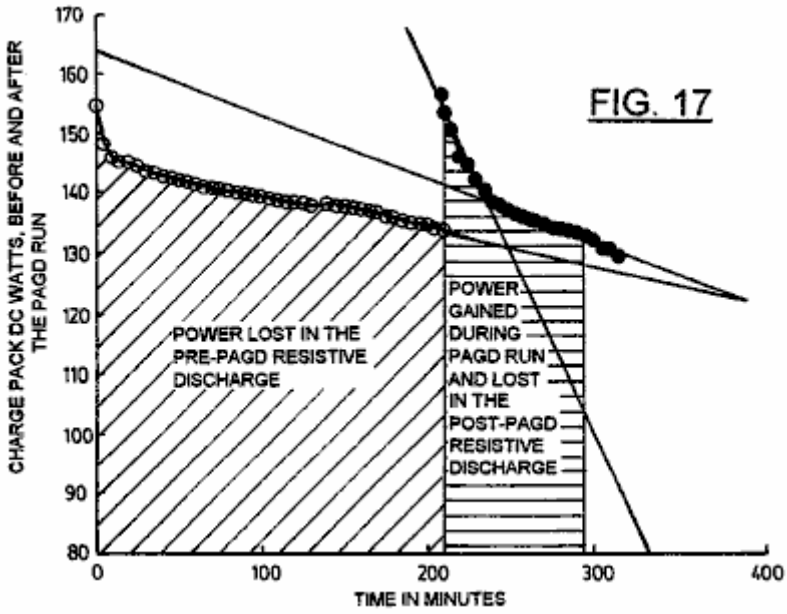

Fig.17 shows resistive discharge slopes for a charge pack before and after capturing energy from the collapse of PAGD pulses in the same test as Fig.15; R = 833 ohms.

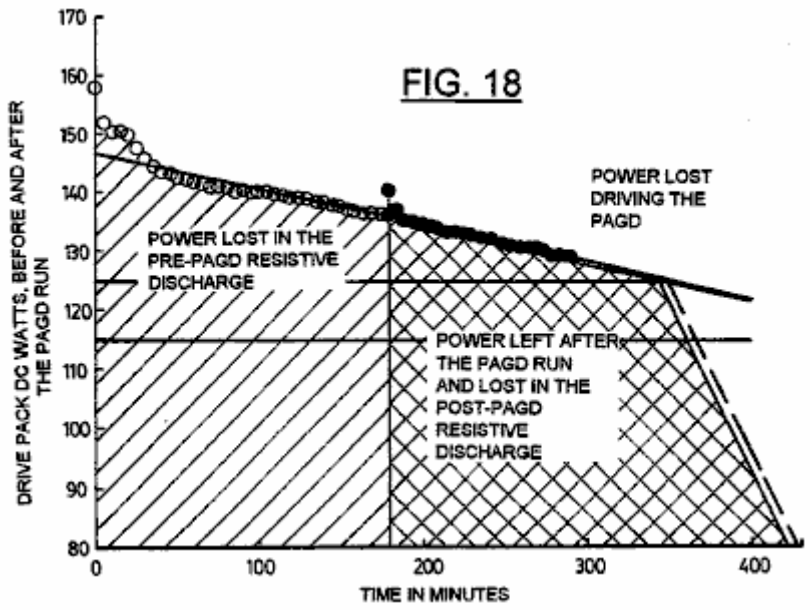

Fig.18 shows resistive discharge slopes for a drive pack before and after a very small expenditure of power in providing energy input to a PAGD run in a further experiment; R = 2083 ohms.

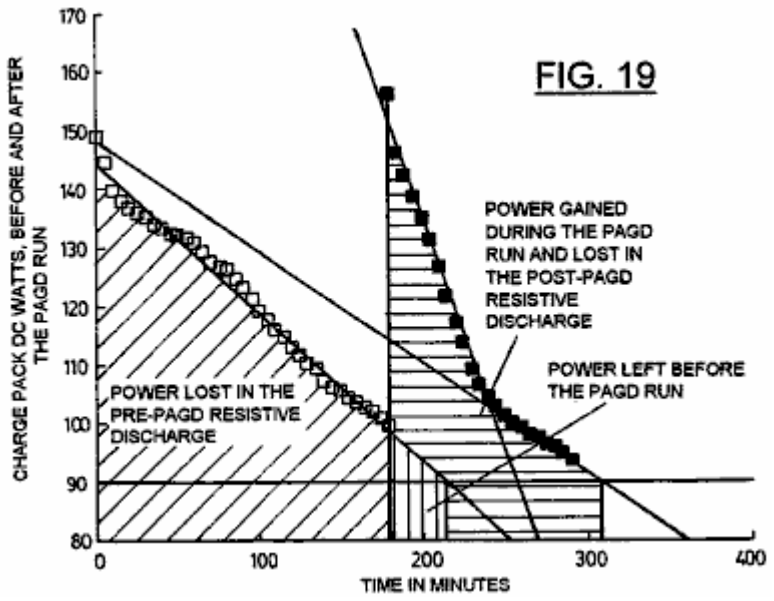

Fig.19 shows resistive discharge slopes for a charge pack before and after capturing energy from the PAGD run of Fig.18; R = 833 ohms.

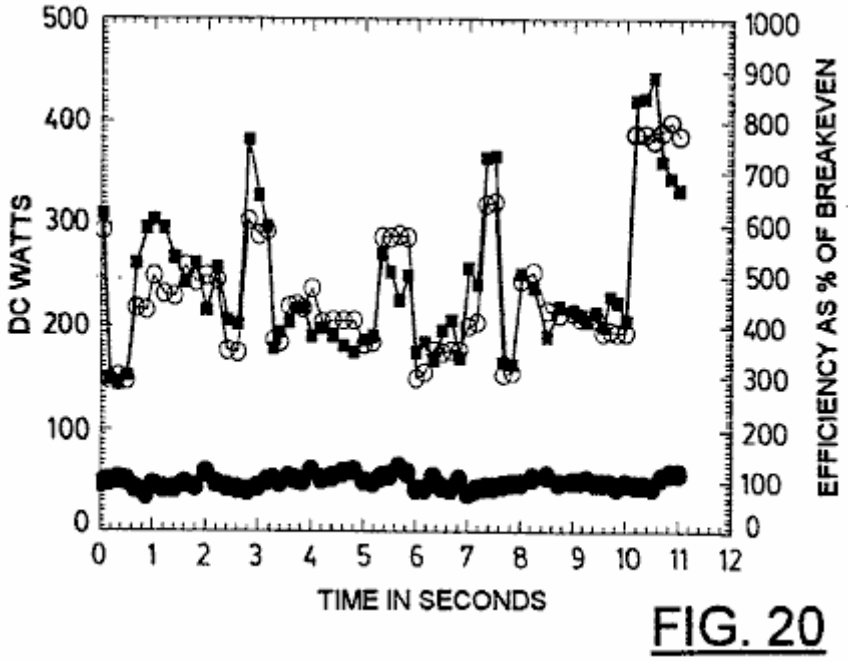

FIG. 20

Fig.20 shows an example of operational measurements taken videographically during a 10 second period for both the power consumption of the drive pack (PAGD input) and the power production captured by the charge pack (PAGD output); the two values are also related by the expression of percent break-even efficiency.

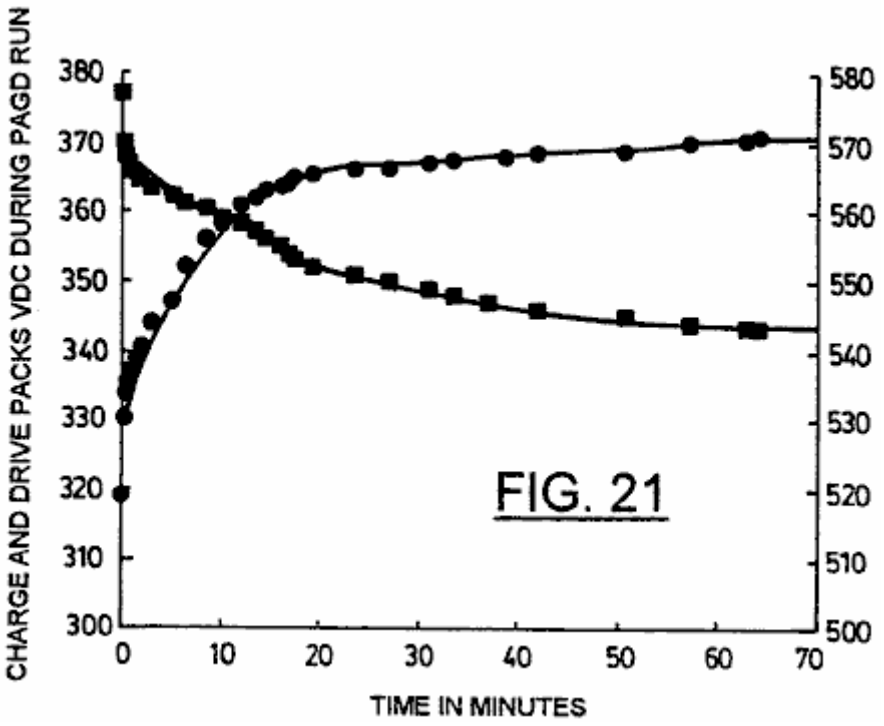

FIG. 21

Fig.21 shows variation of PAGD loaded voltage of a drive pack (in squares) compared with the PAGD charging voltage of the charge pack (in circles), during more than 1 hour of continuous PAGD operation.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The basic PAGD function and the construction of discharge tubes specifically designed for PAGD operation are described in our corresponding co-pending applications Nos. 07/922,863 (the "863" application) and 07/961,531 (the "531" application). For purposes of the experiments described below four aluminium H34 plate devices (one with 64 and three with 128 cm^2 plate areas) and three aluminium (H200) plate devices (one with 64 and two with 128 cm^2 plate areas), with inter-electrode gap lengths of 3 cm to 5.5 cm, were utilised at the indicated vacua, under pump-down conditions and with either air or argon (ultra high purity, spectroscopic grade 99.9996% pure)

constituting the residual gas mixture. The pump-down conditions were as described in the “863” application. Some experiments were performed with the tubes under active evacuation, at steady-state conditions, while others utilised sealed devices enclosing the desired residual gas pressures.

The circuit designs utilised in the various experiments to be described are set out further below, and represent further developments and extensions of the circuits set forth in the “531” application.

Test equipment utilised was as follows:

An Edwards (trade mark) thermocouple gauge (TC-7) was employed for the determination of pressure down to 1 micron of mercury (0.001 Torr).

Banks of Beckman (trade mark) rms multimeters 225 and 330 (30 and 100 kHz bandwidths, respectively) were utilised for all current measurements.

Frequency meters capable of discriminating events up to 0.1 nanosecond apart, and having adjustable amplitude windows, were used. Direct analysis on a Tektronix (trade mark) dual-trace, storage scope (Model 549) was also carried out for both parameters.

Split-phase, single-phase and two-phase motors were employed, of the synchronous, induction and universal types, as previously described in the “531” application, in the accessory electromechanical arm that may be coupled to the power producing circuit described in the present application.

Large banks of 12 V, 6 Ah lead-acid gel cells (Sonnenschein (trade mark) A212/6S) were utilised either as power sources (designated as drive packs) or as accumulators of the energy (referred to as charge packs) captured by the test circuits. Charge packs made of rechargeable 9V NiCad or of nominally non-rechargeable C-Zn or alkaline batteries were also utilised.

PAGD emission areas were determined by metallographic examination of a series of craters produced by PAGDs in clean H34 cathodes, under a metallurgical Zeiss (trade mark) standard 18 microscope equipped with an epi-fluorescent condenser, very high power apochromatic objectives and a 100 W mercury lamp. For best results a focusable oblique source of light (12V halogen) was also added to the incident light.

Following our low and high applied current studies on PAGD production as set forth in the “863” application, we noticed that the AC rms value of the component associated with each abnormal glow discharge pulse varied non-linearly with the magnitude of the applied current. We originally noted the existence of a current induced shift of the entire PAGD region upward in the pressure scale: while the PAGD regime became more clearly defined as the applied constant DC was increased, the pressure required to observe the PAGD increased two to three orders of magnitude. In the course of these rarefaction studies we found that, at applied currents of 1mA or less, the rms value of the different AC waveforms associated with the consecutive regimes of the discharge (TRD --> NGDm --> AGD+PAGD) was, by more than half log, inferior to the value of the applied DC current, during the first two regimes (TRD and NGD) and reached a value equivalent to the applied current with the onset of spontaneous PAGD, at pressures < 0.1 Torr (see **Fig.1**); however, in the downward tail of the PAGD regime (down to 3×10^{-3} Torr), the AC rms current component of each PAGD again decreased to more than half log of the intensity of the applied DC value, in a manner proportional to the log of the decreasing pressure. In stark contrast, at high applied currents of about 500 mA, and aside from the high current-induced upward shift in pressure of the PAGD regime (to the point that the compression of the previous regimes on the pressure scale results in their suppressing, as was the case in the present example), the AC rms component associated with each pulse (see closed circles, **Fig.2**) is, from onset of the discharge at about 8 Torr, greater in magnitude than the value of the applied current (open circles, **Fig.2**). Under the conditions described, the distribution of the field current associated with each pulsed abnormal glow discharge approached (on a linear Y axis; not shown) an uni-modal gaussian distribution with the pressure peak at about 1 Torr, and a corresponding observed maximum of 7.5 times. higher AC rms values than the applied DC values.

We have previously described in the “863” application how the PAGD frequency is affected by several factors, namely:
the magnitude of the parallel discharge capacitance,
the value of the negative pressure for the relevant vacuum PAGD range,
the magnitude of the applied potential, the magnitude of the applied direct current,
the inter-electrode gap distance and
the area of the parallel plate electrodes.

In the “531” application we have also described how the wiring configuration (plate diode versus triode) affects the PAGD frequency by adding tungsten auto-electronic emissions from the axial electrode, to those emissions from

the plate. There are other factors which limit the PAGD regime of discharge and have also been discussed in the "863" application. The following data indicates their specific effect upon PAGD frequency.

In the data presented in Table 1, control of the frequency parameter for the circuit shown in **Fig.9** is by a ballast resistance **R1** within a specific range of interest (about 800-150 ohms, for Table 1 experimental conditions), and this in turn increases the applied current which, at "high current" values (i.e. >100 mA, as for Table 1 conditions), will drive the PAGD frequency up, as previously reported in the "863" application.

Table 2 shows the effect of the progressive displacement of a given frequency, chosen as 200 PPS, with the cumulative pulse count of the same device, in the plate diode configuration. This displacement of the same frequency (cf. group numbers 1-3 of Table 2) on to higher pressure regions is shown to be promoted by the alteration of the work function of the PAGD emitting cathode, such as this is caused by the cumulative pulse count and resultant crater formation on the electrode surface. After the first million pulses, the anode facing cathode surface is completely turned over by emission sites, and this corresponds well to the threshold crossed by group 2 of Table 2. Once the cathode surfaces are broken in, the rates shown in groups 3 and 4 of Table 2, tend to remain constant.

Originally we wondered whether this might be caused by the alteration of the electrostatic profile of the plasma sheaths at the periphery of the envelope, due to the mirroring deposits that result from the sputter of ions and trapped neutral atoms (from air gases or metallic vapour) associated with the auto-electronic emission mechanism (and from further emissions triggered in turn, by secondary ionic bombardment of the cathode with molecular species present in the plasma ball formed over the primary emission site). However, reversal of the plate polarity (firing the ex-anode as a crater-free cathode) for over a million counts, followed by re-reversal to the original polarity, the entire operation being performed in air as the residual gas substrate, led to the partial recovery of the original work function for as long as the test was run (1.5×10^4 pulses), as shown by a comparison of groups 2, 4 and 5, of Table 2. From a metallographic examination of the surfaces of plates used solely as anodes, we have also concluded that prolonged PAGD operation has the effect, not only of cleaning the anode surface from surface films and adsorbed gases, as ionic bombardment promoted by electromagnetic induction coils does, but it also does more: it polishes the target surface and smoothes it by a molecular erosive action. Observations of the surface of reversed cathodes, shows the same smoothing and polishing effects observed in exclusive anodes. Thus the recovery of the PAGD rates promoted by polarity reversal of the plates is not a function of the sputter-promoted mirroring deposits on the envelope wall, but a function of the actual work-function of the emitting cathode.

Another variable that interacts with the PAGD frequency is the molecular nature of the residual gas: Table 3 shows the differential frequency response of air with a halogen quencher, argon, for the same pulse generator employed in the tests of Table 2. It is apparent that argon obtains much higher rates of AGD pulsation for the same range of negative pressure, for the same "broken in" cathode, than does the air mixture. All these measurements were taken at cathode support-stem temperatures of 35^0C.

Time of operation is also a variable affecting the frequency and operating characteristics of the cathode, as it becomes expressed by the passive heating of the cathode, an effect which is all the more pronounced at the higher pressures and at the higher frequencies examined. Utilising the triode circuit discussed in the next section, the pulse rate of a PAGD generator with 64 cm^2 plates can be seen (see **Fig.3**) to decrease, at a negative pressure of 0.8 Torr, from 41 PPS to the operating plateau of 6 PPS within 15 minutes of continuous operation, as the temperature of the cathode support increased from 19^0C to about 44^0C. As the temperature plateaus at about 51^0C +/- 1^0C., so does the pulse rate at 6 PPS, for the remaining 48 minutes of continuous operation.

However, in order to confirm this time-dependent heating effect and threshold, we also performed the same experiment, utilising the same circuit and the same negative air pressure, with twice as large a cathode area (128 cm^2, which should take nearly twice as long to heat), being operated for 18 one-minute long continuous periods equally spaced apart by 15 minutes of passive cooling, with the cathode stem always at 19.7^0C to 21^0C., room temperature at the start of each period. The results surprised us, inasmuch as they showed that for a larger area tube which takes longer to heat to the same temperatures at comparable rates of PAGD triggering, one could observe a much earlier frequency reduction (by half, within the first 5 minutes or periods of interrupted functioning) in the absence of any significant heating effect (< 1.5^0C) of the cathode (see **Fig.4**). Repetition of these experiments has led us to conclude that, as shown in **Fig.5**, the variable responsible for this repeatedly observed reduction in the PAGD frequency, when the PAGD operation sequence is systematically interrupted, is the state of charge/discharge of the battery pack (the charge pack) at the output of the triode circuit in question: the PPM rates in **Fig.5** decrease rapidly with the steepest rate of charging of the charge pack and the fastest recovery rate of its open circuit voltage; above a given state of charge, when the open voltage of the charge pack climbs more slowly (> 340 V), in a log fashion, the PPM rate stabilises at its plateau values.

Confirmation of the importance of the charge pack in the PAGD function of the present circuitry here considered, comes from the fact that the size (the number of cells) and the intrinsic capacitance of the charge pack affect the PAGD frequency dramatically (see Table 4): increasing the charge pack size of 29 cells to 31, by 7% leads to a 10-fold reduction in frequency; further increases in the number of charge pack cells extinguishes the phenomenon. On the upper end of the scale, this effect appears to be tied in to restrictions that it places on the ability of the larger charge packs to accept the discharge power output once the charge pack voltage exceeds the PAGD amplitude potential. All of these measurements were conducted with the same 128 cm^2 plate PAGD generator, at a pressure of 0.8 Torr and in the triode configuration (see **Fig.9**).

Other factors can also affect the frequency: the motion of external permanent magnetic fields oriented longitudinally with the inter-electrode gap, external pulsed or alternating magnetic fields, external electrostatic or electromagnetic fields, specific connections of the earth ground, and the presence of a parallel capacitative, capacitative-inductive or self-inductive arm in the circuit, such as we have described for our electromechanical PAGD transduction method as described in the “531” application.

Analysis of the modulation of PAGD amplitude is simpler than that of its frequency, because fewer factors affect this parameter:
(1) magnitude of the applied potential,
(2) inter-electrode gap distance and
(3) the negative pressure, as shown in the “863” application, for "low" applied currents.

As the magnitude of the applied potential itself is limited by the gap and the pressure, to the desired conditions of breakdown, the important control parameter for the PAGD amplitude is the pressure factor. This is shown in **Fig.6** and **Fig.7**, respectively for "low" (5 mA) and "high" (about 500 mA) applied currents and for the same plate diode configuration of a H34 Al 128 cm^2 plate PAGD generator (5 cm gap), in the simple circuit described in the “863” application; it is apparent that both positive and negative components of the amplitude of these pulses in the oscillograph, are a function of the pressure, but the maximum cut-off limit of our equipment, for the negative component (at 240 volts for the "low" current experiment and at 120 volts for the "high" current), precluded us from measuring the peak negative voltage of these pulses.

However, rms measurements of the pulse amplitude at the plates and DC measurements at the circuit output to the charge pack indicate that the negative component increases with decreasing pressure to a maximum, for a given arrangement of potential and gap distance; no pressure-dependent bell shape variation of the pulse amplitude, as that seen for the positive component at "high" applied currents (**Fig.7**) is observed with the negative amplitude component. For the typical range of 0.8 to 0.5 Torr, the rms value for pulse amplitude varies from 320 to 480 volts, for a 5.5 cm gap distance and applied DC voltages of 540 to 580 volts. PAGD amplitude is a critical factor for the design of the proper size of the charge pack to be utilised in the optimal circuit.

The development of the circuits to be described stemmed from fundamental alterations to the principles implicit in our previous methods of electromechanical transduction of AGD plasma pulses as described in the “531” application. Whereas this electromechanical coupling (capacitative and self-inductive), utilised directly, energises the AGD pulses inverted from the DC input by the vacuum generator, the purpose of the development that led to the presently described experiments was to capture efficiently, in the simplest of ways, most of the pulse energy in a closed circuit, so that power measurements for the energy transduction efficiency of the observed endogenous pulsation could be carried out. Ideally, comparative DC power measurements would be performed at both the input and output of the system, taking into account the losses generated across the components; this would overcome the measurement problems posed by the myriad of transformations implicit in the variable frequency, amplitude, crest factor and duty-cycle values of the PAGD regime, and necessitated some form of rectification of the inverted tube output.

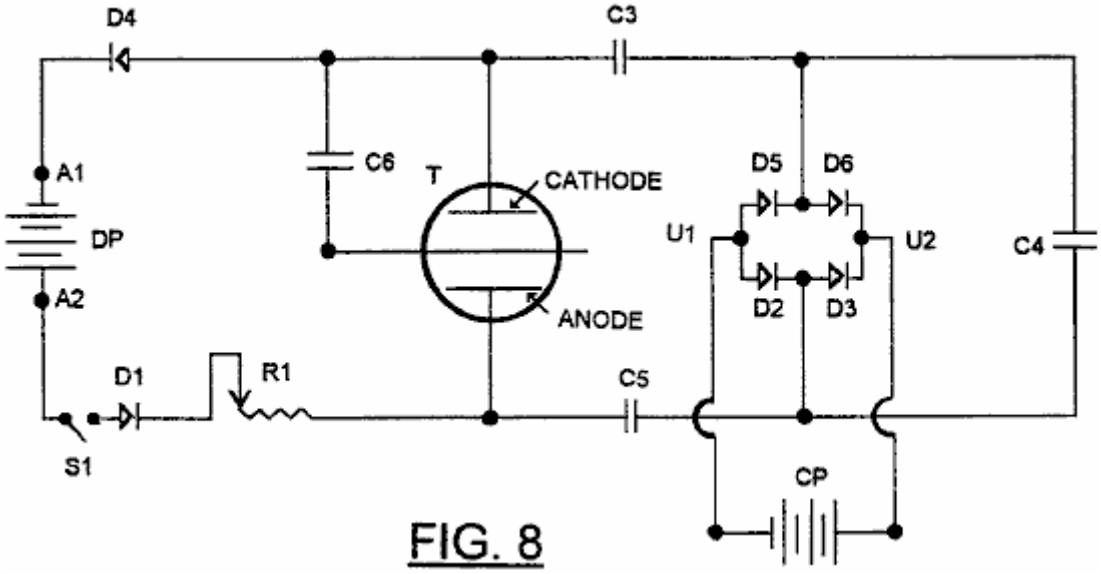

FIG. 8

From the start our objective was to do so as simply as possible. Early circuits utilising half-wave rectification methods coupled in series to a capacitative arm (for DC isolation of the two battery packs), with the charge pack also placed in series, showed marginal recoveries of the energy spent at the PAGD generator input. Attempts at inserting a polar full-wave rectification bridge led, as shown in **Fig.8**, to the splitting of the capacitor into capacitors **C3** and **C5**, at the rectification bridge input, and capacitor **C4** in series with both capacitors, all three being in a series string in parallel with the PAGD generator. Under these conditions a DC motor/generator could be run continuously in the same direction at the transversal output (**U1** and **U2**) of the bridge; but if this inductive load was replaced with a battery pack CP (charge recovery pack), either the parallel capacitor **C4** had to remain in the circuit, for the diode configuration or, less desirably, a further capacitor **C6** could replace **C4** and connect one electrode, preferably the cathode **C**, to the axial member of the discharge tube **T**, thus resulting in a first triode configuration as actually shown in **Fig.8**. Energy recovery efficiencies of the order of 15% to 60% were obtained utilising **C6** in this manner, but measurements of the potential and currents present at the output from the rectifier bridge were substantially lower than those obtained using optimal values of **C4**. Effectively, under these conditions, much of the power output from the tube was never captured by the output circuit formed by the second, right hand arm of the system and, being prevented from returning as counter-currents to the drive pack **DP** by diodes **D1** and **D4**, was dissipated and absorbed by the inter-electrode plasma, electrode heating and parasitic oscillations.

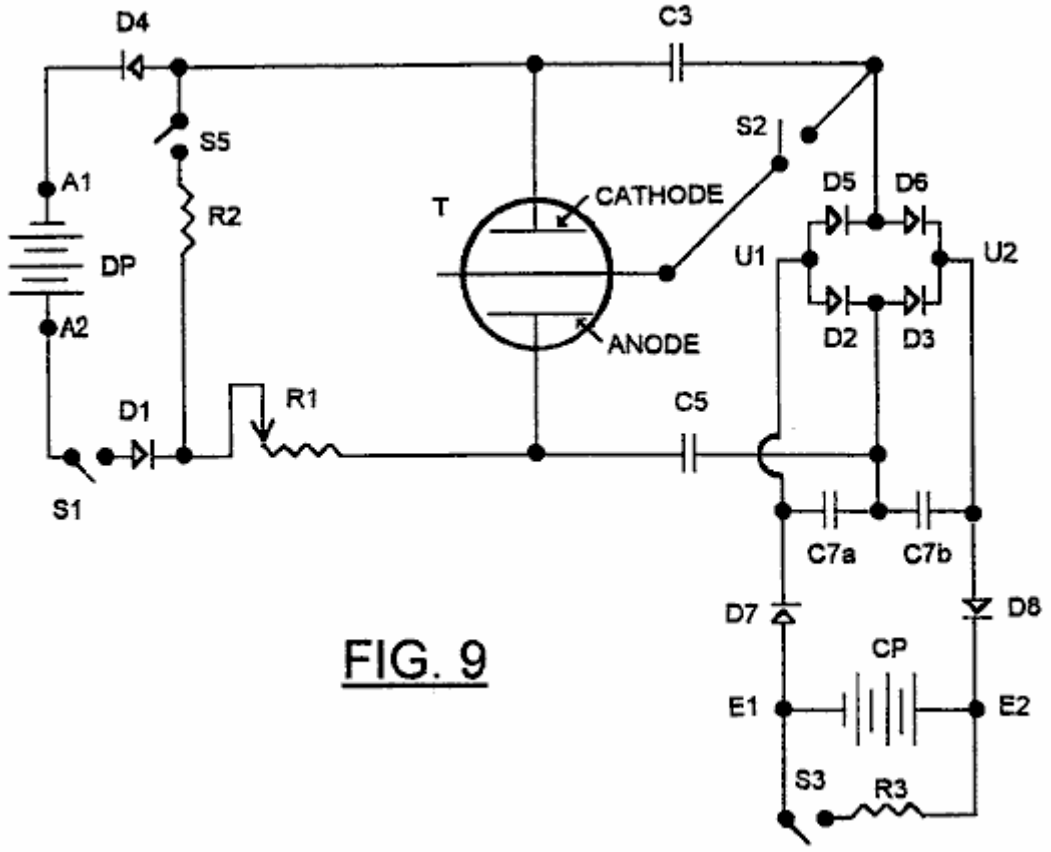

FIG. 9

Solutions to this problem were explored using the circuit shown in **Fig.9**, which still maintains the necessary communication link for the quasi-sinusoidal oscillation of the capacitatively stored charges at the input and outputs of the rectification bridge, but integrated the functions of capacitor **C4** into the single rectification circuit, in the form of an asymmetric capacitative bridge **C7a** and **C7b** placed transversally to the capacitative bridge formed by **C3** and **C5** and in parallel with the charge pack **CP** at the output from the rectification bridge **D5, D6, D2, D3**.

This second capacitative bridge is so disposed as to have its centre point connected to the anode **A** through capacitor **C5**. If the axial member of the Tube **T** were to connect to the junction of **D2** and **D3** instead of at the junction **D5-D6**, the function of bridge **C7a** and **C7b** would be connected to the cathode **C** through capacitor **C3**. The capacitative bridge is insulated from the charge pack whose voltage it stabilises, by rectifiers **D7** and **D8**, which also prevent leakage of charge across **C7a** and **C7b**.
